for pituitary surgery (7). Over the next decade, centers of excellence emerged worldwide and endoscopic endonasal techniques were further developed and applied to a wide variety of ventral skull base pathologies (8–11).

Currently, cranial base surgery encompasses a wide variety of surgical approaches and includes both external and endonasal approaches. The indications for surgery have expanded to include both benign and malignant disease and are applied to adult as well as pediatric populations.

ANATOMY

The skull base may be directly affected by a pathologic process or can be used as a pathway to approach lesions (12). Tumors and other lesions may arise intracranially or extracranially and can involve any of the intracranial fossae, nasal cavity, paranasal sinuses, orbits, pterygopalatine and infratemporal fossae, pharynx and parapharyngeal space, and craniocervical regions. Profound anatomical knowledge is the foundation for cranial base surgery and extensive dissection work in the laboratory is crucial to achieve adequate anatomical proficiency and three-dimensional mastery of the relations between the structures. The modern skull base surgeon must master both intracranial, extracranial, and endonasal surgical anatomy.

The cranial base is divided into three regions (anterior, middle, and posterior) with different anatomical relationships and distinct surgical approaches. There is an extensive connection between the intracranial and the extracranial surfaces of the cranial base through a number of foramina and canals (Table 131.1). Important neurovascular structures travel along those pathways and are a route for intracranial and extracranial spread of tumors.

Anterior Cranial Base

The intracranial surface of the anterior cranial base is formed by three different bones: frontal, ethmoid, and sphenoid (12). The frontal bones compose the majority of the anterior cranial base contributing to its lateral part. The orbital process of the frontal bone articulates posteriorly with the lesser wing of the sphenoid bone. Those two bones constitute the roof of the orbit and the optic canal, which transmits the optic nerve and the ophthalmic artery. Posterolaterally, the optic canals are bounded by the anterior clinoid processes, which are connected to the sphenoid sinus by the optic struts running under the optic nerves. The frontal sinus is located anteriorly between the external and the internal walls of the frontal bone. The internal cortical surface (posterior table of the frontal sinus) corresponds to the anterior limit of the anterior cranial base. The anterior cranial base faces the frontal lobes with the *gyri recti* medially and the orbital *gyri* laterally. In the midline, the superior sagittal sinus continues to the floor of the anterior cranial base where it connects with a small emissary vein at the foramen cecum. The fronto-orbital artery is a branch of the anterior cerebral artery that travels along the inferior and medial surface of the frontal lobe. Because of its proximity with the anterior cranial base, procedures in this region present an increased risk of injury of the

TABLE 131.1 FORAMINA OF THE BASE OF THE SKULL

Foramen	Structures Transmitted
Cribriform plate	Olfactory nerve (CN I)
Foramen cecum	Occasional small vein; origin of sagittal sinus
Optic canal	Optic nerve (CN II); ophthalmic artery
Superior orbital fissure	Cranial nerves III, IV, ophthalmic division of trigeminal nerve (CN V1); superior ophthalmic vein
Inferior orbital fissure	Maxillary division of trigeminal nerve (CN V2); zygomatic branch of trigeminal nerve; filaments from pterygopalatine branch of the maxillary nerve; infraorbital vessels; anastomosis between inferior ophthalmic vein and pterygoid venous plexus
Foramen rotundum	Maxillary division of trigeminal nerve (CN V2)
Foramen ovale	Mandibular division of trigeminal nerve (CN V3)
Foramen spinosum	Middle meningeal artery
Sulcus tubae auditivae	Lodges cartilaginous part of auditory (eustachian) tube
Foramen lacerum	Closed inferiorly by a fibrocartilaginous plate that contains the auditory tube; upper part traversed by the ICA
Carotid canal	Internal carotid artery
Stylomastoid foramen	Facial nerve (CN VII); stylomastoid artery
Jugular foramen	Beginning of the internal jugular vein; cranial nerves IX, X, XI
Internal acoustic meatus	Facial nerve (CN VII); vestibuloacoustic nerve (CN VIII)
Hypoglossal canal	Hypoglossal nerve (CN XII)
Foramen magnum	Spinal cord (medulla oblongata); spinal accessory nerves (CN XI); vertebral arteries; anterior and posterior spinal arteries; occipitoaxial ligament

CN, cranial nerve.

fronto-orbital branch. The olfactory bulbs are situated over the cribriform plates, and the olfactory tracts course posterolaterally over the surface of the brain as they cross over the optic nerves.

The midline of the anterior cranial base is related to the nasal cavity, ethmoid cells, and sphenoid sinus. The ethmoid bone forms the anterior two-thirds of the midline anterior cranial base. The regions of the ethmoid bone related to the intracranial surface from medial to lateral are the *crista galli*, cribriform plate, and *fovea ethmoidalis*. The crista galli separates the anterior half of the cribriform plates in the midline and is attached to the *falx cerebri*. Anterior to the crista galli, the foramen cecum transmits an emissary vein responsible for the venous drainage from the nasal cavity to the superior sagittal sinus. Besides the potential risk of intracranial dissemination of nasal infections, congenital lesions such as nasal dermoids, gliomas, and meningoceles can communicate intracranially through the foramen (13). The thin lateral lamella of the cribriform plate continues laterally as the *fovea ethmoidalis* or roof of the ethmoid sinus. The depth of the lateral lamella is an important risk factor for iatrogenic cerebrospinal fluid (CSF) leak during transethmoidal procedures. The olfactory filaments pass through the cribriform plate from the nasal cavity to the intracranial olfactory bulbs and are a route for intracranial spread of sinonasal malignancy. The posterior third of the midline anterior cranial base is formed by the *planum sphenoidale*, which corresponds to the roof of the sphenoid sinus.

At the junction of the ethmoid sinus and orbit, the anterior and posterior ethmoidal foramina along the frontoethmoidal suture line transmit the anterior and posterior ethmoidal arteries, respectively. The anterior ethmoid artery is located between the second and third ethmoid septations in a coronal plane that is tangential to the posterior surface of the globe. The posterior ethmoid artery is roughly at the junction of the fovea ethmoidalis and planum sphenoidale. These arteries diverge as they cross the roof of the ethmoid and often need to be identified and ligated/coagulated during procedures in the anterior cranial base.

Sphenoid Sinus

The surface anatomy of the sphenoid sinus is important for endonasal approaches to the pituitary and surrounding areas (Fig. 131.1). The degree of sphenoid pneumatization and patterns of septations vary greatly. When there are multiple septations, lateral septations always deviate toward the internal carotid artery (ICA) and care must be exercised when removing the septations. The sella is bounded by the clival recess inferiorly, cavernous sinus and ICA laterally, and optic canal superolaterally. The clival recess is bounded by the paraclival ICA and petrous apex laterally. The sixth cranial nerve courses superolaterally behind the paraclival ICA and is at risk of injury when drilling posterior to the paraclival ICA just below the sellar floor.

Middle Cranial Base

The intracranial surface of the middle cranial base is formed by the sphenoid and temporal bones. The limit between the anterior and the middle cranial bases is the sphenoid ridge joined medially by the chiasmatic sulcus. The limit between the middle and the posterior cranial bases is the petrous ridge joined medially by the *dorsum sellae* and the posterior clinoid process (12).

The intracranial surface of the middle cranial base can be divided in two regions: medial and lateral. The medial

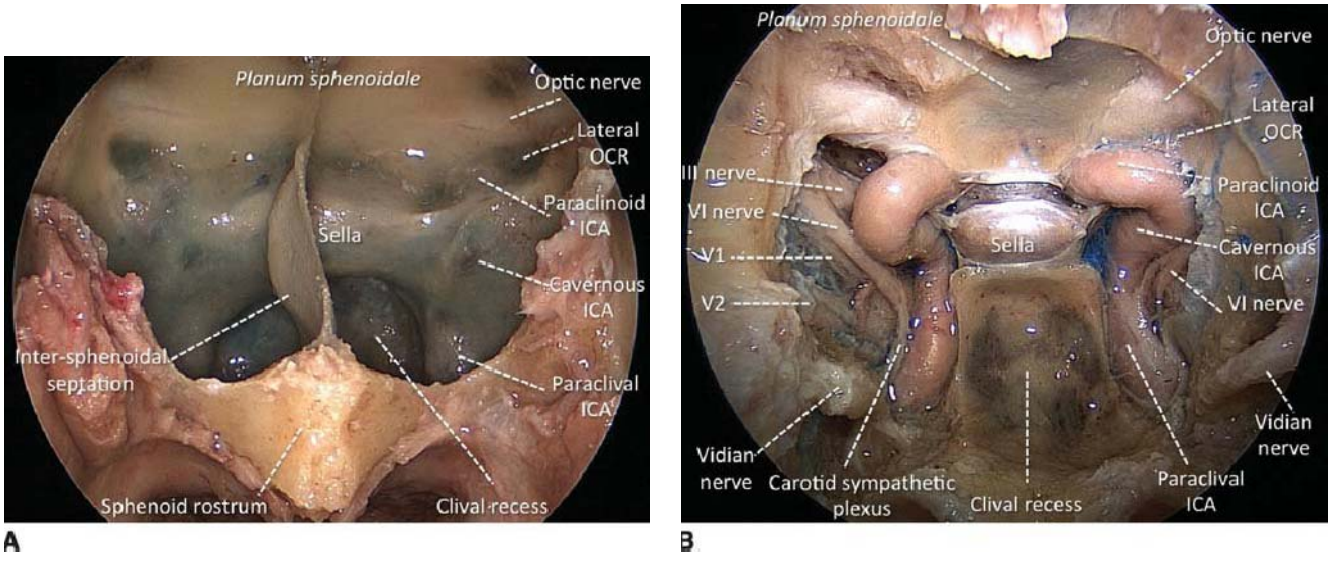

Figure 131.1 Endoscopic view with a 0-degree endoscope during a dissection. **A:** Surface anatomy of the sphenoid sinus after removal of the anterior wall. **B:** Surrounding structures after bony removal.

part of the middle cranial base is composed by the body of the sphenoid bone. The greater wing of the sphenoid bone and the temporal bone (squamosal and petrosal segments) form the lateral portion of the middle cranial base, containing the middle cranial fossa.

The temporal bone has a pyramidal shape, the sides of which form the middle fossa floor (superior face), the anterior limit of the posterior fossa (posterior face), muscle attachments of neck and infratemporal fossa (anteroinferior face), and the muscular–cutaneous–covered side of the head (lateral), which forms the base of the pyramid. The temporal bone consists of four embryologically distinct components: the squamous, mastoid, petrous, and tympanic part.

The greater and lesser petrosal nerves course across the upper surface of the petrous bone. The carotid canal extends upward and medially and provides passage to the ICA. Medially, Meckel's cave forms an impression on the upper surface of the petrous bone. The roof of the carotid canal opens below the trigeminal ganglion near the distal end of the carotid canal. The arcuate eminence approximates the position of the superior semicircular canal. A thin lamina of bone, the tegmen tympani, covers the middle ear and ossicles on the anterolateral side of the arcuate eminence. The internal auditory canal can be identified below the floor of the middle fossa by drilling along a line approximately 60 degrees medial to the arcuate eminence, near the middle portion of the angle between the greater petrosal nerve and arcuate eminence (12).

The area below the middle cranial fossa includes the infratemporal fossa, parapharyngeal space, infrapetrosal space, and pterygopalatine fossa. The boundaries of the infratemporal fossa are the medial pterygoid muscle and the pterygoid process medially, the mandible laterally, the posterior wall of the maxillary sinus anteriorly, the greater wing of the sphenoid superiorly, and the medial pterygoid muscle joining the mandible and the pterygoid fascia posteriorly. The fossa opens into the neck below. The infratemporal fossa contains the branches of mandibular nerve, the maxillary artery, and the pterygoid muscles and venous plexus. The mandibular nerve exits the cranial base through the foramen ovale. The pterygoid venous plexus connects through the middle fossa foramina and inferior orbital fissure with the cavernous sinus and empties into the retromandibular and facial veins (12). From a lateral infratemporal approach, a plane is formed by the lateral pterygoid plate, foramen ovale (third division of the trigeminal nerve), foramen spinosum (middle meningeal artery), and the spine of the sphenoid. On a deeper level, the eustachian tube overlays the petrous carotid canal. These are useful landmarks for locating the petrous ICA.

The pterygopalatine fossa is located between the maxillary sinus in the front, the pterygoid process behind, the palatine bone medially, and the body of the sphenoid bone above. The fossa opens laterally through the pterygomaxillary fissure into the infratemporal fossa and medially through the sphenopalatine foramen to the nasal cavity. Both the foramen rotundum for the maxillary nerve and the pterygoid canal for the vidian nerve open through the posterior wall of the fossa. The fossa contains branches of the maxillary nerve, vidian nerve, the pterygopalatine ganglion, and the pterygopalatine segment of the maxillary artery.

The parapharyngeal space is predominantly a fat-filled space, but also contains the eustachian tube, pharyngeal branches of the ascending pharyngeal and facial arteries, and branches from the glossopharyngeal nerve.

Endonasally, the medial aspect of the middle fossa (Meckel's cave) is anterior to the paraclival ICA and superior to the petrous segment of the ICA. The second division of the trigeminal nerve (foramen rotundum) and the vidian nerve (pterygoid canal) are helpful landmarks. Meckel's cave is bounded by the lateral cavernous sinus superiorly containing the third, fourth, ophthalmic branch of fifth, and sixth cranial nerves. Foramen ovale is just posterior to the pterygoid base.

Posterior Cranial Fossa and Craniocervical Junction

The posterior cranial fossa may be approached posterior, inferior, and medial to the temporal bone. The sigmoid sinus defines the posterior margin of the petrous temporal bone. The infrapetrosal space contains the jugular bulb and lower end of the inferior petrosal sinus; the branches of the ascending pharyngeal artery; the glossopharyngeal, vagus, and accessory nerves; and the opening of the carotid canal through which the carotid artery passes. Below the torcula and transverse sinuses, the occipital bone protects the posterior fossa and cerebellum down to the foramen magnum. From an endonasal view, another portion of the occipital bone, the clivus, protects the brainstem and can be divided into three segments: superior (posterior clinoid to floor of sella), middle (floor of sella to floor of sphenoid sinus), and inferior (floor of sphenoid sinus to foramen magnum). Intracranially, the superior clivus is associated with the third cranial nerve, the middle clivus is associated with the sixth cranial nerve, and the inferior clivus is associated with the lower cranial nerves. Inferolaterally, the hypoglossal foramen is bounded superiorly by the jugular tubercle and the occipital condyle inferiorly. Finally, the occipital condyle is a "ball and socket" joint that articulates with the atlas of the cervical spine.

Scalp

It is important to understand the layers of the scalp in order to preserve function and plan reconstruction with pedicled scalp flaps. The scalp has five layers designated by the acronym SCALP: Skin, subcutaneous tissues, Aponeurosis (galea), Loose areolar layer, and Periosteum. Together, the loose areolar layer and periosteum comprise the pericranial flap whereas the galeopericranial flap includes the galeal layer. The pericranial flap is supplied by the supratrochlear

and supraorbital vessels, which exit from foramina or notch along the superior orbital rim. Laterally, the galea is continuous with the superficial temporal fascia. A temporoparietal flap, derived from this fascia, receives its blood supply from the superficial temporal artery. The temporalis muscle, another important reconstructive flap, is covered by the deep temporal fascia. The deep temporal arteries, terminal branches of the internal maxillary artery, supply the muscle on its deep surface.

Vascular

In many respects, surgical approaches to the skull base are determined by the vascular anatomy. The ICA has five segments: parapharyngeal, petrous, paraclival, cavernous, and supraclinoid. The ophthalmic artery branches off of the ICA just after it exits the cavernous sinus and dural rings and runs inferolateral to the optic nerve inside the optic canal. The vertebral arteries usually enter the posterior fossa through the dura between the lateral lamina of C1 (after exiting the transverse foramen) and lateral foramen magnum. The circle of Willis comprises the ICAs, anterior cerebral arteries, anterior communicating artery, posterior cerebral arteries, and posterior communicating artery. A patent circle of Willis is predictive of collateral cerebral blood flow (CBF), but anatomical variations are common.

CLINICAL DIFFERENTIAL DIAGNOSIS

Cranial base surgery is characterized by a great diversity of pathology and includes benign and malignant neoplasms, traumatic injuries, congenital lesions, inflammatory and infectious disease, and vascular pathology (Table 131.2). The differential diagnosis varies according to age group, with a preponderance of congenital lesions and benign pituitary pathology in the pediatric population. The differential diagnosis will also depend on the anatomic subsite and can often be predicted bases on presentation, location, and radiologic appearance.

Tumors arising in the cranial base can cause an enormous variety of symptoms. Profound knowledge of skull base anatomy and cranial nerve physiology is imperative for a correct clinical topographic diagnosis. An adequate clinical examination can indicate the location and estimate extension of the tumor. However, skull base tumors can present with nonspecific symptoms such as headache, weight loss, vomiting, weakness, and loss of appetite. Anterior cranial base tumors can present with pituitary dysfunction, hyposmia/anosmia, proptosis, epiphora, nasal obstruction, epistaxis, facial deformities, personality change, diplopia, visual loss, facial numbness, or sinusitis. Middle cranial base lesions can cause trigeminal neuralgia or numbness, facial palsy, ptosis, diplopia, trismus, or eustachian tube dysfunction. When the tumor involves the temporal bone, hearing loss, tinnitus, and dizziness can occur. Symptoms associated with tumors from the posterior cranial base include tinnitus, hearing loss, balance problems, swallowing difficulties, hoarseness, speech problems, dysarthria, and shoulder weakness.

Physical examination should include a complete assessment of cranial nerve function. Nasal endoscopy should be performed on all patients with nasal/sinus or orbital symptoms but may provide valuable information for lesions in any region of the skull base. In patients with decreased olfactory function, olfaction can be objectively measured with a scratch-and-sniff test (Sensonics UPSIT test). Visual symptoms should be evaluated further by an ophthalmologist and may include visual field testing in addition to a routine funduscopic examination. Symptoms of hearing loss or vestibular dysfunction can be evaluated further with audiometric testing and vestibular tests if necessary. Lower cranial nerve dysfunction may require assessment of swallowing function and aspiration

TABLE 131.2 TOPOGRAPHIC DIFFERENTIAL DIAGNOSIS OF CRANIAL BASE PATHOLOGY

Anterior Cranial Base/Nasal Cavity/ Maxillary Sinus/Orbit	Middle Cranial Base/Sphenoid/Sella/ Infratemporal Fossa	Posterior Cranial Base

Cerebral Blood Flow Test	Risk of Early Stroke	Risk of Delayed Stroke	Management Options
Clinical neurologic deficit	High	—	ECA–ICA, high flow bypass; preservation of ICA; nonoperative therapy; subtotal resection
Reduction of CBF (15–35 mL/110 g/min)	Low	Moderate	STA–MCA or high flow bypass; preservation of ICA; nonoperative therapy; subtotal resection
No reduction of CBF (>35 mL/100 g/min)	Low	Low	No reconstruction (malignant tumors); consider STA–MCA or high flow bypass to prevent long term flow related aneurysms (benign tumors)

CBF, cerebral blood flow; ECA–ICA, external carotid artery–internal carotid artery; STA–MCA, superficial temporal artery–middle cerebral artery.

risk with a functional endoscopic exam of swallowing exam or radiographic study (barium esophagram). If CSF rhinorrhea is suspected, provocative maneuvers can be performed (Valsalva maneuver). Testing of collected fluid for beta-2-transferrin or beta–trace protein will confirm the presence of CSF.

IMAGING IN CRANIAL BASE SURGERY

Computed tomography (CT) and magnetic resonance imaging (MRI) provide complementary information for the diagnosis, preoperative planning, intraoperative period, and postoperative surveillance in cranial base surgery. CT scan provides significant information regarding the bony structures. Usually the presence of bony erosion, defects, remodeling, or calcification is well recognized with the CT scan. CT angiography is particularly important for the evaluation of the vasculature within and surrounding the tumor. MRI shows better soft tissue detail and is superior for delineating intracranial or intraorbital invasion. Fluid collections (meningocele, obstructed sinus) appear bright on T2-weighted sequences, although chronic sinus obstruction with high-protein content may be dark on both T1 and T2. Fat appears bright on T1 and dark on T2 images, which explains the MRI appearance of lesions with high-lipid content such as cholesterol granulomas. Chondromatous neoplasms (clival chordomas, chondrosarcomas) characteristically enhance on T1-weighted MRI with contrast and exhibit a high signal with multiple septations on T2-weighted sequences. Special sequences such as diffusion-weighted imaging are helpful in confirming an epidermoid tumor or abscess.

The vascularity of tumors is demonstrated by tumor enhancement on contrasted CT or MRI and flow voids on MRI. For example, juvenile nasopharyngeal angiofibroma classically enlarges the pterygopalatine fossa and presents with intense contrast enhancement in both MRI and CT scan. Angiography is used to confirm the diagnosis for highly vascular tumors (angiofibroma, paraganglioma) and for preoperative embolization of feeding vessels.

Preoperative imaging (CT angio and MRI) also provides information regarding intracranial circulation and collateral CBF (patency of circle of Willis). If sacrifice of the ICA or another major vessel is anticipated or planned, preoperative balloon test occlusion with neuromonitoring is performed. Xenon-perfusion CT scan provides an objective measure of CBF. Patients can be grouped into three prognostic groups based on the results of testing and this has implications for clinical management (Table 131.3).

Positron emission tomography shows cellular activity in the body, primarily through detection of labeled glucose taken up by the tissues under examination. Although this technique eventually may be useful for identification of primary tumors, it is most appropriate for detection of metastasis and local recurrence of high-grade malignancies. This can be valuable for preoperative staging to define goals of surgical treatment.

OPERATIVE MANAGEMENT

The choice of the optimal surgical approach is contingent upon multiple factors including the diagnosis, surgical access, reconstructive options, patient comorbidities, experience of the surgical team, potential complications, and available resources. The optimal approach is one that provides good access and visualization and minimizes potential morbidity. An approach should be chosen that minimizes manipulation of neural and vascular structures, especially retraction of the brain.

Cranial base surgery is team surgery and requires close coordination of the team members. Both CT and MRI are used for intraoperative navigation, which provides

accurate anatomical localization during the surgery. Scans are performed using a skull base protocol (thin, overlapping slices) that are appropriate for intraoperative navigation. Navigation is used to identify important neural and vascular structures (and avoid injury), determine tumor margins, and assess the extent of the resection. Intraoperative imaging is sometimes performed (intraoperative CT or MRI) to assess the extent of tumor resection, detect complications (hemorrhage), or to update the navigation scan if there is shift of the residual tumor.

Neurophysiologic monitoring of cortical function (somatosensory-evoked potentials) provides a global assessment of cerebral perfusion and can be adversely affected by hypotension or a subdural collection. Brainstem evoked response is used to monitor hearing during temporal bone surgery and brainstem function during surgeries of the posterior fossa. Electromyography is used to monitor motor function of cranial nerves.

APPROACHES TO THE ANTERIOR CRANIAL BASE

Surgical approaches to the cranial base can be classified based on the anatomical region (Table 131.4). External approaches can be classified by cranial fossa whereas endonasal approaches are classified into surgical modules in the sagittal and coronal planes. With open approaches, craniofacial osteotomies provide access to the cranial base and help minimize brain retraction. The classical skull base operation pioneered by Ketcham and others is the craniofacial resection and deserves special consideration as the gold standard for sinonasal malignancy.

Anterior Cranial Base: Craniofacial Resection

For many years, the craniofacial approach has been the standard surgical option for the treatment of anterior cranial base pathology and generally consists of a transcranial approach in combination with a transfacial approach. A bicoronal incision is made over the vertex of the scalp from ear to ear. The incision may be extended inferiorly in a preauricular skin crease to increase the exposure. The posterior scalp flap can be elevated in a subgaleal plane to expose extra pericranium if needed for reconstruction. Otherwise, the scalp is elevated from the underlying cranium with separation of the periosteum from the deep temporal fascia of the temporalis muscle at its margin. Laterally, the superficial layer of the deep temporal fascia is incised several centimeters above the zygomatic arch and the interfascial fat pad is elevated with the scalp to avoid injury to the temporal branches of the facial nerve.

At the level of the superior orbital rims, the supratrochlear and supraorbital neurovascular bundles are carefully dissected free from their respective foramina to preserve the blood supply of a pericranial flap; small osteotomies may be necessary if the foramina is complete. Periosteum is elevated from the orbital roofs, glabella, and nasal bones, and the scalp is retracted inferiorly.

A bifrontal craniotomy is performed encompassing the anterior and posterior tables of the frontal sinus. The inferior osteotomy is placed just above the prominence of the brow. In order to minimize brain retraction, a subfrontal approach with removal of the supraorbital bar is performed. After the frontal dura is elevated from the orbital roofs, a reciprocating saw is used to transect the orbital rims at the lateral margin of the craniotomy. The orbital contents are protected while the orbital roof is transected with a drill and the bone is drilled anterior to the crista galli. A final transverse bone cut at the level of the nasion transects the nasofrontal ducts and frees the bone segment.

The dura is separated from the crista galli and incised anterior to the cribriform plate and laterally along the medial margin of the orbit. The olfactory bulbs and tracts are dissected free from the frontal lobes, and the olfactory tracts and dura are incised posteriorly over the planum. The bone margins are then drilled to communicate with the sinuses, staying anterior to the optic canals.

Frequently the craniofacial resection combines transfacial approaches with the bifrontal craniotomy. The aim of the transfacial approaches is to provide adequate field for the dissection and resection of the lesion from the nasal cavity, paranasal sinuses, and orbit. Options include a lateral rhinotomy, midfacial degloving approach, or endoscopic endonasal approach. The lateral rhinotomy is characterized by a skin incision starting at the midpoint between the nasal dorsum and the medial canthus. The

TABLE 131.4 CRANIAL BASE APPROACHES

Anterior Cranial Base	Middle Cranial Base	Posterior Cranial Base
Craniofacial resection	*Lateral infratemporal skull base approach*	Retrosigmoid craniotomy

		Endonasal infrapetrous approach

incision respects facial subunits and extends along the lateral surface of the nose to the nasal ala and then curves around the nostril to the nasal sill (14,15). The incision communicates with the nasal cavity along the pyriform aperture. Additional exposure can be obtained by extending the incision with a subciliary or transconjunctival incision superiorly (Weber-Ferguson incision) or by incising the upper lip along the lateral philtrum. After exposure of the facial skeleton through these incisions, osteotomies are performed according to the location and size of the tumor.

The midfacial degloving approach avoids a facial incision and provides better bilateral exposure. A mucosal incision is made in the gingivolabial sulcus and periosteum is elevated from the anterior maxilla. The incision communicates with the nasal cavity along the pyriform aperture and the nasal soft tissues are elevated from the anterior edge of the nasal septum following a full transfixion incision. Bilateral transmaxillary antrostomies and medial maxillectomies provide additional exposure. The midfacial degloving approach may be supplemented with endoscopy to provide better visualization.

After the appropriate transfacial or endoscopic approach, the tumor is removed en bloc, if possible, by dissecting around the periphery of the neoplasm with opening of the sinuses and transection of the nasal septum. The cranial base specimen is then mobilized through the bone cuts in the cranial base and delivered transcranially.

Reconstruction of the resultant defect is necessary to provide separation of the cranial and nasal cavities and prevent CSF leak, meningitis, and pneumocephalus. The dural defect is repaired primarily. Suitable materials include synthetic dural substitutes, fascia lata, temporalis fascia, pericranial graft, or cadaveric pericardium. An inferiorly based pericranial flap is reflected posteriorly to cover the entire defect in the anterior cranial base. Rigid reconstruction using a bone graft or alloplastic material is not necessary. It is important to place the flap inferior to the replaced supraorbital bar, leaving a small gap to prevent compression of the vascular pedicle.

Endoscopic Endonasal Resection of Anterior Cranial Base

Endoscopic endonasal techniques can be used for resection of sinonasal malignancies. The intranasal portion of the tumor is first debulked to provide visualization of the margins and assess the extent of the tumor. Uninvolved sinuses are opened to allow visualization of the medial orbits, nasofrontal recesses, and sphenoid sinus. Bony landmarks (optic canals, carotid canals) are identified, and the margins of resection are defined. In most cases, this includes the posterior wall of the frontal sinus, the medial walls of the orbit, the roof of the sphenoid sinus, and the nasal septum. The nasal septum is transected inferior to the area of tumor involvement from the frontal sinus to the rostrum of the sphenoid bone. Margins from the nasal septum mucosa are sent for frozen section analysis. If the septal mucosa is not involved by the tumor, a septal flap can be harvested for later reconstruction.

A septal flap is pedicled on the posterior septal branches of the sphenopalatine artery. The inferior incision is initiated at the superior margin of the posterior choana and extends along the posterior margin of the vomer to the nasal floor. The inferior incision continues anteriorly along the junction between the septum and nasal floor to the nasal vestibule. If additional width is needed, the nasal floor mucosa (including the inferior meatus) can be incorporated into the flap. The superior incision starts at the sphenoid ostium and connects to the superior transection margin of the septum. Anteriorly, a vertical cut is made at the mucocutaneous junction to join the superior and inferior incisions. The nasoseptal flap is elevated from the septum in a subperichondrial and subperiosteal plane to the anterior face of the sphenoid sinus, and the vascular pedicle is preserved (16,17).

After harvesting of the septal flap, bilateral frontal sinusotomies are performed with removal of the floor bilaterally (Draf III procedure). The bone of the medial orbit is removed on the side of greatest tumor involvement. The tumor is devascularized by sacrifice of the anterior and posterior ethmoid arteries bilaterally. The arteries are identified at the junction of the orbit and skull base and cauterized with bipolar electrocautery or ligated with hemoclips.

The bone of the anterior cranial base is then removed to fully expose the dura and the area of dural invasion. Thinning of the bone with a drill is followed by fracturing and elevation of the thinned bone. Bone removal extends from the *crista galli* to the *planum sphenoidale* and to the medial orbits bilaterally. The dura is then cauterized and incised lateral to the tumor. Cortical blood vessels are identified and carefully freed from the dura. The falx is cauterized and transected anteriorly to allow mobilization of the dural specimen. The olfactory bulbs are dissected from the surface of the brain and remain attached to the dural specimen. If there is a focal area of brain invasion, the surrounding cortical tissue is removed by suction dissection to achieve clear margins. The olfactory nerves are then transected posteriorly and the final posterior dural incision is made to free the specimen. Additional dural margins may be excised for frozen section analysis (18).

After complete resection of the anterior cranial base, an inlay fascial graft is placed and the septal flap is positioned to cover the defect. If a septal flap is not available because of tumor involvement or insufficient dimension, an extracranial pericranial flap is used. A bicoronal scalp incision is made and the scalp is elevated to the level of the nasal bones. The bone at the level of the nasion is removed with a drill to create a window large enough to transmit the pericranial flap (~1 × 2 cm). The flap is then transposed through the defect inferior to the frontal sinusotomy and positioned over the dural defect, maintaining a drainage pathway for the frontal sinuses on one side (Fig. 131.2).

APPROACHES TO THE MIDDLE CRANIAL BASE

Open Approach: Lateral Infratemporal Skull Base Approach

The middle cranial fossa is typically accessed using a lateral transcranial approach. A bicoronal scalp incision is extended laterally in a preauricular skin crease to the inferior margin of the tragus. If transcervical exposure is required, it may be continued into the neck (parotidectomy incision). The scalp is elevated superficial to the deep temporal fascia to the level of the zygomatic arch, and the temporal branches of the facial nerve are preserved as described previously. The masseter muscle is detached from the inferior margin of the zygomatic arch and periosteum is dissected circumferentially. If a limited exposure of the infratemporal skull base is needed, the zygomatic arch is transected with a reciprocating saw anteriorly at its junction with the lateral orbit and posteriorly at the root of the zygoma.

If additional exposure is needed, an anterolateral skull base approach with orbitozygomatic osteotomies is utilized. The temporalis muscle is elevated and retracted inferiorly, and a frontotemporal craniotomy is performed. This provides access to the orbital roof. With retraction of orbital contents, an osteotomy of the superior orbital rim and roof is followed by an osteotomy from the inferior orbital fissure across the lateral orbital wall and zygoma. The capsule of the temporomandibular joint is dissected free, and osteotomies of the glenoid fossa detach the posterior end of the bone segment (Fig. 131.3).

A subtemporal craniectomy is performed and bone is removed to foramen ovale and foramen spinosum. Exposure of the petrous carotid artery requires division of the mandibular nerve and middle meningeal artery and then transgression of the eustachian tube. This approach provides access to the sphenoid sinus between the second and third divisions of the trigeminal nerve.

At the completion of the surgery, the temporalis muscle can be rotated into the defect to separate the sinuses from the cranial cavity and to protect the ICA. The orbitozygomatic bone segment is replaced and secured with titanium microplates. The temporal depression that results from transposition of the temporalis muscle can be filled with a fat graft or alloplastic material.

Endoscopic Endonasal Approach: Middle Cranial Base

The endoscopic endonasal approach permits access to the middle cranial base from the sella turcica to the cavernous sinus, Meckel's cave, petrous apex, and infratemporal fossa. The course of the petrous ICA divides the coronal plane into suprapetrous (middle fossa) and infrapetrous (posterior fossa) approaches. Key anatomical landmarks for the petrous ICA include the pterygoid canal (vidian nerve) and foramen rotundum (V2). A transpterygoid approach provides access to these structures and the middle fossa. Performing a middle meatal antrostomy and removing the posterior wall of the maxillary sinus expose the pterygopalatine space, and the contents are displaced laterally to expose the base of the pterygoids. The descending palatine artery and the greater palatine nerve run vertically in the palatine bone posterior to the antrostomy and are preserved. The vidian nerve and V2 are identified inferolaterally and superolaterally to the lateral recess of the sphenoid, and the sphenoidotomy is extended laterally. The vidian nerve can be sacrificed to provide additional exposure of the petrous ICA. The bone medial to the paraclival segment of the ICA is drilled to expose the medial petrous apex. Exposure of Meckel's cave requires removal of bone between the vidian nerve and V2 and lateral to the paraclival ICA. Foramen ovale can be accessed by following V3 from Meckel's cave or by following the lateral pterygoid plate posteriorly (19) (Fig. 131.4).

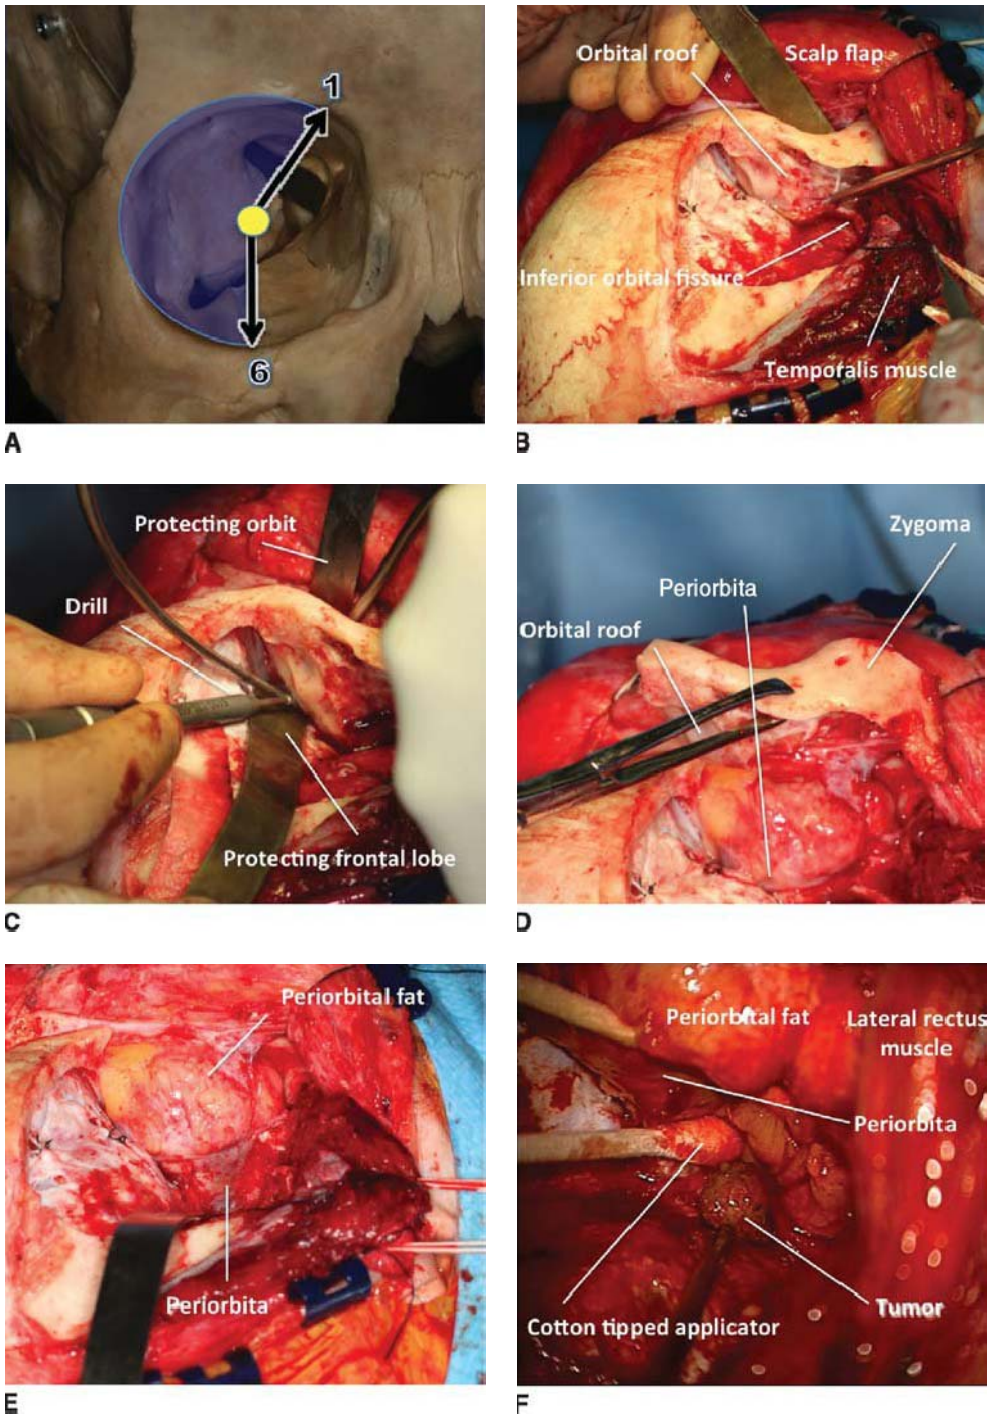

Figure 131.3 Orbitozygomatic approach for orbital apex meningioma. **A:** Right orbit in a dry skull. The highlighted area corresponds to the orbital region feasible to be reached with the orbitozygomatic approach. **B:** Exposure of the orbital lateral wall and part of the zygoma after elevation of the temporalis muscle and pterional craniotomy. **C:** Orbital burr hole. **D:** Osteotomies are performed to remove part of the zygoma and the lateral orbital rim in a single piece. **E:** Exposure of the periorbita. **F:** Microscopic view of the tumor situated between the lateral and superior rectus muscle.

More lateral access to the infratemporal skull base and masticator space is achieved with a medial maxillectomy, anteromedial maxillotomy (Denker approach), or transmaxillary approach. The lateral nasal wall is resected to the nasal floor and the lacrimal duct is sharply transected at its junction with the lacrimal sac to prevent stenosis. An endoscopic anteromedial maxillotomy requires a mucosal incision along the pyriform aperture, and periosteum is elevated from the anterior maxilla. The medial buttress is removed with a drill or bone rongeurs. Preservation of periosteum is important to minimize alar retraction postoperatively. More lateral exposure can be achieved with a

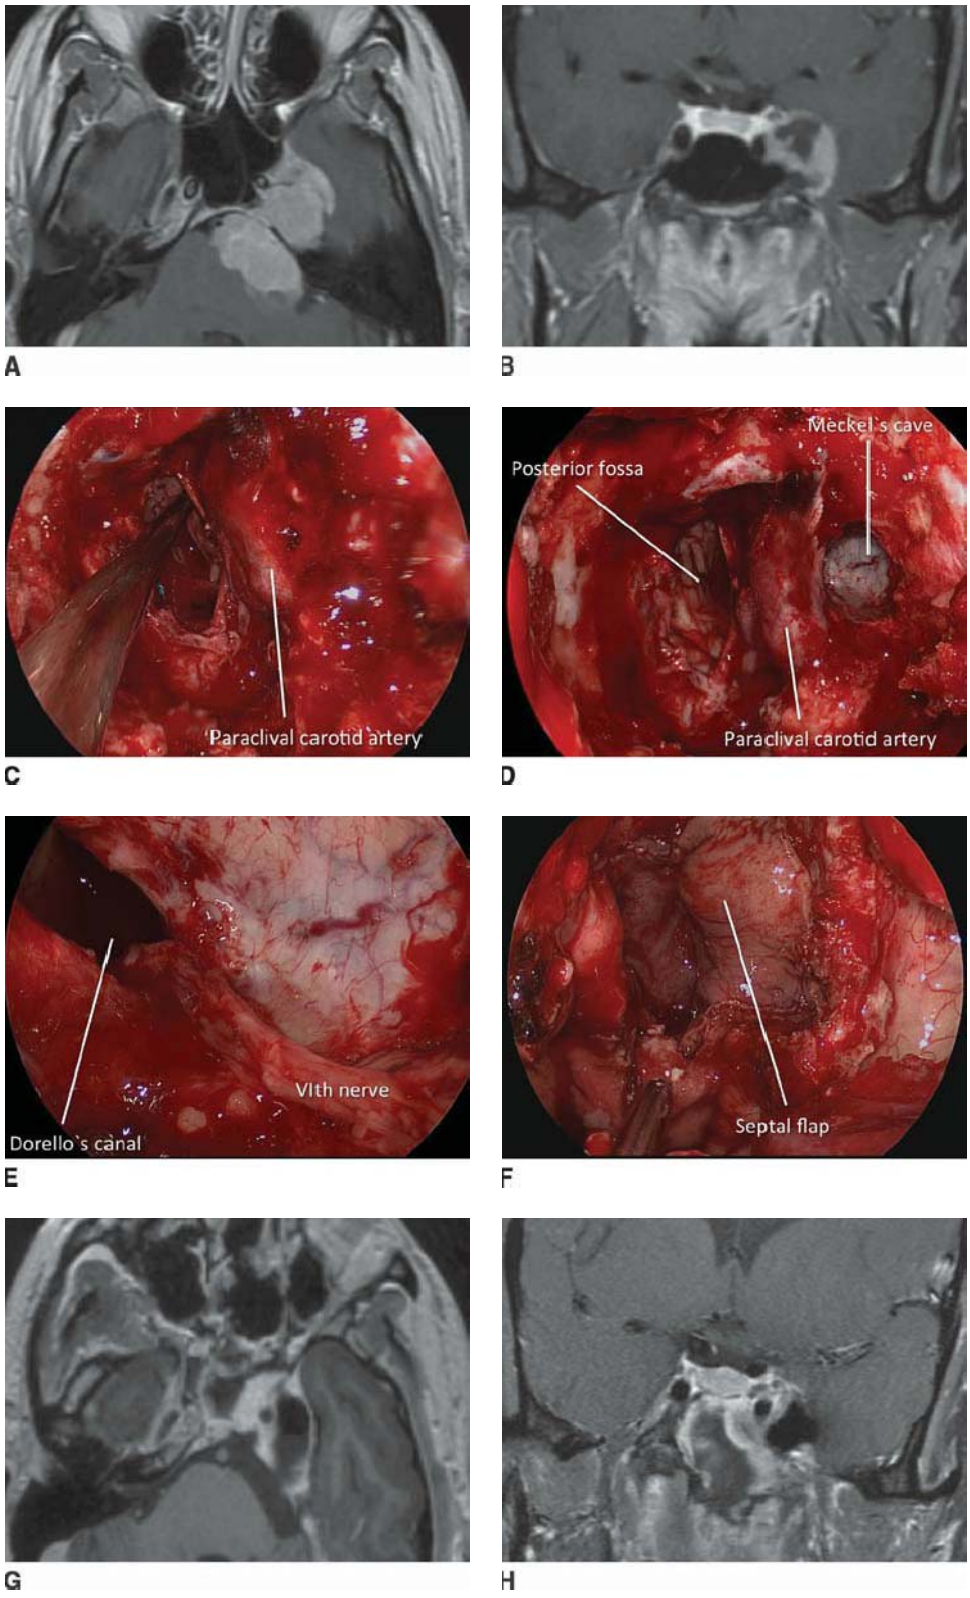

Figure 131.4 Endoscopic endonasal approach to the middle and posterior cranial fossa for resection of a left trigeminal schwannoma. **A:** Preoperative MRI T1 with contrast axial view. The tumor occupies the middle and posterior cranial fossa. **B:** Preoperative MRI T1 with contrast coronal view. Meckel's cave is filled with tumor. **C:** Endoscopic view with a 0-degree endoscope showing the resection of the tumor from the posterior cranial fossa. The paraclival carotid artery is just anterior to the anterior limit of the dissection. **D:** Endoscopic view with a 0-degree endoscope showing the posterior cranial fossa and Meckel's cave completely free of tumor. The paraclival carotid artery is seen between these two areas approached. **E:** Endoscopic close-up view of Meckel's cave with a 45-degree endoscope looking inferiorly to show the trajectory of the sixth nerve from the posterior fossa through an enlarged Dorello's canal. **F:** Right septal flap covering both cranial base defects: clival and Meckel's cave. **G:** Postoperative MRI T1 with contrast axial view and (**H**) coronal view to show the complete removal of the tumor from the middle and posterior cranial fossa.

transmaxillary approach. A sublabial mucosal incision provides exposure of the anterior maxillary wall and a maxillotomy is performed to the infraorbital nerve. The bone of the posterolateral maxilla is removed to expose the pterygoid muscles, branches of V3, and branches of the internal maxillary artery. Dissection can proceed as far as the ramus of the mandible and temporomandibular joint.

Surgical defects of the middle cranial fossa can be covered with a contralateral septal flap or with nonvascularized fascial and fat grafts. With combined endonasal and infratemporal approaches, alternative reconstructive flaps include a temporalis transposition or temporoparietal fascial flap.

APPROACHES TO THE POSTERIOR CRANIAL BASE

Open Approach: Retrosigmoid Craniotomy

A postauricular incision is made and a subperiosteal flap is elevated. The incision may be extended into the upper cervical region for control of the proximal ICA and isolation of the lower cranial nerves. The upper cervical musculature (sternocleidomastoid and trapezius muscles) is detached from the mastoid and suboccipital region, and a craniotomy is performed posterior to the mastoid and sigmoid sinus. A mastoidectomy with removal of the tip provides greater access to the jugular foramen.

If a large tumor involves the temporal bone and complete access to the extracranial ICA is needed, a Fisch type C approach provides wide exposure of the middle and posterior cranial fossae. The incision extends from the temporal area to the upper cervical region. A conchal bowl incision through the skin and cartilage allows elevation of the auricle with the skin flap; the stump of the external auditory canal remains. The facial nerve can be transposed for additional exposure or remain in situ. A transtemporal approach is then performed with dissection of the ICA to the carotid canal.

The surgical defect can be reconstructed with temporalis-muscle transposition or a posteriorly based pericranial flap (occipital artery). The craniotomy site is covered with titanium mesh or a plate and cervical musculature is reattached.

Endonasal Transclival and Transodontoid Approach

The endonasal approach provides optimal access to the clival region from the posterior clinoids to the foramen magnum. A sphenoidotomy is performed and the mucosa of the nasopharynx and underlying musculature (longus capitis muscle) is resected from the floor of the sphenoid to the ring of C1 and between the eustachian tubes. It is important to localize the parapharyngeal ICAs with image guidance to avoid injury with dissection or electrocautery. The clivus is divided into thirds. The upper third includes the posterior clinoids to the floor of the sella. Exposure of the posterior clinoids requires transposition of the pituitary gland. The sella is opened widely and the lateral attachments of the pituitary gland are lysed with possible sacrifice of the inferior hypophyseal arteries on one or both sides. If the posterior planum is removed, the gland can be displaced into the suprasellar space with preservation of the pituitary stalk and the superior hypophyseal vessels. The middle clivus extends from the floor of the sella to the floor of the sphenoid sinus. Drilling of bone in this area is bounded by the parapharyngeal ICAs, and the sixth cranial nerve is susceptible to injury posterolateral to the vessels (20). The inferior clivus extends to the foramen magnum. The bone thins as you proceed inferiorly and intense venous bleeding from the clival plexus is often encountered. This is controlled with application of hemostatic materials (Surgifoam, Floseal). The sixth cranial nerve exits the brainstem at the level of the vertebrobasilar junction and is susceptible to injury with opening of the dura (Fig. 131.4).

If exposure of the upper cervical spine is necessary (basilar invagination, foramen magnum tumor), the anterior ring of C1 is exposed and removed. The odontoid and upper body of C2 can be drilled and ligamentous attachments are resected. Laterally, dissection is limited by the vertebral arteries.

Extradural defects of the clivus can be simply covered with fibrin glue. Septal mucosal flaps are usually inadequate in size and reach for large and deep clival defects and supplementation with fat grafts may be necessary.

Endonasal Infrapetrous Approach

The infrapetrous approach is defined by the course of the petrous and parapharyngeal ICA. A lower transclival approach is combined with a transpterygoid approach, and the location of the petrous ICA is defined using the vidian nerve as a landmark. Bone inferomedial to the pterygoid canal is carefully drilled, and the dense fibrocartilage of the foramen lacerum is exposed. The medial eustachian tube is resected and the fibrocartilage is transected inferior to foramen lacerum. This provides access to the inferior aspect of the petrous bone. Lateral dissection is limited by V3 and the parapharyngeal ICA.

At the level of the foramen magnum, removal of bone laterally exposes the hypoglossal canal and nerve. The bone superior to the hypoglossal nerve is the jugular tubercle and is bounded laterally by the jugular bulb. The occipital condyle is inferior to the hypoglossal nerve; excessive removal of this bone on both sides can destabilize the spine (21).

COMPLICATIONS

Complications associated with cranial base surgery are myriad and can be life-threatening or trivial, temporary or permanent. There is no standardized classification of skull base complications. A list of possible complications is provided in Table 131.5. For the purposes of this chapter, the more common and clinically relevant complications are discussed.

TABLE 131.5 COMPLICATIONS OF CRANIAL BASE SURGERY

- CSF leak
- Pneumocephalus
- Meningitis
- Epidural, subdural, or brain abscess
- ICA injury
- Stroke
- Venous thrombosis
- Thrombophlebitis
- Encephalomalacia
- Seizure
- Psychiatric disorders
- Diabetes insipidus
- Syndrome of inappropriate antidiuretic hormone secretion
- Hypopituitarism
- Cranial nerve deficit
- Flap necrosis

Pituitary: Hypopituitarism and Diabetes Insipidus

Injury to the pituitary gland and loss of function may result from aggressive resection of tumor or loss of blood supply (superior hypophyseal vessels). The effects of hypopituitarism will depend on the age of the patient but include cortisol deficiency, hypogonadism, and hypothyroidism. Endocrinologists are involved in the perioperative management of these patients and hormonal replacement therapy can be instituted. In patients who are at risk for cortisol deficiency, stress steroids are administered perioperatively.

Diabetes insipidus is a consequence of injury to the posterior gland or hypothalamus. It is characterized by a sudden increase in urine output because of impairment in the secretion of antidiuretic hormone. During the postoperative period, urine output greater than 250 mL in 2 hours is suggestive of diabetes insipidus. Manifestations include polyuria, dehydration, hypovolemia, and polydipsia. The diagnosis is confirmed if serum level of sodium exceeds 150 mEq/L, the urine is dilute with a specific gravity less than 1.005, and urine osmolality is between 50 and 150 mOsm/kg. Treatment includes fluid and electrolyte replacement. Administration of Desmopressin (DDAVP) is indicated when dehydration and electrolyte disturbances are severe or not responding to the replacement therapy. In the postoperative period, diabetes insipidus usually is a self-limited condition and pharmacologic treatment tends to be temporary.

CSF Leak/Pneumocephalus

A CSF leak occurs in up to 5% of patients undergoing endonasal cranial base surgery and is one of the most frequent major complications. Risk factors for a CSF leak include patient demographics, patient comorbidities, diagnosis, location and size of dural defect, method of reconstruction, and perioperative management. Younger and older patients appear to be at increased risk, but this may be due to other related factors. Morbidly obese patients have elevated CSF pressures. Similarly, patients presenting with a spontaneous CSF leak and those with significant mixing of blood and CSF have elevated CSF pressures postoperatively. In our experience, craniopharyngiomas have an increased risk of CSF leak that may be a consequence of a high-flow defect as well as transient hydrocephalus from the cyst contents. Large dural defects and those that communicate with CSF cisterns or ventricles pose a greater risk. Successful repair of dural defects has been achieved using a variety of nonvascularized and vascularized tissues. The use of vascularized septal flaps and pericranial flaps has decreased the incidence of postoperative CSF leaks to less than 5%. Although lumbar spinal drainage is often used to treat minor CSF leaks, the routine use of CSF diversion to prevent a postoperative CSF leak has not been convincingly demonstrated.

Usually, a postoperative CSF leak is readily apparent based on the symptoms (unilateral watery rhinorrhea, reservoir sign due to pooling of fluid in the sinuses, "double-ring" sign of blood-tinged drainage) and physical examination (endoscopic findings, Valsalva maneuver). Persistent postoperative pneumocephalus or increasing pneumocephalus imply a dural opening. In questionable cases, a postoperative CSF leak can be confirmed by testing of collected fluid for beta-2-transferrin or beta–trace protein, or with a CT cisternogram.

Aggressive management of postoperative CSF leaks is warranted to prevent the sequela of meningitis. For small leaks in the early postoperative period, a lumbar spinal drainage can allow the leak to seal. CSF diversion can increase the risk of meningitis, however, due to reversal of flow. Prophylactic antibiotic therapy for CSF leaks is not recommended due to lack of efficacy and selection of antibiotic-resistant bacteria. Following endonasal skull base surgery, aggressive management with surgical intervention within 24 hours has been an effective strategy. Lumbar drains are reserved for recurrent leaks, high-flow leaks, and patients with suspected elevated CSF pressure.

Infection/Meningitis

The incidence of meningitis following cranial base surgery is very low with reports of 0.9% to 2.5% for transcranial surgery and 1% to 2% for endonasal skull base surgery (22–24). Surprisingly, endonasal approaches through a clean–contaminated environment have not been associated with an increased risk of infection. There is no consensus for the best regimen for antibiotic prophylaxis, but a single agent with moderate CSF penetration (e.g., third- or fourth-generation cephalosporin) is sufficient. Factors that contribute to postoperative meningitis include active infection (sinusitis, wound infection), postoperative CSF leak, and use of nonvascularized tissues for reconstruction. Factors that delay healing (malnutrition, Cushing's disease, radiation therapy) may also contribute. Patients with sinusitis should be treated prior to surgery that transgresses the infected sinus. Early intervention for CSF leaks decreases the risk of delayed meningitis.

Vascular Injury

The risk of a vascular injury depends on multiple factors including the extent of the pathology, the experience of the surgeon, and the region of dissection. Vascular injury to small vessels can be as devastating as injury to the ICA. When dissecting tumors from the optic chiasm, loss of small branches of the superior hypophyseal artery can result in visual loss or hypopituitarism. Injury to small perforating vessels when dissecting tumors from the brainstem can result in stroke or hyperphagia syndrome. Tumors of the anterior cranial fossa that encase the anterior cerebral arteries pose a greater risk for dissection. Injury may result in memory and personality changes. Large tumors are internally debulked first to collapse the tumor and allow extracapsular dissection of the tumor margin without retraction. Pulling of tumor is avoided so that small vessels are not avulsed on the backside of the tumor. If tumor cannot be safely dissected from these small vessels, it is better to perform a partial resection.

Injury to the ICA is avoided with a detailed knowledge of skull base anatomy and good surgical technique. Bleeding from the ICA may result from avulsion of small branches or direct injury. Small arterioles can be sealed with bipolar electrocautery. Larger injuries should be sutured if possible or controlled with application of a crushed muscle patch. If this is not possible, intraoperative sacrifice of the ICA with packing or placement of aneurysm clips is usually necessary. Postoperative angiography should be performed in all of these patients to detect a pseudoaneurysm. Management includes insertion of a covered stent or angiographic sacrifice of the vessel. The adequacy of collateral cerebral circulation can be assessed with a combination of CT/MRI studies, angiography, and xenon-CT or single photon emission computed tomography (SPECT) balloon occlusion tests. If collateral circulation is inadequate, a bypass graft from the carotid artery to the middle cerebral artery (MCA) may be considered.

Neural Injury

Cerebral contusions are a direct consequence of brain retraction and the surgical approach should be designed to minimize retraction. The incidence of radiographic encephalomalacia is as high as 60% of patients undergoing transcranial surgery of the anterior cranial base. Risk of contusion is increased if there is preoperative cerebral edema secondary to tumor disruption of the blood–brain boundary.

Cranial nerve injury is a consequence of manipulation or ischemia. Surgical approaches should be designed to minimize manipulation of nerves and small vessels to the nerves from the cranial circulation should be preserved. The sixth cranial nerve is particularly susceptible to injury due to its long course and small diameter. It can be injured medial (brainstem) or lateral (Dorello's canal) to the paraclival segment of the ICA. Neurophysiologic monitoring of the motor component of the cranial nerves and the use of intraoperative nerve stimulation decrease the risk of permanent injury. Sacrifice of cranial nerves is often necessary due to tumor involvement. Care should be taken to avoid loss of the first division of the trigeminal nerve in association with the vidian nerve since the combination of corneal anesthesia and decreased tearing places the cornea at high risk of ulceration. Loss of the vidian nerve is generally well tolerated in young patients (loss of emotional tearing) but may contribute to a dry eye in older patients with decreased baseline tearing.

Quality of Life

Studies of postoperative quality of life (QOL) using the anterior skull base questionnaire in patients undergoing anterior craniofacial resection for sinonasal malignancy demonstrate good function across all domains (19). In patients undergoing endoscopic endonasal surgery of the skull base, excellent QOL scores are noted using the anterior skull base questionnaire (20). Limited data suggest that QOL is superior to open transcranial approaches. Nasal morbidity has been assessed in the endonasal surgical group using the SNOT-22 questionnaire, a validated instrument. As expected, increasing nasal morbidity (decreased QOL) was noted in nontransellar sagittal plane and coronal plane surgical modules compared to transsellar surgery.

CONCLUSIONS

Cranial base surgery is a rapidly evolving subspecialty that requires a vast knowledge of anatomy and encompasses a wide variety of pathologies and surgical approaches. The same principles apply to pediatric and adult populations. Cranial base surgery is best practiced by teams of surgeons with expertise in open and endonasal approaches. Morbidity is acceptable and overall QOL is good following cranial base surgery. Good oncologic outcomes can be obtained for a variety of benign and malignant neoplasms.

HIGHLIGHTS

- The depth of the lateral lamella is an important risk factor for iatrogenic CSF leak during transethmoidal procedures.
- The olfactory filaments pass through the cribriform plate from the nasal cavity to the intracranial olfactory bulbs and are a route for intracranial spread of sinonasal malignancy.
- The sixth cranial nerve courses superolaterally behind the paraclival ICA and is at risk of injury when drilling posterior to the paraclival ICA just below the sellar floor.

- The arcuate eminence approximates the position of the superior semicircular canal. The internal auditory canal can be identified below the floor of the middle fossa by drilling along a line approximately 60 degrees medial to the arcuate eminence, near the middle portion of the angle between the greater petrosal nerve and arcuate eminence.
- The scalp has five layers designated by the acronym SCALP: Skin, subcutaneous tissues, Aponeurosis (galea), Loose areolar layer, and Periosteum.
- If CSF rhinorrhea is suspected, provocative maneuvers can be performed (Valsalva maneuver). Testing of collected fluid for beta-2-transferrin or beta–trace protein will confirm the presence of CSF.
- Chondromatous neoplasms (clival chordomas, chondrosarcomas) characteristically enhance on T1-weighted MRI with contrast and exhibit a high signal with multiple septations on T2-weighted sequences.
- A septal flap is pedicled on the posterior septal branches of the sphenopalatine artery and the pericranial flap is supplied by the supratrochlear and supraorbital vessels, which exit from foramina or notches along the superior orbital rim.
- During endoscopic endonasal approaches, the course of the petrous ICA divides the coronal plane into suprapetrous (middle fossa) and infrapetrous (posterior fossa) approaches. Key anatomical landmarks for the petrous ICA include the pterygoid canal (vidian nerve) and foramen rotundum (V2).
- Diabetes insipidus is a consequence of injury to the posterior gland or hypothalamus. It is characterized by a sudden increase in urine output because of impairment in the secretion of antidiuretic hormone. Treatment includes fluid, electrolyte replacement and/or administration of DDAVP.

Odontogenic Cysts, Tumors, and Related Jaw Lesions

132

William L. Chung *Kurt F. Summersgill* *Mark W. Ochs*

The term *odontogenic* implies being derived from tooth-forming structures. Odontogenic cysts and tumors are a unique group of lesions due to their complex and variable history, histologic characteristics, and clinical behavior. Odontogenic cysts vary significantly in their frequency, behavior, and treatment. Odontogenic tumors are relatively uncommon lesions (1). Collectively, lesions of the jaws deserve considerable attention by surgeons because of their potential for tissue destruction and the related challenges they pose for reconstruction. This chapter reviews the more common odontogenic cysts and tumors along with several other related jaw lesions. The salient clinical, radiographic, and histologic features of each lesion will be discussed, in addition to its treatment and prognosis. Many of the odontogenic cysts and tumors share similar radiographic features, so the patient's history and eventual histopathology ultimately dictate the specific surgical therapy. Furthermore, a frozen section is not typically obtained for jaw lesions discussed in this chapter because they are not malignant lesions and a frozen section will not change the ultimate treatment plan for each lesion.

ODONTOGENIC CYSTS

In 1992, the World Health Organization (WHO) classified odontogenic cysts as either inflammatory or developmental, including odontogenic and nonodontogenic. Most cysts of the oral cavity are true cysts because they contain an epithelial lining. The lining of these cysts is derived from one of three epithelial structures: (a) reduced enamel epithelium—residual epithelium that surrounds the crown of the tooth after enamel formation is complete; (b) rests of Malassez—remnants of the Hertwig root sheath that persist in the periodontal ligament after root formation is complete; or (c) remnants of dental lamina (rests of Serres)—islands and strands of epithelium that originate from the oral epithelium and remain in tissues after inducing tooth development (2). Odontogenic cysts can become inflamed or infected, causing significant signs or symptoms.

INFLAMMATORY CYSTS

Radicular Cyst

The radicular cyst is by far the most common odontogenic cyst. It develops at the apex of an erupted tooth in response to pulpal necrosis secondary to dental caries or trauma. The cyst arises from inflammatory stimulation and proliferation of the rests of Malassez. The cyst lining forms as the epithelial elements proliferate. Cellular debris within the lumen produces an osmotic gradient, and fluid is transported across the lining. This gradient slowly increases the volume of fluid inside the lumen, ultimately expanding the cyst by hydraulic pressure from within the cyst.

Clinical and Radiographic Features

Most radicular cysts are asymptomatic and are discovered incidentally during routine radiographic evaluation (Fig. 132.1). Radicular cysts rarely exceed 1 cm in diameter except when several adjacent teeth become devitalized as a result of trauma. Radiographically, the radicular cyst is round to ovoid, well circumscribed, and contiguous with the apex of the involved tooth.

Histopathology

The cyst is lined by stratified squamous epithelium of varying thickness. The cyst wall typically supports a variable inflammatory cell infiltrate, including lymphocytes and neutrophils. The cystic lumen will frequently contain necrotic cellular debris. A small percentage of radicular cysts have crescent-shaped hyaline (Rushton) bodies within the epithelial lining. Although unique to odontogenic cysts, the biologic significance of Rushton bodies is unknown. Multinucleated foreign body giant cells, cholesterol crystal clefts, and hemosiderin may be seen throughout the connective tissue of the cyst wall.

Figure 132.1 Periapical cyst. Radiograph demonstrating periapical lesion associated with grossly carious tooth # 20.

Treatment and Prognosis

These cysts are treated by extraction of the infected tooth followed by enucleation of the cyst. Extraction of the tooth without removing the cyst may allow for persistent growth of the cyst. If the cyst is incompletely removed, a *residual* cyst may develop. Complete bony healing is typically seen within 6 months if the radicular cyst has been thoroughly removed.

DEVELOPMENTAL CYSTS

Dentigerous Cyst

The dentigerous cyst is the second most common odontogenic cyst. A dentigerous cyst must be associated with the crown of an unerupted tooth (3). The cyst is attached to the cervical region of the tooth, usually a mandibular third molar. However, variants exist where the cyst is seen lateral to or completely enveloping the associated tooth. Maxillary third molars, maxillary canines, and mandibular second bicuspids are also commonly involved, as these teeth are among those frequently impacted.

Clinical and Radiographic Features

Dentigerous cysts usually occur in the second and third decades with a slight male predilection. Because they are associated with an impacted tooth, the arch will appear to be missing a tooth. The cysts usually do not produce symptoms and can achieve significant size, causing bony expansion (Fig. 132.2A and B). The dentigerous cyst is usually a well-circumscribed, unilocular, radiolucency surrounding the crown of an unerupted tooth (Fig. 132.2C). Mandibular

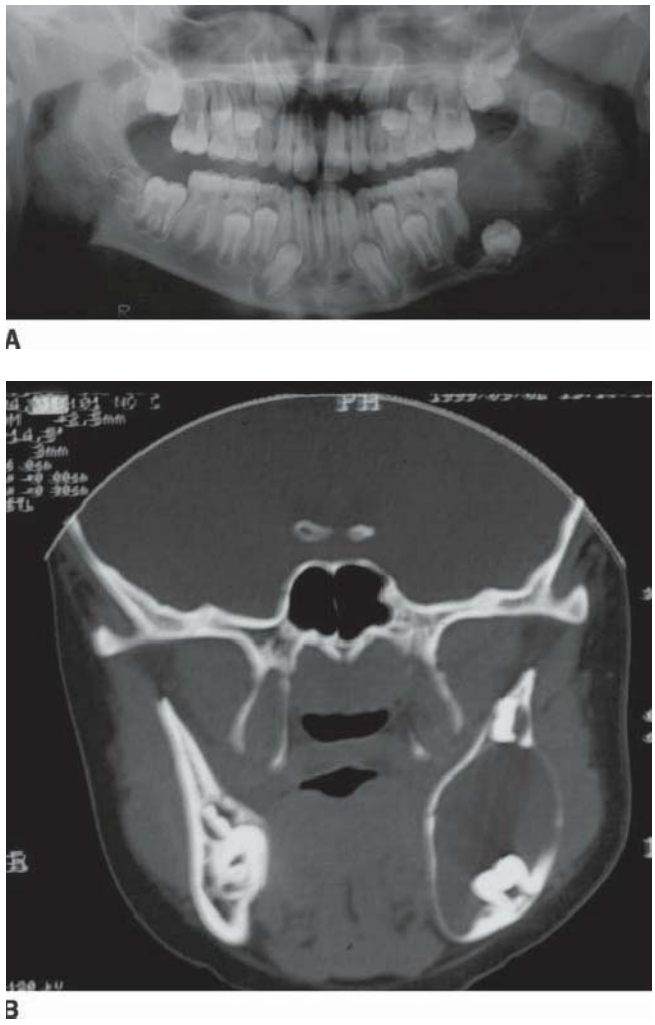

Figure 132.2 **A,B:** Dentigerous cyst. Panorex radiograph and computed tomography (CT) scan of 14-year-old who presented with facial swelling. Radiograph reveals considerable left mandibular angle and ramal involvement. Note thinning of buccal and lingual cortices and displacement of multiple permanent teeth within lesion on CT. **C:** Surgical specimen from above patient. Note adherence of cyst to permanent tooth crown.

cysts can displace the tooth into the ramus or the inferior border of the mandible, while maxillary cysts can displace the tooth into the maxillary sinus toward the orbital floor. It is important to understand that the above-stated clinical and radiographic features are not specifically diagnostic

for a dentigerous cyst, although highly consistent (4). The differential diagnosis for similar-appearing radiographic lesions should include an ameloblastoma, keratocystic odontogenic tumor (KCOT), and adenomatoid odontogenic tumor (AOT).

Histopathology

The cystic lumen is lined by nonkeratinized, stratified squamous epithelium that is anywhere from 2 to 10 cell layers thick. It is common for the lining to be inflamed. The dentigerous cyst can share several microscopic features with the radicular cyst, such as Rushton bodies, cholesterol crystal clefts, and hemosiderin deposits. Chronic dentigerous cysts may exhibit areas of keratinized epithelium, which require the lesion to be differentiated from the KCOT (5). The epithelial lining of the dentigerous cyst is capable of ameloblastoma expression (3). Thus, timely diagnosis and treatment is critical.

Treatment and Prognosis

Removal of the impacted tooth along with thorough enucleation of the cyst is usually definitive therapy. When a mandibular dentigerous cyst reaches considerable size, the cyst can be marsupialized to allow for decompression and shrinkage of the cyst with compensatory bone fill prior to definitive removal of the lesion.

Calcifying Odontogenic Cyst (Gorlin Cyst)

This lesion is thought to arise from remnants of the dental lamina within the gingiva or jaws. Approximately one-fourth of all calcifying odontogenic cysts (COCs) occur extraosseously, within the gingiva anterior to the first molar in individuals older than 50 years (6).

Clinical and Radiographic Features

The COC behaves like most other odontogenic cysts, and it has little recurrence potential. The COC has a wide age range, but the peak incidence occurs in the second decade. The lesion has a predilection for females, and most are located in the anterior portion of either jaw. The extraosseous lesion may present with painless gingival expansion. These cysts are often discovered as incidental findings on routine radiographic evaluation. They initially appear lucent. As the cyst develops, calcifications may develop causing a well-circumscribed mixed radiolucent/radiopaque appearance. However, these opacities are only seen in approximately one-third to one-half of all cases.

Histopathology

These usually unilocular cysts are lined by odontogenic epithelium. The basal layer is distinct with its columnar to cuboidal cells with hyperchromatic nuclei that are polarized away from the basement membrane (Fig. 132.3). Another characteristic histologic feature of the COC is the ghost cell—an altered epithelial cell with loss of the nucleus and bright eosinophilic cytoplasm—that represents abnormal keratinization. With time, these ghost cells tend to become calcified, sometimes even forming calcified masses. When these cells contact the connective tissue, a foreign body reaction occurs due to the release of keratin.

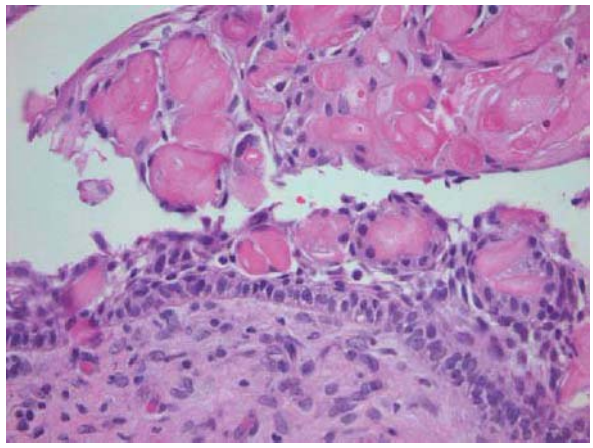

Figure 132.3 Calcifying odontogenic cyst (Gorlin cyst). Cyst lined by odontogenic epithelium. The basal cells are palisaded and columnar. Large, eosinophilic "ghost cells" are seen within and on the surface of the epithelium.

Treatment and Prognosis

Surgical enucleation usually results in complete resolution. The extraosseous lesions are often associated with other odontogenic tumors and due to their low recurrence potential are managed conservatively with lesion removal only.

Glandular Odontogenic Cyst (Sialo-Odontogenic Cyst)

The glandular odontogenic cyst was first described in 1987 (7). Although only a few cases have been reported, it is worth mentioning due to its locally aggressive behavior and its propensity to recur. This lesion is generally considered odontogenic in origin with numerous mucus-secreting cells within its epithelial lining.

Clinical and Radiographic Features

This lesion occurs most commonly in middle-aged adults. The majority of glandular odontogenic cysts have been reported in the mandible especially in the anterior region. They appear as multilocular radiolucencies and may cross the midline.

Histopathology

This lesion has several unique microscopic features: (a) an epithelial lining of variable thickness and a flat epithelial–connective tissue junction; (b) small microcysts and gland-like structures within the epithelial lining; and (c) a single layer of cuboidal or columnar cells lining the gland-like structures (Fig. 132.4).

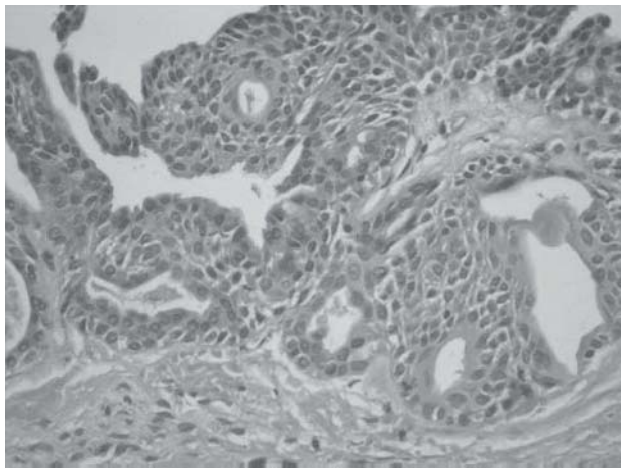

Figure 132.4 Glandular odontogenic cyst. Stratified squamous epithelium forming gland-like structures.

Treatment and Prognosis

Most glandular odontogenic cysts are amenable to enucleation and curettage. However, due to its recurrence potential, some advocate marginal resection (8). Regardless, long-term follow-up is advisable.

NONODONTOGENIC CYSTS

Nasopalatine Duct Cyst (Incisive Canal Cyst)

The nasopalatine duct cyst originates from the epithelial remnants of the two embryonic nasopalatine ducts (9). The majority of these cysts arise in the anterior maxilla near the incisive foramen.

Clinical and Radiographic Features

Men are affected twice as often as females, and this cyst occurs most frequently in the fourth to sixth decades. The nasopalatine duct cyst is either asymptomatic or presents as a soft tissue swelling in the midline of the anterior hard palate once the lesion has perforated the bone. The lesion is typically a well-circumscribed, oval-pear or heart-shaped, unilocular radiolucency in the midline of the anterior palate. If the cyst reaches large proportions, it can resorb the roots of the adjacent teeth. Some normal incisive canals are radiographically wide, which may make diagnosis of this lesion less precise. It is generally accepted that any radiographic lesion greater than 6 mm should be considered a cyst and not an enlarged incisive foramen. If no soft tissue or bony swellings are present and the patient is asymptomatic, then a diagnosis of nasopalatine duct cyst becomes unlikely.

Histopathology

The lining of this lesion can be either stratified squamous epithelium, ciliated columnar or cuboidal epithelium, or a combination of the two. This variable lining reflects whether the cyst has arrived from epithelium closer to the palate (stratified squamous) or more closely associated with the nasal cavity (ciliated columnar). The fibrous tissue contains elements of nerve and vascular tissue consistent with the surrounding incisive canal contents. Mucus glands are occasionally seen within the wall of the cyst as these glands are native to the adjacent nasal cavity.

Treatment and Prognosis

Surgical enucleation is usually curative, but may result in sacrificing the nasopalatine nerve and vessel, resulting in denervation of the mucosa of the anterior palate and maxillary incisors. Recurrence is rare.

Stafne Bone Cyst (Lingual Salivary Gland Depression, Static Bone Cyst)

The Stafne bone cyst is not a true cyst. Rather, it is a depression on the lingual aspect of the posterior body of the mandible. This condition has a pathognomonic radiographic appearance of a small ovoid, well-circumscribed radiolucency often surrounded by cortical bone, located below the inferior alveolar canal in the second or third molar region. This radiographic appearance is due to the relative thinning of the mandible. Most reported cases have occurred in males. Sialography, biopsy, and autopsy have revealed that the depression is characteristically filled with an accessory lateral lobe of the submandibular salivary gland, although occasionally connective tissue, adipose tissue, and lymphoid tissue have been seen (10). No treatment is required.

Idiopathic Bone Cavity (Traumatic Bone Cyst or Traumatic Bone Cavity)

The traumatic bone cavity is not a true cyst because it does not contain a true epithelial lining. It is usually found in the posterior mandible and presents on radiograph as a less well-defined radiolucency compared to most odontogenic cysts. These lesions are typically empty on surgical exploration or contain some straw-colored fluid. There is no lining or tissue to submit for biopsy, but exploration of the lesion will be curative, since hemorrhage within the cavity will allow for granulation tissue formation and ultimate resolution of this condition.

ODONTOGENIC TUMORS

Odontogenic tumors are collectively a rare but diverse and complicated group of lesions. They arise from epithelial or mesenchymal cells, or both, that are associated with tooth structures. Most odontogenic tumors are true neoplasms, but some behave as hamartomatous growths. Odontogenic tumors commonly present as asymptomatic swellings, which can eventually cause bone loss, tooth displacement, and jaw expansion. They rarely cause sensory nerve dysfunction. Understanding the biologic behavior of this group of lesions will assist in choosing the appropriate

treatment to best attain a cure or to optimize the outcome (11,12). The tumors discussed in this chapter were selected based upon their frequency, locally aggressive behavior, and/or likelihood of recurrence.

Odontoma

Odontomas are not true neoplasms, but rather hamartomatous growths because they form during normal tooth development and then reach a fixed size. The lesion contains elements of enamel, dentin, cementum, and pulp tissue. Depending on the degree of morphologic differentiation, an odontoma can be classified as either compound, if the lesion resembles tooth-like structures or complex, if the lesion appears as an amorphous mass.

Clinical and Radiographic Features

The odontoma is the most common odontogenic "tumor." The lesion is typically asymptomatic and is discovered in the first two decades on radiographic examination, often initiated to evaluate lack of expected eruption of a permanent tooth. Radiographically, both the compound and complex odontomas are radiopaque masses and have a well-demarcated border. The compound odontoma resembles multiple tiny tooth structures, while the complex odontoma appears as a dense irregular mass.

Histopathology

Although reduced enamel epithelium may be present, odontomas are essentially composed of enamel, dentin, cementum, and pulp tissue. Fibrous tissue is sparse.

Treatment and Prognosis

Removal of the lesion may be necessary to rule out other lesions or if the mass is impeding the eruption of a tooth. Enucleation and curettage is considered curative, and the lesion is not known to recur.

Keratocystic Odontogenic Tumor (Odontogenic Keratocyst)

The KCOT is a uni- or multicystic, intrabony lesion of odontogenic origin. It develops from remnants of the dental lamina and can occur in any location of the jaws (13,14). Its previous traditional term, odontogenic keratocyst (OKC), emphasized the benign behavior of this lesion. However, in 2005, the WHO Working Group recommended the newer term KCOT because it more accurately described its neoplastic behavior (15). These lesions mimic the radiographic appearance of any other odontogenic cyst and some odontogenic tumors. The mandibular ramus and posterior body are the most common locations for the KCOT (Fig. 132.5A and B). The KCOT in the maxilla typically favors the posterior or canine regions.

A

B

Figure 132.5 **A:** Keratocystic odontogenic tumor. Panoramic radiograph of a 18-year-old man with bilateral mandibular and maxillary KCOT. Patient also had NBCCS. **B:** Axial computed tomography (CT) scan of same patient, revealing bilateral maxillary lesions. Lesions were noted to extend to the orbital floors intraoperatively.

Clinical and Radiographic Features

The KCOT differs from other odontogenic lesions with regard to its growth potential and recurrence rate. It can display aggressive growth, causing bony expansion and destruction, and reports have shown recurrence rates from 5% to 60% (16,17). The KCOT occurs over a wide age range; however, its peak incidence is within the second and third decades. When multiple KCOTs occur in a patient, the nevoid basal cell carcinoma syndrome (NBCCS) must be considered. The mean age of patients with multiple KCOTs, with or without NBCCS, is lower than those with single, nonrecurrent KCOTs. Radiographically, the KCOT appears as a well-circumscribed radiolucency with a distinct border, and many cause bony expansion or erosion of either cortex. Involved teeth may become displaced, but root resorption rarely occurs.

Histopathology

The KCOT has the following distinct microscopic appearance: its lining is parakeratinized, stratified squamous epithelium, which is six to eight cell layers thick; the luminal surface is covered by a corrugated layer of parakeratin; the basal layer is palisaded and cuboidal, with prominent, intensely stained hyperchromatic nuclei; and a lack of rete pegs. This flat epithelial–connective tissue interface results in a separation of the epithelium on histopathologic processing. Exfoliated parakeratin often fills the cyst lumen and presents during surgery as a creamy, white material. Daughter (satellite) epithelial islands and cysts may be seen in the surrounding connective tissue and may be indicative of the NBCCS.

Treatment and Prognosis

The KCOT requires surgical enucleation and osseous curettage, and every attempt should be made to remove it in one piece (18). Modified Carnoy solution is a tissue fixative that can aid in a more complete lesion removal. Treatment of the residual bony cavity may devitalize microscopic remnants, thus decreasing the chance of recurrence (19,20). Some clinicians have advocated marginal resection to avoid recurrence (21). When large lesions are present, marsupialization may be performed to decompress the KCOT to allow for easier removal of the cyst at a later surgery (22,23). Secondary infection, need for high patient compliance, and variable results limit the use of marsupialization techniques. Most recurrences occur within 5 years, but reports of recurrence as long as 10 years later have been documented. Thus, close follow-up is mandatory. Recurrence of KCOT has been speculated based on several theories: incomplete removal of the cyst due to its thin friable membrane and adherence to adjacent tissues, residual satellite cysts following enucleation, and remnants of dental lamina not associated with the KCOT in question causing de novo cyst formation. The orthokeratinized odontogenic cyst is considered by some to be a unique cyst, and by others to be a variant of the KCOT. It is much less common than the KCOT and has a much lower recurrence rate (24). Unlike the KCOT, the orthokeratinized odontogenic cyst is lined by orthokeratinized stratified squamous epithelium. There is a prominent granular layer below a noncorrugated surface, and the basal layer is less prominent.

Nevoid Basal Cell Carcinoma Syndrome (Basal Cell Nevus Syndrome, Gorlin Syndrome)

The NBCCS is an autosomal dominant inherited condition that exhibits high penetrance and variable expressivity (25,26). It is a result of a mutation of the PTCH tumor suppressor gene located on chromosome 9q22.3-q31. Patients may manifest a combination of the following clinical and radiographic features: multiple KCOTs of the jaws, multiple basal cell carcinomas of both exposed and non–sun-exposed areas, frontal bossing, mandibular prognathism, palmar and plantar pitting, bifid ribs, and calcification of the falx cerebri. The KCOTs associated with NBCCS should be treated in a similar manner as an isolated KCOT. However, increased vigilance with 6 month or yearly clinical follow-up and imaging (panoramic radiograph or computerized tomography) are warranted to allow early detection of new lesions. This is particularly true of children and adolescents. Once adulthood is reached, the formation of new KCOTs is less problematic, but the risk of basal cell carcinomas rises. Other than the skin lesions and those conditions that may be correctable, many of the other related abnormalities do not require any surgical intervention. Genetic counseling should be recommended to both the patient and family members due to the condition's autosomal dominant inheritance.

Ameloblastoma

With the exception of the odontoma, the ameloblastoma is the most common odontogenic tumor (27). It arises from any number of residual epithelial elements of tooth development: reduced enamel epithelium, rests of Serres, rests of Malassez, or the basal layer of the oral mucosa. The lesion can also develop from within a dental follicle or a dentigerous cyst (3). Some confusion has arisen regarding the classification schema of ameloblastomas. Most references broadly categorize ameloblastomas into one of three groups: unicystic, solid or multicystic, or peripheral ameloblastomas. A misuse of terms and/or a lack of understanding of these same terms with their overlapping meanings can lead to an inadequate treatment decision, increasing the likelihood of recurrence. One example is the term *unicystic* ameloblastoma. Unicystic ameloblastoma generally implies being amenable to enucleation and curettage. An invasive ameloblastoma may be unicystic, having just one cystic space. However, that does not suggest that this invasive lesion should be treated by enucleation and curettage merely because it was defined, properly or not, as a unicystic ameloblastoma.

Clinical and Radiographic Features

This benign, locally aggressive neoplasm is characterized by a slow growth pattern and may grow to profound proportions, causing gross facial deformities. It is usually asymptomatic and does not alter sensory nerve function. The posterior mandible appears to be a preferred site. The lesion has a very wide age range with a peak occurrence in the third and fourth decades, and it has no sex predilection. Radiographically, the lesion can appear as a unilocular or multilocular radiolucency with ill-defined borders, making it difficult to determine the exact size of the lesion. Buccal and lingual cortical expansion is common, even progressing to cortical perforation (Fig. 132.6A and B). Tooth displacement and root resorption can occur but infrequently. A variant, the desmoplastic ameloblastoma, is commonly

Figure 132.6 **A:** Ameloblastoma. Panoramic radiograph of a 17-year-old girl with unilocular ameloblastoma of right mandible. Note resorption of multiple tooth roots in right mandible. **B:** Coronal computed tomography (CT) scan of maxillofacial bones of patient from **(A)**. Note extreme buccal and lingual cortical expansion of right mandible. Focal areas of perforation were noted intraoperatively. **C:** Ameloblastoma (follicular pattern). Islands of odontogenic epithelium characterized by peripheral columnar cells exhibiting reverse polarity. The central portion of these islands resemble stellate reticulum in areas. **D:** Ameloblastoma (plexiform pattern). **E:** Preoperative photo of patient from previous images. Note significant vestibular expansion. Right mandibular teeth exhibited significant clinical mobility. **F:** A resection of the right mandible from the angle to the contralateral parasymphysis through a neck incision. Focal areas of buccal cortical perforation were noted intraoperatively. Specimen is viewed from the buccal aspect.

found in the anterior maxilla or mandible. It contains dense connective tissue, and thus has a more opaque radiographic appearance. Another variant, the peripheral ameloblastoma, is usually present on the gingival and has no radiographic features, except perhaps a "cupping" of underlying alveolar bone.

Histopathology

Ameloblastomas are histologically diverse. They may exhibit areas of focal variation, so adequate sampling must be undertaken. The ameloblastoma is unencapsulated, so it typically exhibits an infiltrative growth pattern into surrounding tissues. The basal cells in the epithelium are columnar and hyperchromatic. The nuclei are polarized away from the basement membrane ("reverse polarity"). Numerous histologic patterns have been noted in ameloblastomas; however, there is no current consensus that these different histologic patterns have different biologic behaviors (28,29). The two most frequent patterns are the follicular and plexiform (Fig. 132.6C and D).

Treatment and Prognosis

The primary treatment principle for any intrabony ameloblastoma is complete removal, regardless of the technique, due to its locally destructive potential and high risk for recurrence (30). Enucleation and curettage was once considered the recommended treatment for the unicystic ameloblastoma. However, curettage of the bone adjacent to an ameloblastoma is now discouraged because of the risk of seeding foci of ameloblastoma either deeper into the bone or into adjacent tissues. Furthermore, enucleation alone should be avoided when the lesion of concern is large enough that a pathologic fracture could occur. Recurrence rates between 15% and 35% have been reported with unicystic ameloblastomas treated by enucleation and curettage alone. A 1.0- to 1.5-cm bony margin is recommended for a unicystic ameloblastoma. When an ameloblastoma grows into or completely through the connective tissue layer surrounding the lesion, or if it recurs, then a more aggressive treatment is required. When resection is warranted, one uninvolved overlying anatomic barrier margin is advocated (Fig. 132.6E and F) (3). A bony margin of 1.5 to 2.0 cm is recommended for solid or multicystic ameloblastomas. When hard and soft tissue margins are negative, a cure rate of nearly 98% can be achieved. Recurrence rates as high as 90% have been reported when more aggressive ameloblastomas are inadvertently, or inadequately, treated with curettage. A 5-year follow-up is required, but a 10-year follow-up is prudent. When metastases have been reported, the lesions were histologically benign like the primary tumor. These lesions are referred to as *malignant ameloblastomas*, although they do not show cytologic features typically associated with malignancy. When the primary lesion is found to contain cytologic features of malignancy, it is classified as an *ameloblastic carcinoma*.

Peripheral Ameloblastoma

The peripheral variant of the ameloblastoma is a soft tissue mass involving the gingiva and mucosa that often causes separation of involved teeth (31). If radiographs confirm involvement of the underlying alveolar bone, then a block resection containing the involved mucosa, underlying periosteum, alveolar bone, and teeth, is performed. A 1.0- to 1.5-cm margin of uninvolved tissue is recommended. An en bloc resection is not necessary if supportive radiographic studies confirm that sufficient bone will still exist after a sufficient margin of tissue is excised to avoid a pathologic fracture.

Adenomatoid Odontogenic Tumor

The AOT is a benign hamartoma of odontogenic epithelium characterized by slow, progressive growth.

Clinical and Radiographic Features

The AOT typically occurs in adolescent or teen females. It has a strong predilection for the anterior maxilla and is often associated with an unerupted canine tooth (32). Most AOTs are less than 3 cm in diameter, but they can approach significant size and cause pain and displace tooth roots. Radiographically, the AOT usually is a well-circumscribed unilocular radiolucency associated with an impacted tooth. Some lesions may have radiographically evident small foci of calcifications. Root resorption is rarely seen with the AOT, and is typically mild.

Histopathology

The AOT is highly cellular with spindle-shaped cells in whorls or rosettes (Fig. 132.7). Enameloid, dentinoid, or cementum-like material can be found throughout this lesion. These calcifications suggest the lesion's development

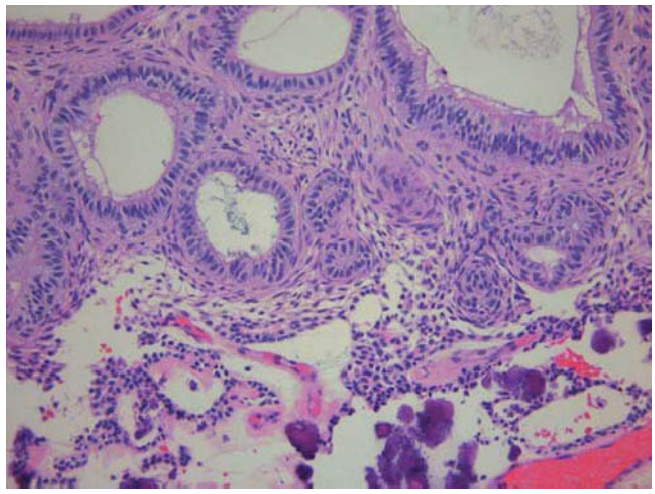

Figure 132.7 Adenomatoid odontogenic cyst. Odontogenic epithelium forming duct-like structures lined by columnar cells exhibiting reverse polarity. Calcifications, a common feature of this lesion, are seen in the lower right portion.

from Hertwig root sheath. These lesions can be mistaken for ameloblastoma by an inexperienced pathologist. If the demographic and radiographic features are not consistent with a diagnosis of ameloblastoma, a second opinion should be sought.

Treatment and Prognosis

Recurrence is not seen in this benign encapsulated lesion, so enucleation and curettage alone is curative. If the capsule is inflamed and becomes compromised during enucleation of the lesion, the surgeon should thoroughly irrigate the surgical field. Bony regeneration of the defect usually occurs in about 1 year in younger patients.

Calcifying Epithelial Odontogenic Tumor (CEOT, Pindborg Tumor)

The calcifying epithelial odontogenic tumor (CEOT) is a rare odontogenic tumor, representing less than 1% of all odontogenic tumors. It originates from the epithelial rests of the dental lamina or reduced enamel epithelium. The CEOT has distinct histologic features and a variable radiographic appearance. Like the ameloblastoma, it is considered a locally aggressive neoplasm that can be highly infiltrative and destructive and must be surgically excised (33,34).

Clinical and Radiographic Features

The CEOT has been reported in patients over a wide age range, but has a peak incidence in the fifth decade. It presents as a slow-growing, firm, painless swelling usually in the posterior mandible. The molar area is the most frequent region in either jaw. Like most other benign odontogenic tumors, the CEOT does not alter nerve function. A peripheral variant exists and typically presents as a soft tissue swelling in the anterior aspect of the mouth (35). Most of these lesions appear as diffuse radiolucent lesions, unless they are large or mature; then they will exhibit areas of faint opacities consistent with the presence of calcifications in the lesion. It is typically associated with the crown of an impacted tooth. Radiographic borders are variable, ranging from distinct lines to diffuse opacified areas fusing with adjacent bone.

Histopathology

The most common pattern of the CEOT is one of sheets or strands of polyhedral epithelial cells connected by intercellular bridges. The nuclei have prominent nucleoli, and the cells may even appear pleomorphic, but this does not imply a malignant state, and mitotic figures are not routinely found. Scattered calcifications are a distinct feature of the CEOT, and the calcifications form concentric rings referred to as *Liesegang rings*. Another histologic variant containing clear cell features has been described and associated with increased clinical aggressiveness (36). Large areas of amorphous eosinophilic material are dispersed throughout the lesion. These areas stain positive for amyloid with Congo red, crystal violet, or thioflavin T. This prominent amyloid presence is another unique characteristic feature of the CEOT (37).

Treatment and Prognosis

Much like the ameloblastoma, the CEOT is treated by resection, but no current study has stated an adequate bony margin to achieve a cure. A minimum of a 1.0-cm bony margin along with any necessary soft tissue to still achieve one layer of an uninvolved anatomic barrier is recommended unless determined otherwise by a frozen section. Recurrence has been reported, so long-term follow-up is recommended. The *peripheral* variant is treated by local excision with a 5-mm margin, which should include the underlying periosteum. The remaining wound may be closed either primarily or by local advancement flaps.

Odontogenic Myxoma

The odontogenic myxoma, although a rare tumor, is worthy of mention due to its locally aggressive behavior and high recurrence rate due to its infiltrative nature. In the jaw bones, it is derived from odontogenic ectomesenchyme that is very similar to the mesenchymal tissue of the follicular sac or dental papilla. The odontogenic myxoma only rarely occurs in non–tooth-bearing portions of the jaws or other facial bones (38).

Clinical and Radiographic Features

The odontogenic myxoma has some clinical and radiographic features in common with the ameloblastoma. It is usually asymptomatic and slow growing. It rarely displaces teeth or resorbs roots and does not alter sensory function. Although it has been reported over a wide age range, it is most commonly seen in the third decade, which is slightly younger than the peak occurrence of the ameloblastoma. The lesion has been reported in all portions of both jaws, but usually occurs in the posterior mandible. Radiographically, the lesion is radiolucent and more often multilocular, but can be unilocular (Fig. 132.8). The lesion also has been described as having a "honeycomb" appearance, with its faint, wispy trabecular bone mixed within cortical plate displacement.

Figure 132.8 Odontogenic myxoma. Panoramic radiograph revealing diffuse, mixed radiolucent/radiopaque involvement of left hemimandible. Lesion extends from midline up to sigmoid notch.

Histopathology

The odontogenic myxoma is an infiltrative and gelatinous tumor. It contains scant, randomly arranged spindle-shaped mesenchymal cells within a myxoid ground substance, which stains predominantly basophilic with hematoxylin and eosin. When these lesions have a more significant collagenous component, they are referred to as myxofibromas or fibromyxomas. However, this classification does not alter the lesion's clinical behavior.

Treatment and Prognosis

Curative treatment requires resection with a 1.0-cm bony margin and a layer of overlying soft tissue. The lesion is unencapsulated, so infiltration into adjacent bone is common making recurrence likely if only enucleation and curettage is undertaken. Enucleation and curettage may be considered only for small, unilocular lesions (less than 1 cm in diameter), but aggressive bony curettage is recommended. The inferior alveolar nerve is not routinely sacrificed, even in large lesions that require an en bloc resection, unless the nerve has been significantly compromised by the lesion.

Ameloblastic Fibroma

The ameloblastic fibroma is a true neoplasm composed of both odontogenic epithelium and ectomesenchyme. The epithelium resembles dental lamina or ameloblastoma, and the mesenchyme resembles the developing dental papilla or myxoma.

Clinical and Radiographic Features

The ameloblastic fibroma is a tumor of young patients with rare occurrence over the age of 40. It presents as a painless swelling usually in the third molar region of the mandible. Enlargement of the affected jaw is the only frequent clinical sign. The lesion can be either a unilocular or multilocular radiolucency with a sclerotic border. It often occurs over an unerupted tooth and can displace the tooth but does not cause root resorption. The ameloblastic fibroma does not have a pathognomonic radiographic feature and can resemble a dentigerous cyst.

Histopathology

Microscopically, the tumor consists of islands of odontogenic epithelium resembling the dental lamina and cap stage of odontogenesis. This columnar epithelium is palisaded and shows striking nuclear polarity similar to that of the ameloblastoma (Fig. 132.9). The stroma is myxoid in appearance, resembling the dental papilla, a cell-rich myxoid tissue.

Treatment and Prognosis

The ameloblastic fibroma can be cured through enucleation and curettage since it is well encapsulated. Owing to its predilection for young patients, the bony defect will repair itself within approximately 1 year. Larger lesions (greater than 5 cm) may require a resection based on the specific anatomic boundaries involved. Reported recurrences were likely due to regrowth of the tumor, which is not completely unusual for embryonal-type tumors. A diagnosis of ameloblastic fibrosarcoma should be considered if this lesion recurs.

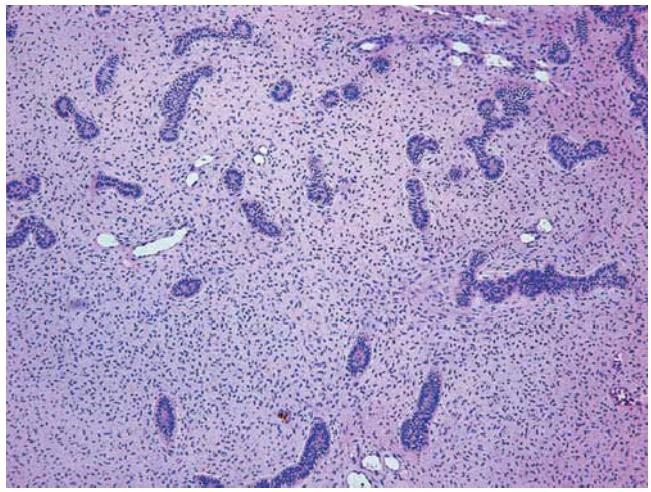

Figure 132.9 Ameloblastic fibroma. Cords of odontogenic epithelium in a background of cellular, primitive mesenchymal tissue.

RELATED JAW LESIONS

Various nonodontogenic lesions of the jaws are worthy of mention due to their biologic behavior as well as the diagnostic and surgical challenges they pose. Some believe that these conditions may indeed be odontogenic because many are only found in the jaws even though they do not reveal histological features consistent with odontogenic-derived structures.

Torus

A torus is a developmental overgrowth rather than a tumor or hamartoma and is thought to arise due to bone stress (39). It develops in one of two intraoral sites. When it occurs on the midline of the palate, it is termed *torus palatinus*. When tori occur on the lingual aspect of the mandible, they are typically bilateral and adjacent to the canine/bicuspid region. These are termed *torus mandibularis* or lingual tori. When a histologically similar lesion develops on the buccal aspect of either jaw, the lesion is referred to as an *exostosis*.

Clinical and Radiographic Features

The palatal torus develops after puberty. It can be found in approximately 20% of adults and has a slow growth pattern. Palatal tori can either have a smooth ovoid appearance or multiple pedunculated loculations, but both presentations should have normal pink overlying mucosa. Tori can grow to large dimensions, impairing speech or feeding or prohibiting fabrication of a maxillary prosthesis (Fig. 132.10). Also, large lesions are often prone to mucosal ulceration

Figure 132.10 Palatal torus.

from mastication. These larger lesions may require surgical excision. Mandibular tori are commonly bilateral and also have a slow growth pattern. They too can reach sizable dimensions, adversely affecting speech or feeding or the use of a lower prosthesis.

Histopathology

Tori consist of nodular masses of dense cortical, lamellar bone with central trabecular bone containing few areas of fibrofatty marrow.

Treatment and Prognosis

Tori only require removal if they interfere with normal function or the fabrication and placement of a prosthesis such as a denture. An elliptical or double-Y-shaped mucosal incision is designed, and the lesion is taken down to the level of surrounding bone with a rotary instrument. The torus can also be scored in the shape of a cross with a surgical drill then removed with an osteotome and mallet. Care must be taken not to perforate through the nasal floor. A surgical stent can be created preoperatively so that the surgical site can be postoperatively protected from irritation from either the tongue or foods. Removal of mandibular tori requires attention to the submandibular salivary ducts when one is using an osteotome and mallet to excise these lesions. A drill can be used to make vertical cuts along the inner aspect of the torus between the lesion and the alveolus. An osteotome is then used to outfracture the torus. Then a rotary instrument is used to smooth the edges of the lingual shelf prior to closure of the flap.

Osteoma

Osteomas are hamartomas or reactive proliferations of bone and are not considered to be true tumors. They are composed of dense compact bone and arise either on the surface of bone (*periosteal osteoma*) or within bone (*endosteal osteoma*). When multiple osteomas are present, one should consider that the patient may have *Gardner syndrome*, an autosomal dominant condition also associated with intestinal polyposis, epidermoid cysts, and desmoid tumors of the skin, impacted normal and supernumerary teeth, and odontomas (40). The formation of the osteomas will usually precede other manifestations of the syndrome. If this syndrome is suspected, the appropriate referral should be made to rule out intestinal lesions, particularly polyps, which have a high rate of malignant transformation to colorectal cancer. The frequency of malignant transformation is essentially 100% in these patients as they reach older age.

Clinical and Radiographic Features

These slow-growing, asymptomatic exophytic bony masses occur in either jaw in areas not typically affected by tori or exostoses. The mandibular angle is a common location. The lesion is usually an incidental finding on routine radiographic evaluation and appears as a well-circumscribed radiopaque mass.

Histopathology

Osteomas have similar microscopic features as tori or exostoses. The periosteum can be more active in the osteoma than the other two lesions.

Treatment and Prognosis

Asymptomatic single lesions can be followed clinically and radiographically. Those lesions requiring biopsy are surgically excised with little chance for recurrence.

Osteochondroma

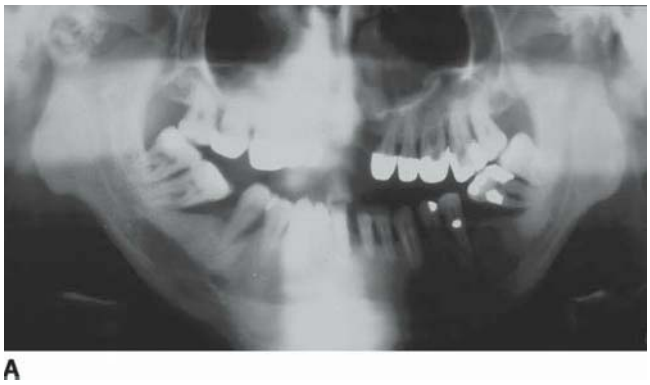
Osteochondromas are benign hamartomas that develop most commonly in long bones, but also occur in the mandibular condyle or coronoid process (41). The lesion is believed to be associated with proliferation of epiphyseal cartilage into the surrounding tissues.

Clinical and Radiographic Features

The absence of this lesion in other portions of the mandible, skull, or facial bones serves to confirm its development in endochondral bone. Osteochondromas are lesions of younger patients, usually occurring in the second and third decades, and are found in twice as many males as females. The lesion is slow growing and known to cause swelling and pain along with deviation of the teeth and chin point toward the unaffected side. Radiographically, it appears as an irregular "popcorn-like" radiopaque mass on the medial side of the condyle or replacing the coronoid process (Fig. 132.11A and B).

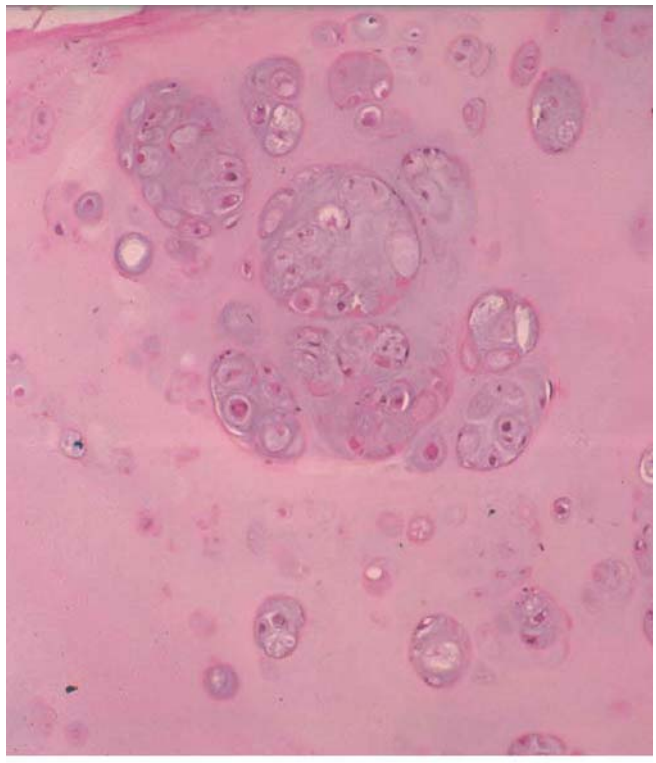
Histopathology

Osteochondromas are bony masses that have a cartilaginous cap. Endochondral ossification is noted between the cartilage and bone (Fig. 132.11C).



A

B



C

D

Figure 132.11 **A:** Osteochondroma. Panoramic radiograph of a 53-year-old man who presented with right preauricular swelling, discomfort, and left-sided shift in his occlusion. Radiograph demonstrates inhomogeneous lesion of right condyle that appears to have replaced entire normal bony architecture. **B:** Three-dimensional reformatted computed tomography (CT) scan of right side as viewed from below. Lateral and more extensive medial extension of the lesion is seen. **C:** Osteochondroma. Chondroid matrix with foci of developing osteocytes and osteoid. **D:** A right condylectomy was performed through a combined preauricular and retromandibular approach. A soft tissue capsule surrounding entire region was encountered. Specimen seen from anterior view.

Treatment and Prognosis

Lesions affecting the coronoid process are managed by a coronoidectomy with minimal removal of the attached temporalis muscle tendon. Lesions of the condyle are treated by condylectomy with a preauricular as well as a neck incision (Fig. 132.11D). Immediate reconstruction can be treatment planned with either a costochondral graft or an alloplastic condyle. Recurrence is very rare.

Ossifying Fibroma (Cementoossifying Fibroma)

Ossifying fibromas are true benign neoplasms of mesenchymal origin that have a strong predilection for the tooth-bearing portion of the jaws, although they have been reported in long bones (42). This slow-growing expansile lesion can reach enormous dimensions resulting in profound facial disfigurement.

Clinical and Radiographic Features

The typical patient with an ossifying fibroma is a woman in her second to fourth decade, although the lesion has been reported over a wide age range and in both sexes. Immature lesions initially present as a radiolucency, but become more mixed as they mature and eventually can become completely radiopaque. More aggressive lesions expand the cortices of the jaws and frequently displace adjacent structures. In the mandible, they typically appear as a mid-body growth at the inferior border, enlarging outward and downward as if "hanging off the lower lateral border" of the mandible.

Histopathology

Ossifying fibromas are well demarcated from the surrounding bone and are composed of dense cellular fibrous tissue with variable amounts of calcified trabeculae of osteoid or bone and/or spherical cementum-like structures (Fig. 132.12). The ossifying fibroma is usually well circumscribed and does not exhibit diffuse infiltration of adjacent tissues, unlike fibrous dysplasia.

Treatment and Prognosis

These lesions are amenable to enucleation and curettage if detected early, or resection for larger lesions. Because ossifying fibromas do not display aggressive infiltration of surrounding tissues, for those requiring surgical resection due to large size or problematic location, a conservative 5-mm margin is appropriate, and recurrence is rare. The juvenile (aggressive) ossifying fibroma is a rare variant of the above and is considered a more aggressive lesion, appearing at a younger age with a predilection for the maxilla.

Fibrous Dysplasia

Fibrous dysplasia is not a true neoplasm; rather, it is a genetic, tumor-like condition where normal medullary bone is replaced with fibrous connective tissue mixed with irregular bony trabeculae. Fibrous dysplasia most commonly occurs in one bone (*monostotic*), or more rarely multiple bones (*polyostotic*). Polyostotic fibrous dysplasia may be seen as a component of *McCune-Albright syndrome*, which includes café-au-lait skin macules, and multiple endocrinopathies, including hyperthyroidism and/or precocious puberty (43). Although genetically based, it is usually a sporadic condition involving a mutation in the α-subunit of a signal-transducing G protein.

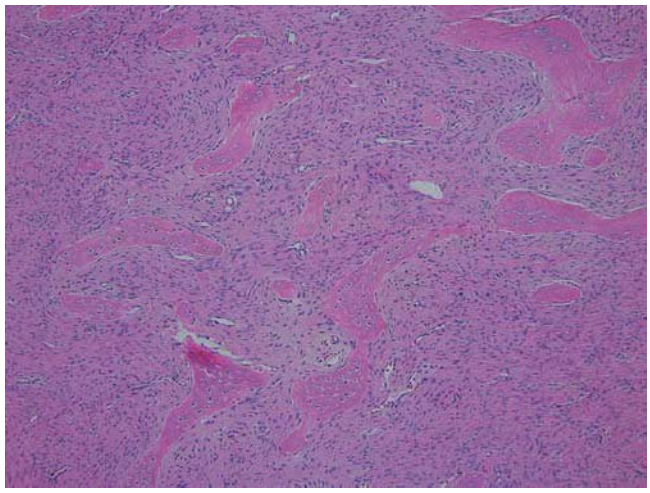


Figure 132.12 Ossifying fibroma. Irregular trabeculae of bone are seen throughout a cellular, fibrous connective tissue stroma.

Clinical and Radiographic Features

Fibrous dysplasia is a slow-growing, typically asymptomatic process that often produces a bony hard swelling (Fig. 132.13A–C). The condition can be self-limiting, beginning in the first decade and ceasing when the affected bone reaches maximum growth and maturation. It is capable of tooth displacement with resultant malocclusion. Lesions located in the paranasal sinuses can cause nasal obstruction. Fibrous dysplasia involving the midface, calvarium, or skull base can cause progressive severe facial distortion and cranial nerve dysfunction via compression. In such individuals, serial visual acuity and audiology testing correlated with 1-mm cut computerized tomography is warranted to monitor progression and guide timing of any necessary surgical intervention. Early lesions are radiolucent but become more opaque as the lesion matures. The normal medullary bone is replaced with a fine trabecular bone, giving the lesion its "ground-glass" appearance on radiographs. Fibrous dysplasia does expand the cortices but does not displace the inferior alveolar canal. The margins of the lesion are usually not well demarcated.

Histopathology

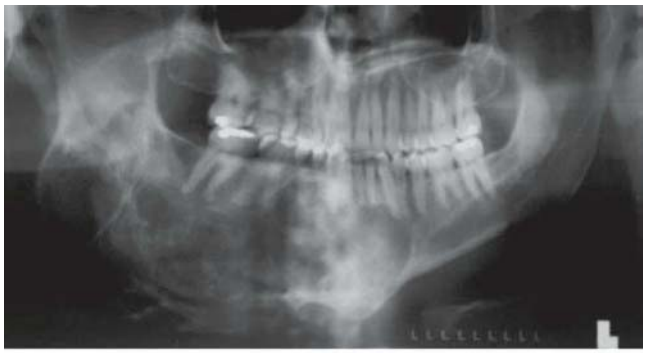
Fibrous dysplasia is seen microscopically as irregularly shaped trabeculae of woven bone in a background of a loose and cellular, fibrous connective tissue (Fig. 132.13D). Fibrous dysplasia has a distinctive microscopic picture of abnormal bone coalescing with the normal surrounding tissue, which is in contrast with the features of the ossifying fibroma.

Treatment and Prognosis

Fibrous dysplasia does not require surgery unless the lesion is disfiguring and the patient desires a more normal and esthetic appearance or rarely if there is cranial nerve dysfunction (44). Recontouring of the affected jaw or facial bone is performed rather than resection, and surgery is usually delayed until the affected bone has reached maturity (Fig. 132.13E). Reports of sarcomatous transformation have been documented, and recurrence is more likely if the lesion is treated during an active growth period.

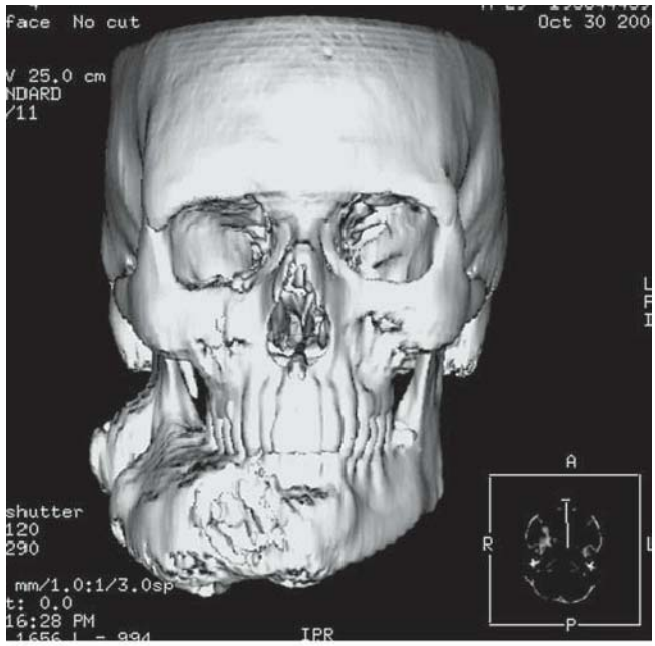
Central Giant Cell Lesion

The central giant cell lesion (CGCL) is a locally aggressive benign lesion that occurs in both long bones and the jaws. Jaw lesions may have similar histopathologic features as

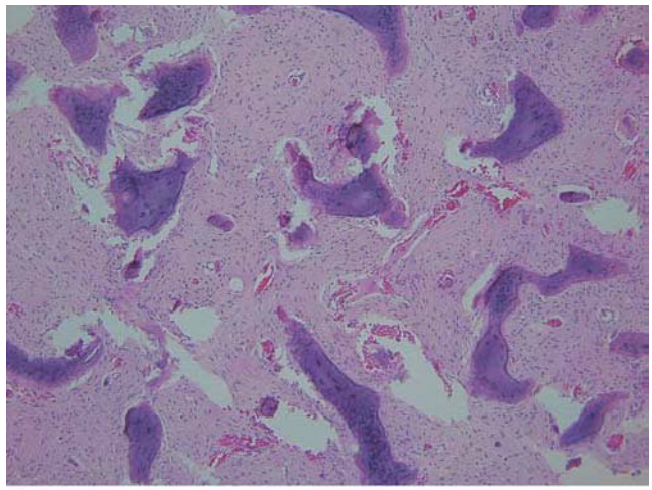


A

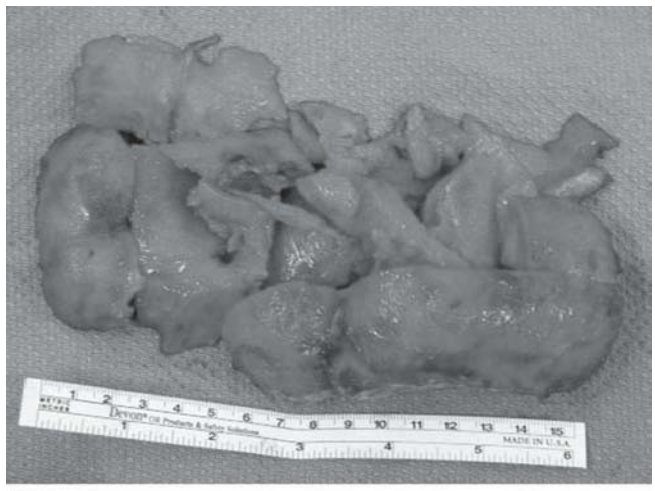
B



C



D



E

Figure 132.13 **A:** Fibrous dysplasia. Panoramic radiograph of a 28-year-old man who presented with steadily increasing right mandibular and facial enlargement, which had been monitored over several years' time. Biopsies established diagnosis of fibrous dysplasia. **B:** Coronal computed tomography (CT) scan of maxillofacial bones demonstrates frontal, maxillary, and mandibular bony involvement. **C:** Three-dimensional reformatted CT scan depicting the gross deformity of the right mandibular lesion. **D:** Fibrous dysplasia. Curvilinear portions of woven bone, without appositional osteoblasts, in a background of connective tissue stroma. **E:** Gross specimen of the fibrous dysplasia.

those that appear in long bones, but the biologic behavior differs. The CGCL is an osteolytic lesion that has been referred to as a central giant cell reparative granuloma in the past, but current understanding is that it does not represent a reparative process (45,46).

Clinical and Radiographic Features

CGCLs of the jaws most often are asymptomatic and are not recognized until they present as a painless swelling. A more aggressive form of the CGCL can cause pain or paresthesia. Clinically, the condition can appear as a bluish mass as a result of the thinning of the overlying bone and mucosa and its highly vascular nature. Most cases develop in the second to third decades, and women outnumber men 2:1. The lesion favors the anterior region of the jaws, particularly the mandible, often crossing the midline, and is occasionally seen bilaterally. The CGCL appears as either a well-circumscribed radiolucency or a multilocular radiolucency. Larger lesions can cause cortical displacement (Fig. 132.14A). The CGCL can also displace teeth, but root resorption is not typical.

Histopathology

The associated giant cells behave much like osteoclasts. Multinucleated giant cells varying in size and their number of nuclei are dispersed throughout a background of spindled mesenchymal cells. The lesion is unencapsulated, and fibrous tissue is also present to varying degrees (Fig. 132.14B). Areas of hemorrhage and hemosiderin deposits are commonly found. Immunologic studies support the biologic behavior and notion that the giant cells represent osteoclasts. Histologic features are not predictive of its biologic behavior, and the CGCL is identical to several other conditions affecting the jaws, including cherubism, the brown tumor of hyperparathyroidism, and focal areas of fibrous dysplasia. Thus, it is prudent to rule out these similar lesions if the clinical features suggest that the lesion may be something other than a CGCL.

Treatment and Prognosis

Curettage is usually curative, but recurrent or larger lesions occasionally require resection (Fig. 132.14C and D). Recurrence becomes an issue if the lesion is associated with difficult removal—attachment to multiple roots or neurovascular structures, or larger, more vascular lesions. Several nonsurgical therapies have been reported with some degree of success. Intralesional steroid injections using triamcinolone (10 mg/mL) weekly for 6 weeks is advocated by some as a first line of therapy (47). Another reported injectable therapy is calcitonin (48). The precise mechanism of action of calcitonin on the giant cell tumor is unknown, but the giant cells have been shown to have calcitonin receptors, and calcitonin somehow interferes with the progression of the tumor.

Aneurysmal Bone Cyst

The aneurysmal bone cyst (ABC) is a rare, expansile osteolytic bone lesion. It contains large blood-filled spaces that do not have an endothelial or epithelial lining, and is thus not a true cyst.

Clinical and Radiographic Features

The ABC commonly occurs in the first three decades of life. They have a predilection for the posterior portions of the jaws. They present as firm swellings that can be diffuse. Teeth may become loosened and displaced, and root resorption may occur, but the teeth remain vital. Radiographically, ABCs are expansile, often multilocular, radiolucencies. The borders are usually well demarcated, but cortical perforations with extension into the soft tissues do occur.

Histopathology

The large blood-filled spaces are separated by connective tissue septa. Hemosiderin, bone, and osteoid can be found within the septa. Osteoclast-type multinucleated giant cells, similar to those found in the CGCL, are a common feature at the periphery of the lesion. Mitoses are commonly found, but atypical forms are not.

Treatment and Prognosis

The ABC is managed by curettage, and intraoperative bleeding can become a challenge. Embolization may become necessary in select cases.

Vascular Malformations

Vascular malformations are developmental lesions that can affect soft tissue or bone. They do not present at birth like hemangiomas, which are actual neoplasms. Vascular malformations can be broadly classified as either arterial (high-flow) or venous (low-flow) malformations. Arteriovenous fistulas may also be considered high-flow lesions.

Clinical and Radiographic Features

Most vascular malformations within the jaws present as slow-growing, asymptomatic, expansile lesions (49). The associated teeth become clinically mobile and may even appear elevated. Thrills or bruits may be detectable on physical examination. When the tongue is involved, lingual veins become distended. Vascular malformations take on a variable radiographic appearance. Some may appear as well-circumscribed radiolucencies, whereas others may appear as more mixed radiolucent/radiopaque. Tooth roots may be resorbed with high-flow lesions. A CT scan or MRI should be obtained to aid in ascertaining the extent of the lesion, and angiography is performed to assist in determining the primary vascular inflow and the presence of any contralateral vascular contributions.

Figure 132.14 **A:** Central giant cell lesion. Panoramic radiograph demonstrating expansive ill-defined lesion at right angle of mandible. Patient noticed a gradually increasing swelling over the right mandible, while her occlusion was shifting to the left. **B:** CGCL. Numerous multinucleated giant cells in a background of plump, primitive mesenchymal cells. Abundant hemorrhage is seen throughout. **C:** A right hemimandibulectomy was performed via a right submandibular approach. The specimen demonstrates the well-vascularized appearance of the lesion. **D:** Post-op panoramic radiograph reveals reconstruction with an iliac crest bone graft. Endosseous implants were placed 7 months after initial graft.

Histopathology

Tortuous endothelium-lined, dilated vessels comprise the microscopic appearance of this condition. Adjacent smaller feeding vessels can also be seen in some cases.

Treatment and Prognosis

Any radiolucent lesion of the jaw, which might be clinically considered to be a vascular malformation, requires needle aspiration prior to biopsy or surgery to rule this condition out. Arterial malformations are treated with preoperative selective embolization followed by resection surgery. The purpose of embolization is to limit the blood flow to the lesion so as to minimize blood loss when the lesion is excised. A variety of materials can be used to embolize these lesions: coils, polyvinyl alcohol beads, or 100% alcohol (50). Overaggressive embolization must be avoided to prevent ischemic necrosis and sloughing of tissues. Hypotensive anesthesia can also be used to further reduce intraoperative bleeding. Venous malformations can be treated with coils or intralesional injections of sclerosing agents. If adequate thrombosis is achieved, then the lesion can be curettaged.

CONCLUSION

Collectively, odontogenic cysts and tumors do not occur with considerable frequency. Many of these lesions are amenable to surgical enucleation and curettage. Some of the cysts and tumors possess locally aggressive behavior and are capable of great tissue distortion and/or destruction. Thus, they present challenges regarding their treatment and ultimate reconstruction. Long-term follow-up is advisable for many of these lesions, as recurrences do occur.

HIGHLIGHTS

- The most common inflammatory cyst is the radicular cyst. Treatment is tooth extraction and enucleation.
- All cystic lesions should be aspirated prior to performing a biopsy to rule out a vascular lesion.
- The dentigerous cyst is associated with the crown of an unerupted tooth.
- The WHO recommended reclassifying the OKC to KCOT to more appropriately reflect its aggressive behavior.
- The basal cell nevus syndrome, an autosomal dominant condition, can manifest with multiple KCOTs.
- Ameloblastoma, the most common odontogenic tumor, requires resection with one additional uninvolved margin when it grows into adjacent soft tissue.
- Tori require removal only if they impair function or the fabrication of a prosthesis.
- Asymptomatic osteomas need not be removed. Multiple osteomas may be indicative of Gardner syndrome.
- Ossifying fibroma, a benign tumor, is amenable to curettage or resection with a close margin.
- Fibrous dysplasia is not a neoplasm. Surgery is indicated in cases of disfigurement. Recontouring of the involved jaw bone may be appropriate.
- ABC is not a true cyst. Curettage is effective.

Treatment of Thyroid Neoplasms

133

Irene Zhang *Samantha DeMauro-Jablonski*
Robert L. Ferris

It is estimated that 45,000 new cases of thyroid cancer were diagnosed and 1,690 of them will die of this disease in 2010 (1,2). The lifetime risk of developing thyroid cancer is 0.9%, and the annual incidence has increased from 3.6 per 100,000 in 1973 to 10.2 per 100,000 in 2007 (1). This trend may be due to increasing use of neck ultrasound as well as other imaging modalities during routine physical exam. CT, MRI, or PET scans performed for other medical reasons can subsequently result in the detection of incidental benign and malignant thyroid nodules. Thyroid nodules are a common presentation of thyroid cancer. Although the prevalence of thyroid nodules is around 50% at autopsy, and up to 67% detected by ultrasonography (US), only 5% to 10% of these are malignant (3,4). The challenge exists to identify the 5% to 10% of patients with malignancy of clinical significance. Recent advances in molecular markers for thyroid cancer have improved the ability to detect subsets of cancer with aggressive behavior and to assist in the setting of indeterminate fine-needle aspiration (FNA). The diagnosis and treatment of thyroid cancer have significantly evolved over last decade, emphasizing the need for a thorough understanding of the underlying molecular pathways and risk factors, as well as the surgical anatomy, diagnostic, and treatment algorithms necessary to provide excellent care for patients with thyroid neoplasm.

SURGICAL ANATOMY AND EMBRYOLOGY

The thyroid gland originates from both primitive pharyngeal and the neural crest cells. It is the first endocrine gland to develop in the human body. The medial portion of the gland derives from the endodermal diverticulum of the first and second pharyngeal pouches at the foramen cecum. It then descends to its pretracheal position along the midline neck during 4 to 7 weeks of gestation, and the proximal portion degenerates into a fibrous stalk. If any of these portions persists, a thyroglossal duct cyst (TGDC) may result. The distal portion gives rise to the pyramidal lobe. The lateral portion of the gland derives from the fourth and fifth pharyngeal pouches, which descend to fuse with the medial portion of the gland.

Parafollicular C cells originate from the ectoderm neural crest cells as the ultimobranchial body, which secretes calcitonin. In mammals, the ultimobranchial body and medial portion of the fourth pharyngeal fuse into the lateral lobes of the thyroid. Because of this, the majority of C cells are located deep within the upper one-third of the lateral lobe, the most common location for medullary thyroid carcinoma (MTC).

Ectopic thyroid tissue can be found anywhere along the course of its developmental descent in the midline anterior neck. Lingual thyroid can be found at its origin at the foremen cecum due to failure to descend. Seventy percent of the patients with lingual thyroids have no thyroid tissue in the neck. Thyroid function should be evaluated before the surgical removal of the lingual thyroid glands. A TGDC is the most common congenital midline cervical anomaly. It may develop at any location along the thyroglossal duct tract, most commonly at the midline upper cervical location close to the hyoid bone. Rarely, this entity can occur in a lateral position. The hyoid bone divides this tract into upper and lower segments. Thus, surgical management of the TGDC (Sistrunk procedure) should remove the middle segment of hyoid bone to prevent recurrence. Preoperative imaging will aid in delineating the nature of a midline mass as well as identifying functional thyroid tissue prior to complete TGDC excision. High-resolution ultrasound, CT, and MRI are commonly used in detecting TGDC. Calcification seen in a CT scanning raises suspicion of papillary carcinoma arising from TGDC.

RISK FACTORS OF THYROID CANCER

Risk factors for thyroid cancer have been studied extensively. They include age of the patient, gender, history of previous radiation, family history, environmental exposures, and molecular genetic factors. It has been widely accepted that papillary thyroid carcinoma (PTC) is twice as common in women as in men (5). Young patients have a better prognosis than older patients. The clinical presentation differs significantly in terms of the size, extent of the cancer, the presence and the number of lymph node metastases, and response to the treatment (6). Indeed, AJCC has incorporated age as part of the staging criteria for differentiated thyroid cancer (DTC).

Although there is no clear association between dietary iodine supplementation and thyroid cancer, the pattern of thyroid cancer in iodine-sufficient areas differs significantly from iodine-deficient areas, with the shift from high proportion of follicular carcinoma to PTC (6,7).

It is well established that exposure to ionizing radiation to the head and neck region during childhood increases the risk of thyroid cancer. Radiation therapy (RT) was once a therapy for tonsil and adenoid hyperplasia, thymic enlargement, acne, hemangioma, and Hodgkin disease (mantle irradiation) to the head and neck. The risk of thyroid cancer often RT exposure is dose dependent and is greatest for children less than 15 years old. The 25-year follow-up after the Chernobyl accident demonstrated that children and adolescents exposed to radioiodine from the Chernobyl fallout have a substantial dose-related increase in thyroid cancer, with the risk greatest in those less than 18 years old at exposure (8). Fortunately, the disease-specific mortality rate in this patient population is quite low, at 1% or less (9). The increased incidence of thyroid cancer in those greater than 18 years old during the Chernobyl fallout is less definitive.

A patient with a family history of thyroid cancer has an increased risk to develop thyroid cancer, and 5% to 10% of all thyroid carcinoma cases are hereditary (10). Gardner syndrome and Peutz-Jeghers syndrome are both associated with PTC. Cowden disease is associated with follicular thyroid carcinoma (FTC). MEN IIA and MEN IIB are associated with family history of MTC (11).

MOLECULAR BASIS OF THYROID NEOPLASM

The knowledge of molecular genetics and signaling pathways in thyroid cancer has expanded in recent years. Numerous molecular alterations in thyroid cancer have been identified, and are actively studied in clinical trials as therapeutic targets for recurrent disease. Among them, four major mutations involved in development of differentiated thyroid cancer (DTC), BRAF and RAS point mutation, RET (REarranged during Transfection)/PTC, and PAX8/peroxisome proliferator-activated receptor γ (*PPARγ*) rearrangements, seem to have most relevant clinical implications (12). Like many other malignancies, genetic alterations in the mitogen-activated protein kinase (MAPK) signaling pathway are involved in development of PTC (Fig. 133.1) (13).

PTC often carries mutually exclusive BRAF and RAS point mutations and RET/PTC rearrangements, which are activated in MAPK signaling pathway. Mutation in one of these genes presents in more than 70% of PTC (14–16).

BRAF point mutations have been reported in 40% to 45% of PTC. BRAF V600E mutation has been found in 70% to 80% of tall-cell variant of PTC and 60% of classical PTC and strongly correlated with aggressive features of this disease including extrathyroidal extension (ECE), lymph node, or distant metastases (14,17,18). BRAF V600E is not found in FTC or other benign thyroid nodules, which makes it a specific tumor marker of PTC. This association has also been reported in papillary microcarcinomas, which might have some clinical implications in the management of these tumors (19). RET/PTC rearrangements are found in 20% of adult papillary carcinomas, most commonly in patients with history of radiation (20,21). It is common in patients with history of radiation and young adults with PTC. However, it has been found in other benign thyroid lesions or hyalinizing trabecular tumors (21,22). In MTC, RET is activated by point mutation rather than chromosomal rearrangement, as found in PTC. Point mutations of the RAS genes (HRAS, KRAS, and NRAS) are found in FTC, PTC, and follicular adenoma. In thyroid carcinoma, KRAS and NRAS are the most commonly altered. RAS mutations are found in 45% of follicular carcinoma and 10% papillary carcinoma (13). In the latter, PTC with RAS mutation is almost always of the follicular variant (12). These are also found in other follicular adenomas/hyperplasia or goiters. PAX8/*PPARγ* rearrangement is present in 35% of classic follicular carcinomas. RAS mutation and PAX8/*PPARγ* rearrangement are rarely overlapping. Mutations in the RAS genes or PAX8/PPARg rearrangement occur in approximately 70% of FTC (23).

Compelling data indicate that molecular testing of thyroid FNA specimens may significantly improve the accuracy of preoperative cytologic diagnosis of thyroid nodules, especially in the subgroups including follicular lesion of indeterminate significance (FLUS), follicular neoplasm, and suspicious for malignancy. Current ATA guidelines recommend that the molecular test results may be considered for indeterminate FNA cytology to help guide the management of those patients. The feasibility and diagnostic utility of molecular testing in FNA of thyroid nodules has been reported in a recent large prospective study including 470 FNA samples. Molecular testing demonstrated 100% accuracy for malignancy in all mutation-positive FLUS cases (24). BRAF was the most common mutation and had 100% positive predictive value (PPV) for PTC, whereas RAS mutation confers 87.5% probability of malignancy (24). In light of the finding in this study, the patients with

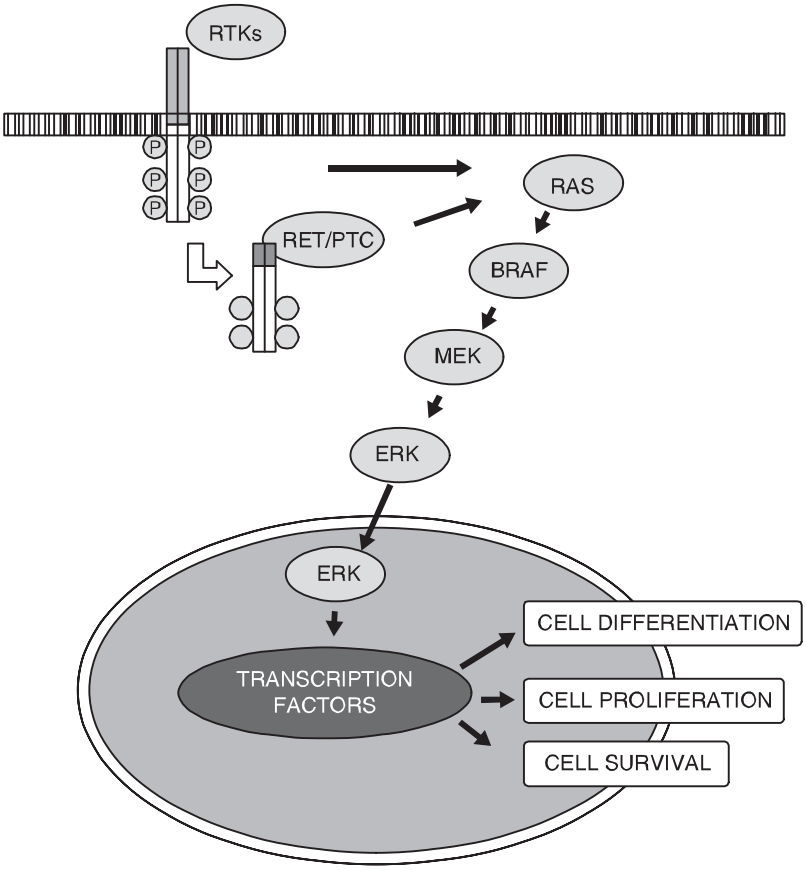

Figure 133.1 MAPK signaling pathway is activated by binding of growth factors to receptor tyrosine kinases (RTKs), such as RET. The activated receptor, via a series of adaptor proteins, leads to activation of RAS, BRAF, and subsequently MAPK/ERK pathway, which regulates cell differentiation, proliferation, and survival. Alteration of this pathway in thyroid cancer can occur at different levels as a result of BRAF and RAS point mutation or RET rearrangement. (From Nikiforov YE. Thyroid carcinoma: molecular pathways and therapeutic targets. *Mod Pathol* 2008;21:S37–S43 with permission.)

mutation-positive and cytologic indeterminate nodules are considered for total thyroidectomy, especially with BRAF mutations, to reduce the need for intraoperative pathologic consultation and to avoid a second surgery. In addition to the diagnostic value of molecular testing, the aggressive behavior of BRAF-positive PTCs provides prognostic information to refine patients' management, including consideration of central neck dissection. Although still early in clinical application, the expanding knowledge of thyroid tumor biology has started translating into clinical practice, and molecular testing in thyroid FNA will be a valuable tool for diagnosis and better prognostication of thyroid cancer.

EVALUATION OF THYROID NODULES

Most commonly thyroid neoplasms present as either palpable thyroid nodules or nonpalpable nodules incidentally found by imaging studies, so-called incidentalomas. These "incidentalomas" carry the same risk of malignancy as palpable nodules with the same size. Generally, any nodule greater than 1 cm warrants evaluation. Occasionally, subcentimeter nodules with worrisome ultrasound features, previous history of head and neck irradiation, family history of thyroid cancer, or associated neck lymphadenopathy require further evaluation. Recent studies demonstrated 27% to 42% risk of malignancy in focal or unilateral uptake in ^{18}FDG-PET scan (25–27). The term "PAINs" (PET-Associated Incidental Neoplasm) was introduced, and the prompt evaluation and treatment of these patients are warranted (28).

Clinical Assessment

For patients presenting with a thyroid nodule, a thorough history and physical examination should be performed. Pertinent elements increasing the possibility of malignancy in the history are previous history of irradiation to the neck, history of thyroid cancer in first-degree relatives, rapid growth, dysphasia, hoarseness, male gender, and presentation at extreme age (less than 20 or older than 70) (29).

The worrisome findings on physical examination which raise concern for malignancy are size of the nodules greater than 4 cm, lateral cervical lymphadenopathy, vocal cord immobility, and fixation of the nodule to surround structures. The accuracy of physical examination may be limited by the patient's body habitus, and further imaging may be of value for the patients with large BMI or posterior located nodules.

Laboratory Studies

Most patients with thyroid nodules are euthyroid. A serum thyroid stimulating hormone (TSH) level should be obtained as part of the evaluation. Subsequent T3, T4, and

a radionuclide thyroid scan should be obtained for those with a low TSH to further evaluate the thyroid function. Thyroglobulin (Tg) level is not routinely measured as initial evaluation of thyroid nodule due to its lack of sensitivity and specificity as a screening tool. Serum calcitonin level and urine metanephrine should be obtained in patients with family history of medullary thyroid cancer or MEN IIA or IIB.

Imaging Modalities

Ultrasound

High-resolution thyroid ultrasound should be performed in all patients with thyroid nodule(s) to assess the thyroid bed, central compartment, as well as lateral neck, according to the 2009 ATA guideline. US helps to confirm the presence of a nodule corresponding to the physical examination, size of the nodule(s), presence of other nodules in the thyroid bed and/or lymphadenopathy in lateral necks, components of the nodule(s) (cystic vs. solid), and posteriorly located nodules. It also plays an important role for monitoring the interval changes of preexisting nodule(s) and posttreatment surveillance for thyroid cancer. In addition, it allows identification of certain suspicious ultrasound features suggesting malignancy. Although no single sonographic finding is pathognomonic for thyroid malignancy, certain ultrasound features of thyroid nodule are associated with higher probability of malignancy (30,31). These include hypoechogenicity, increased intranodular vascularity, irregular or infiltrated margins, presence of microcalcifications, absence of halo (for papillary carcinoma), and length greater than the width in transverse dimension. The sonographic features highly predictive of benign nodules are pure cystic, coarse calcifications, and regular margins. These features also help to select appropriate nodule(s) and/or site within the nodule (cystic vs. solid) to aspirate for fine needle aspiration biopsy (FNAB).

Radionuclide Thyroid Scan

The role of radionuclide scanning in the initial workup of a thyroid nodule is limited. It is indicated in a nodule(s) with low TSH to determine the functional status of the nodule, since the rate of malignancy in hyperfunctioning thyroid nodule is less than 1%. A hyperfunctioning nodule demonstrated on a radionuclide scan obviates the need for FNAB.

CT, MRI, and PET/CT

Unlike high-resolution, US, CT, or MRI imaging are insensitive for intrathyroid nodule(s), and routine use is rarely indicated in initial workup for thyroid nodule(s). However, both CT and MRI are excellent to evaluate the mediastinal extension or to assess, trachea, esophageal, and/or extrathyroid invasion. CT with contrast as a preoperative evaluation will delay potential postoperative radioactive iodine (RAI) therapy by roughly 3 months. Although PET/CT has been used in initial staging of oncocytic (Hurthle cell) carcinoma or poorly differentiated thyroid carcinomas, it is not indicated in initial workup for a thyroid nodule. On the other hand, PAINs deserves prompt evaluation due to its substantial risk of malignancy. Although, some suggest that PET/CT might play a role to reduce the need of diagnostic lobectomy for nodules with inconclusive cytologic results due to its high negative predictive values, further study is needed before this expensive test becomes universally accepted.

Fine-Needle Aspiration and Molecular Markers

FNA is the procedure of choice to evaluate the thyroid nodule and may be performed via palpation or via US guidance. According to 2009 ATA guideline, FNA is indicated in following situations:

1. Any nodule with high-risk history if it is greater than 5 mm, with microcalcification, or any abnormal cervical lymph nodes
2. Greater than 1-cm solid nodule
3. Greater than 1.5-cm mixed nodule with any suspicious ultrasound features
4. Greater than 2.0-cm spongiform nodules or mixed nodule without any suspicious ultrasound features

FNA is not indicated for pure cystic nodule. In case of multinodular gland, preference should be given to those hypo- or isofunctioning nodules with suspicious ultrasound features. The diagnostic accuracy is improved with US-guided FNA because of a decreased number of inadequate samples or false negative results (32). According to 2009 ATA guidelines, US-guided FNA is recommended for nonpalpable nodules, predominately cystic nodules, and posterior nodules. The cytologic results from FNA should be reported under six categories to reflect the risk of malignancy according to 2007 Bethesda system for reporting thyroid cytopathology (Table 133.1) (33). PTC can be reliably diagnosed from FNA due to its characteristic nuclear features. Benign or malignant follicular neoplasm cannot

TABLE 133.1 THE BETHESDA SYSTEM FOR REPORTING THYROID CYTOPATHOLOGY

Diagnostic Category	Risk of Malignancy (%)
Nondiagnostic or unsatisfactory	1–4
Benign	0–3
Atypia of undetermined significance or FLUS	5–15
Follicular neoplasm or suspicious for a follicular neoplasm	15–30
Suspicious for malignancy	60–75
Malignancy	97–99

Modified from Cibas ES, Ali SZ. The Bethesda system for reporting thyroid cytopathology. *Am J Clin Pathol* 2009;132:658–665.

be distinguished on cytology alone, because capsular or angiolymphatic invasion is required to make the diagnosis, which cannot be assessed from cytopathology.

As discussed before, recent advances in molecular testing in thyroid FNA specimens have enhanced the ability to distinguish malignant from benign nodules. The most commonly studied molecular markers in thyroid neoplasm are BRAF and RAS point mutations, as well as RET/PTC and PAX8/PPARγ rearrangements. Although the exact indications of molecular testing need to be defined, it seems that most clinical utility lies in assisting the decision making between thyroid lobectomy and total thyroidectomy when the cytology is under the category of "follicular neoplasm" or "follicular lesion of undetermined significance (FLUS)." Also, BRAF V600E-mutated cancers may be considered for central neck dissection, particularly if greater than 1 cm, to reduce the need for reoperation.

Workup

The authors have proposed the algorithm in Figure 133.2 for workup of a thyroid nodule. It is based on the 2009 American Thyroid Association guideline, 2009 Bethesda system for reporting thyroid cytopathology, and the most recent advances in thyroid FNA molecular basis of thyroid cancer.

Any symptomatic thyroid nodule should be evaluated with TSH level and diagnostic ultrasound. Thyroid uptake scan should be ordered in those with low TSH levels. The patients with hyperfunctioning nodule can be worked up by an endocrinologist, and no FNA is recommended. FNA is indicated in the patients with normal or high TSH.

A repeat FNA should be performed if FNA is reported as "unsatisfactory." Patients who have a benign FNA report can be followed. There is a 3% false negative rate. Annual US is used to monitor the nodule for growth or

development of suspicious sonographic features for malignancy, at which time a repeat FNA is warranted. Total thyroidectomy is recommended when the FNA report indicates malignancy. The FNA has a sensitivity of 97% to 99% (9). Recent prospective data from University of Pittsburgh Medical Center demonstrated 100% PPV and 100% specificity for BRAF-positive "follicular neoplasm" or "suspicious for malignancy" FNA (15). Another study showed 100% PPV in mutation-positive "FLUS" group, while the probability of malignancy for mutation-negative FLUS group is only 7.6% (34). The asterisk part in Figure 133.2 reflects our clinical practice based on above findings. Currently, it has not yet been fully validated or universally accepted. We believe the treatment algorithms will change in the near future as more data accumulate and molecular testing becomes more widely available.

OVERVIEW OF THYROID NEOPLASM

Thyroid Adenoma

Thyroid adenomas are true benign thyroid neoplasms, distinctly separate from surrounding thyroid tissue. They are often encapsulated and arise from normal thyroid follicular cells, in multinodular goiter or in thyroiditis. Clinically, patients usually are asymptomatic, and the nodule is often found in routine physical examination. Spontaneous bleeding into the adenoma may cause sudden increase in size and pain. Follicular adenomas are the most common. Other types include oncocytic (Hurthle cell) adenoma, hyalinizing trabecular adenoma, and nodular adenomatous goiter. Thyroid adenomas with benign FNA results warrant follow-up due to the false negative rate of 5% (35). Nodule growth during the follow-up warrants repeat FNA. The 2009 ATA guidelines recommend serial US every 6 to 18 months following initial FNA. The follow-up interval can extend up to 3 to 5 years if the nodule is stable over time. Routine TSH suppression is not recommended for benign thyroid nodules. If surgery is indicated, the minimal surgical intervention should be thyroid lobectomy.

Papillary Carcinoma

PTC is the most common type of malignant thyroid neoplasm, both in adult and children. It is twice as common in women as in men (5). The hallmark for PTC is its papillary architecture, psammoma bodies, and characteristic nuclear features. The distinct nuclear features include nuclear grooves, nuclear pseudo-inclusions, powdery chromatin, and micronucleoli. These features allow a diagnosis of PTC based on cytology of FNA. Several histologic variants of PTC have been identified, including papillary thyroid microcarcinoma, follicular variant, encapsulated variant, diffuse sclerosing variant, and oxyphilic cell variant and two aggressive types—tall cell and columnar cell variant.

Most patients present with a slow growth neck mass. Thirty-five percent PTC were found to have cervical lymph nodes involvement at the presentation. Multicentric involvement and ECE are common. Previous exposure to ionizing radiation, especially during childhood, is well-established risk factor for papillary carcinoma. Although most of the cases are sporadic, several syndromes involving familial PTC have been described, which include Cowden syndrome and familial adenomatous polyposis coli.

Follicular Carcinoma

FTC is more aggressive compared with PTC. It is more prevalent in iodine-deficient regions. Although most radiation-induced thyroid cancers are papillary carcinoma, it also plays a role in development of FTC. There are two types of FTC: minimally invasive and widely invasive, each of which carries different prognosis. Diagnosis of FTC is based on capsular and lymphovascular invasion, which makes this entity almost impossible to diagnose based on cytology or frozen section.

The clinical presentation is similar to PTC. The incidence of nodal involvement at presentation is lower than papillary carcinoma, ranging from 15% to 20%. However, the incidence of distant metastasis at presentation is more common than PTC, ranging from 10% to 15% (36,37). The most common sites of metastasis are lung and bone.

Hurthle Cell Carcinoma

Oncoytic (formerly Hurthle cell carcinoma, HCC) is uncommon and currently considered as a variant of follicular carcinoma according to World Health Organization classification. It is twice as common in males as in females. Hurthle cells are large follicular epithelial cells with dense eosinophilic cytoplasm. Similar to follicular carcinoma, diagnosis of HCC is based on its capsular and vascular invasion. The incidence of lymph node involvement is around 6% to 9%. HCC has the highest rate of distant metastases compared to PTC and conventional type FTC. Thirty-four percent of HCC developed distant metastases, and most common sites are lung and bone (36,38).

Anaplastic Carcinoma

Anaplastic thyroid carcinoma, accounting 1% to 3% of primary thyroid malignancy, is the most aggressive thyroid neoplasm. It is more common in women than in men, affecting patients in their fifth or sixth decades. Many cases are associated with preexisting papillary or follicular carcinomas, or preexisting goiter. Thirty percent cases are found in the specimen of well-differentiated carcinoma.

Patients usually presented with rapid growing neck mass with symptoms of airway obstruction and/or dysphasia. On physical exam, the tumor is usually large, firm, and fixed to surrounding structures and may result in tracheal/esophageal invasion, unilateral or bilateral vocal cord paralysis, and carotid artery and sympathetic trunk involvement. Distal metastases are not uncommon. Anaplastic carcinoma must be differentiated from lymphoma, which

presents with a similar clinical picture. Airway control is the important measure for these patients. Overall, prognosis is extensively poor. Treatment protocols include doxorubicin and external bean RT. In some situations, surgical debulking might be an option for the purpose of airway management. Surgical cure may occur when an anaplastic carcinoma is encountered prior to infiltration and metastasis.

Lymphoma

Thyroid lymphoma accounts for less than 5% of thyroid malignancy and can arise from preexisting Hashimoto thyroiditis. The majority of thyroid lymphomas are non-Hodgkin B cell lymphoma. The clinical presentation is similar to anaplastic carcinoma. Patients usually have rapid response to chemotherapy with or without radiation. The most common chemotherapy regimen is CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone). Surgery is not a primary treatment modality, and its role is limited to the diagnosis of lymphoma.

Other Forms of Thyroid Cancer

Primary squamous cell carcinoma of the thyroid has been reported. In these situations, metastases from other sites should be ruled out. Other cancers metastasizing to thyroid can occur. The primary sites include renal cell carcinoma, breast, bronchogenic carcinomas, ovarian cancer, and melanoma.

STAGING AND PROGNOSTIC CLASSIFICATIONS

Both histologic diagnosis and age were considered important factors for tumor behavior and prognosis for DTC and therefore included in the AJCC classification. Separate grouping systems are recommended for DTC (papillary and follicular), medullary, and anaplastic (or undifferentiated) thyroid carcinoma (Tables 133.2 and 133.3).

In thyroid cancer, the AJCC staging system does not include several other prognostic factors, such as histologic grade. Although many other risk stratification systems (AGES, AMES, MACIS, etc.) have been developed to address this issue, none of these prognostic classifications is able to encompass all risk factors. In addition, these classifications do not apply to patients with MTC or anaplastic carcinomas.

INITIAL SURGICAL MANAGEMENT OF DTC

Surgical Techniques

Some important steps must be taken in order to ensure a successful thyroid surgery. Preoperative laryngoscopy to

TABLE 133.2 TNM STAGING FOR THYROID CANCER

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension limited to thyroid
T1a	Tumor 1 cm or less, limited to thyroid
T1b	Tumor more than 1 cm but not more than 2 cm in greatest dimension, limited to the thyroid
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension, limited to the thyroid
T3	Tumor more than 4 cm in greatest dimension limited to the thyroid, or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissue)
T4a	Moderate advanced disease—tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or RLN
T4b	Very advanced disease—tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels
All anaplastic carcinomas are considered T4 tumors	
T4a	Intrathyroidal anaplastic carcinoma
T4b	Anaplastic carcinoma with gross extrathyroid extension
Regional lymph nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical (levels I, II, III, IV, or V) or retropharyngeal or superior mediastinal lymph nodes (level VII)
Distant metastases (M)	
M0	No distant metastasis
M1	Distant metastasis

visualize the vocal cords should be performed for every patient prior to thyroid surgery. This is especially important for revision surgery. Patients with vocal cords paralysis or symptoms of dysphagia should be thoroughly evaluated by thin-cut CT scan to assess for tracheoesophageal invasion. Patients with hyperthyroidism warrant medical management to avoid intraoperative and postoperative complications. Pheochromocytoma must be ruled out preoperatively in patients with MTC.

The patient should be placed in supine position with neck fully extended and adequate head support. A transverse incision along a skin crease below the cricoid cartilage is made and carried down to the platysma. The exact length and level of the incision depends on the location of the nodule and glands, habitus of the patients, and extent and approach of the surgery. Subplatysmal flaps are elevated superiorly to the level of the cricoid cartilage and inferiorly to the clavicle.

The midline cervical fascia was dissected to expose trachea, isthmus, and cricoid cartilage. The sternothyroid muscle is dissected off the thyroid gland capsule and retracted laterally to expose the entire thyroid gland. Occasionally, the strap muscle can be divided to gain access to a large superior pole nodule. This should be reapproximated toward the end of the case. An avascular plane between cricothyroid muscle and superior pole was developed, and superior vessels should be meticulously ligated and divided close to the gland to avoid the injury to superior laryngeal nerve (SLN). At this point, the thyroid gland was retracted medially and anteriorly to facilitate identification of recurrent laryngeal nerve (RLN) and parathyroid glands (Fig. 133.3).

To successfully identify and preserve the RLN, the knowledge to RLN is key to a thyroid surgeon. On the right neck, RLN loops around right subclavian artery and follows an oblique course. On the left neck, RLN traverses the ductus arteriosus and follows a more medial course, running along the tracheoesophageal groove. The RLN can be identified superiorly at the laryngeal entry point, (cricothyroid joint), at a lateral approach, at midpole level, or inferior approach where the RLN is found in the triangle bounded by trachea medially, inferior pole superiorly, and carotid sheath laterally. Preservation of the parathyroid glands is the key for thyroid surgery. The relationship between parathyroid glands and RLN is demonstrated in Figure 133.4. Superior parathyroid glands are immediately posterior and lateral to the entry point of RLN. Caution should be taken to preserve the parathyroid glands and its blood supply when we dissect RLN using superior approach. The rate of permanent RLN paralysis is 1% in experience hands. After RLN is identified, it is traced to its laryngeal entry point. The middle thyroid vein and inferior thyroid vessels are

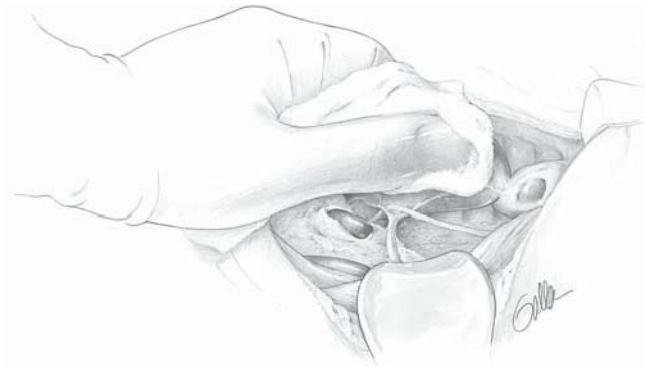

Figure 133.3 Exposure of the lateral border of the thyroid showing the relationship of the RLN to the inferior thyroid artery and parathyroid glands. (From Randolph G. *Surgery of the thyroid and parathyroid glands.* Philadelphia, PA: WB Saunders, 2003, with permission.)

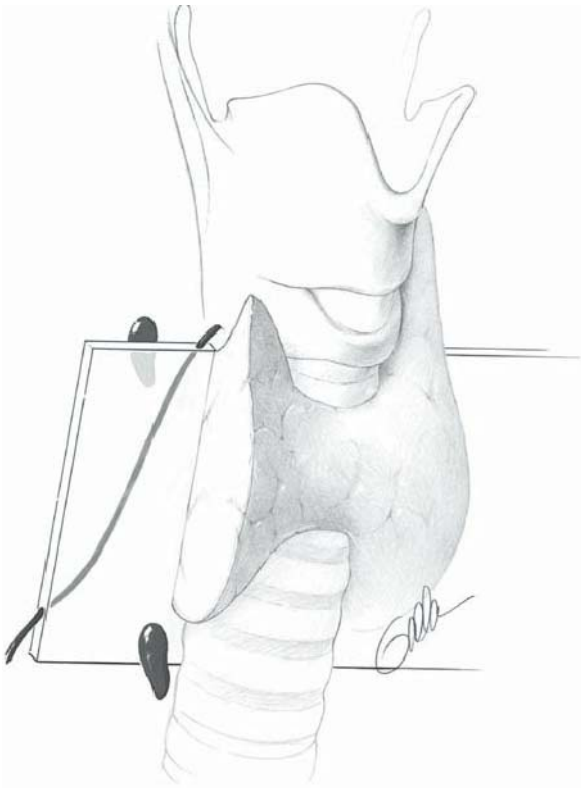

Figure 133.4 Coronal plane formed by the RLN and its relationship to parathyroid glands. (From Randolph G. *Surgery of the thyroid and parathyroid glands.* Philadelphia, PA: WB Saunders, 2003, with permission.)

dissected and ligated near the gland to preserve parathyroid blood supply. The thyroid is dissected medially from its cervical attachments after Berry ligament is carefully dissected. Dissection at this area might be difficult due to potential bleeding and close association between Berry ligament and distal course of the RLN. This is also the area where small remnant of thyroid tissue should not be left after total thyroidectomy. For a total thyroidectomy, the similar steps are repeated on the contralateral side.

Every effort must be made to preserve the function of parathyroid glands. Autotransplantation should be performed if a parathyroid gland becomes devascularized intraoperatively. A small portion of suspicious parathyroid gland is sent for frozen section to obtain histologic confirmation, especially in the situation of thyroid carcinoma. Once the confirmation is obtained, the remaining gland is minced into small pieces and autotransplanted into ipsilateral sternocleidomastoid muscle. Autotransplantation of parathyroid glands is also indicated if extensive nodule disease is seen in central neck compartment with high likelihood for reoperation.

As the specimen is removed, it should be examined carefully for the presence of any parathyroid glands before the thyroid specimen is sent to pathology. Homeostasis was then achieved meticulously, and neck should be closed with multiple layers after the strap muscles are reapproximated.

The indication of routine use of RLN monitoring varies between different institutions. It may be useful if any difficulty is anticipated to identify the RLN, especially in reoperative cases, large tumor or goiters, and extensive central compartment dissection.

Novel Approaches to Thyroid Glands

With the advancement of technology, many novel approaches to thyroid surgery have developed during last decade. Among them, minimally invasive video-assisted thyroidectomy (MIVAT) has gained considerable attention and controversy (39,40). The indications for MIVAT include indeterminate nodules (less than 3.5 cm), no previous neck surgery, no evidence of metastasis, and small, low-risk PTCs (2). The oncologic efficacy of this approach continues to be debated. Other approaches including anterior chest and transaxillary approaches and transoral video-assisted thyroidectomy have been described to avoid cervical incision. These approaches are used in very limited situations for cosmetic purpose only (41,42). In recent years, transaxillary robotic thyroidectomy is evolving through extensive transaxillary approach to avoid cervical incision, which might be more important in some Asian countries for culture and cosmetic purpose (43). It is still too early to predict the level of adoption in North America. These approaches should be considered with caution to provide equal surgical outcomes in comparison to conventional open approaches.

Extent of Surgery

Surgery is the primary treatment modality for thyroid neoplasms. The goal of initial surgery is to eradicate all gross disease; to reduce local, regional, or distal recurrence; and to facilitate possible RAI therapy if required. The minimum thyroid surgery should be lobectomy. Total thyroidectomy is generally indicated in patients with thyroid cancer greater than 1 cm and some subcentimeter PTC with high-risk group and/or poor prognosis molecular alteration. Thyroid lobectomy may be sufficient for small (less than 1 cm), low-risk, and intrathyroidal papillary carcinomas. Although there is no survival benefit based on different surgical treatment for patients with less than 4 cm, intrathyroidal tumors, several studies found that the rates of recurrence are reduced by total thyroidectomy among low-risk patients (43–45).

Special Surgical Considerations

Management of the Regional Lymphatics

Regional lymph node metastases are more common in PTC and less common in FTC. Data are conflicting for the relationship between cervical lymph node metastases and overall survival. A recent SEER registry study concluded that cervical lymph node metastases conferred an independent risk of decreased survival only in patients with

FTC and in PTC patients over 45 years of age. The 2009 ATA guidelines recommend consideration of central neck dissection for patients with clinically involved central or lateral neck lymph nodes along with total thyroidectomy or completion of thyroidectomy. Elective central neck dissection is recommended in T3 or T4 PTC patients with clinically uninvolved central neck lymph nodes and MTC patients. Therapeutic lateral neck dissection should be performed for biopsy-proven lateral cervical metastases.

Recurrent Laryngeal Nerve Invasion

Surgical sacrifice of the RLN is rare. If carcinoma of RLN by carcinoma is found intraoperatively and preoperative vocal cord paralysis is present, the RLN may be sacrificed. If the RLN is involved and preoperative nerve function is normal, it should be saved and dissected to be as free of gross disease as possible. Microscopic disease should then be treated with postoperative RAI therapy. RLN sacrifice should be considered if it is involved in MTC due to the lack of treatment response of MTC to RAI therapy.

Tracheal and/or Esophageal Invasion

For patients with tracheal and/or esophageal invasion, optimal treatment dictates surgical resection if feasible, including postoperative RAI therapy or external beam radiation. Shaving techniques can be used to remove all gross disease. In cases of intraluminal invasion, tracheal resection with anastomosis is warranted. Partial laryngectomy can be performed, and total laryngectomy is indicated in rare cases; after all, conventional treatment options fail.

Special Patient Populations

The diagnostic and therapeutic approaches to thyroid neoplasms in children are similar to adults with consideration of familial and syndromic associations. It is utmost important to balance between the potential treatment morbidity and indolent nature of the disease. MTCs in children are discussed in different sections. Thyroid nodules in pregnant women should be evaluated in the same way as nonpregnant women except that use of RAI is contraindicated. If FNA is consistent with PTC during the pregnancy, surgery is recommended and should be done before 24 weeks gestation. However, data also suggest that treatment delays for less than 1 year do not significantly affect patient outcome. A nodule with PTC diagnosed early in pregnancy should be monitored by ultrasound for growth or spread. If substantial growth is evident before 24 weeks gestation, surgery should be performed. If it is stable, or diagnosed after 24 weeks gestation, surgery may be performed after delivery.

Surgical Complications

Thyroidectomy is a safe procedure in experienced hands. Mortality rates are extremely low, and serious complications occur in less than 2%. The most common complications are injuries to RLN and parathyroid glands.

Postoperative Hematoma

Postoperative bleeding is very uncommon and usually happens during first few hours postoperatively. An expanding hematoma can lead to life-threatening airway obstruction. Airway decompression by evacuating the hematoma should be performed in urgent fashion at the bedside, and patients will then be taken back to operating room immediately for neck exploration to identify and control the bleeding.

Recurrent Laryngeal Nerve Injury

Transient RLN injury is not uncommon, but permanent paralysis should comprise approximately 1% after total thyroidectomy. All patients should undergo pre- and postoperative laryngoscopy to evaluate laryngeal function. The incidence may increase during reoperative surgery or after extensive central neck dissection. Unilateral RLN paralysis may be well compensated and asymptomatic. Symptomatic patients should be managed by vocal cord medialization including vocal cord injection or thyroplasty. Bilateral vocal cord paralysis is a devastating complication from thyroid surgery, and impending airway obstruction is the major concern in these patients. The patients may be managed using transverse cordotomy, arytenoidectomy, or tracheostomy.

Superior Laryngeal Nerve Injury

Injury to the SLN is more common than recognized, and may be temporary or permanent. Patients will have difficulty shouting. Many surgeons do not routinely visualize the SLN. However, adequate exposure and individual ligation of superior pole tributary vessels close to the glands are the keys to avoid SLN injury, in addition to nerve monitoring techniques.

Hypocalcemia

Transient hypocalcemia after total thyroidectomy is the most common complication from thyroid surgery. The rate of transient hypocalcemia has been reported to occur in up to 25% of cases, and permanent hypoparathyroidism is reported to occur in 0.4% to 13% of cases. The extent of surgery, central neck dissection, revision cases, and substernal goiter surgery all may increase the risk of hypoparathyroidism. Serum calcium level, symptoms of hypocalcemia, along with Chvostek and Trousseau signs should be closely monitored in immediate postoperative period. Symptomatic patients should be managed in timely fashion to avoid severe tetany, seizure, altered mental status, and cardiac arrhythmias. Oral and/or intravenous (IV) calcium should be given along with calcitriol. In difficult cases, an endocrinologist can be consulted to adjust the dose of IV calcium and vitamin D.

TABLE 133.4 POSTOPERATIVE RISK STRATIFICATION

Risk stratification	Local/Distal Metastases	Tumor Invasion of locoregional tissue(s)	Aggressive Histology/ Vascular Invasion	Posttreatment Whole-Body RAI Scan (RxWBS)
Low	No	No	No	No
Intermediate	Cervical lymph node metastases	Microscopic invasion	Yes	^{131}I uptake outside thyroid bed
High	Distant metastases	Macroscopic invasion	Yes/No	Tg out of proportion to uptake in RxWBS

Modified from 2009 ATA Guidelines: Cooper DS, et al. *Thyroid* 2009; 19(11):1167–1214.

POSTOPERATIVE MANAGEMENT OF DIFFERENTIATED THYROID CANCER

Postoperative Staging System and Risk Stratification

Postoperative staging is an important part of postoperative management. It allows to assess an individual patient's risk for recurrence and mortality and to tailor the decision making for RAI treatment and TSH suppression. In WDTC, the AJCC staging system is based on age and pTNM parameters to predict the risk of mortality, not recurrence. Many other schemes, including AGES, AMES, and MACIS, were developed to achieve more accurate risk stratification for recurrence. A three-level risk stratification system was suggested in the 2009 ATA guidelines to assess the risk of recurrence (Table 133.4).

In the 2009 ATA guidelines, indications for RAI treatment are based on the AJCC TNM staging. The three-level risk stratification system is also used to recommend the appropriate degree of initial TSH suppression.

RADIOACTIVE IODINE TREATMENT

The roles of RAI treatment are to facilitate postoperative staging and follow-up and to decrease the risk of recurrence and disease-specific mortality (46–48). RAI therapy is given either as remnant ablation, adjuvant therapy, or treatment of known persistent or metastatic disease. There is no therapeutic benefit observed in patients with intrathyroidal microscopic PTC, or microscopic multifocal PTC; thus, RAI ablation is not always recommended for those patients (49,50). RAI ablation is recommended for all patients with distant metastases, T4, and selective T3 disease (≥45 years old) due to decreased risks of recurrence and mortality. There remains conflicting data for 1- to 2-cm intrathyroidal T1 and T2 disease in terms of reduction of risks of recurrence. RAI ablation may be used in selective cases to facilitate staging and postoperative follow-up. There are no sufficient data to demonstrate the benefit of RAI in patients with specific aggressive histology or molecular abnormalities, and this remains the area of future research.

RAI ablation requires TSH stimulation (TSH greater than 30 mU/L) to increase iodine uptake by thyroid cancer cells. The two methods available are thyroid hormone withdrawal or rhTSH (*Thyrogen*) stimulation. Although thyroid hormone withdrawal was the gold standard, recent prospective randomized studies have demonstrated that rhTSH stimulation was equally effective as thyroid hormone withdrawal, with improved quality of life and similar short-term rates of recurrence (51,52). Thyrogen stimulation permits the patient to receive synthroid immediately postoperatively. The method used in preparation for RAI ablation is usually patient, disease status, and center specific. A low-iodine diet and avoidance of iodine exposure (e.g., IV contrast, amiodarone use) prior to RAI ablation have been suggested to prevent interference with the treatment (53).

Current guidelines recommend utilizing the minimum ^{131}I activity necessary to achieve successful remnant ablation, particularly for low-risk patients (54). Usually 30 to 100 mCi is employed. Patients with cervical or distant metastases, suspected or documented residual disease, or a more aggressive tumor histology (e.g., tall-cell variant, insular, columnar cell carcinoma), ^{131}I activity of 100 to 200 mCi was suggested (55). RAI is a relatively safe treatment modality. The side effects associated with RAI ablation include dose-dependent transient acute sialadenitis, short-term taste disturbance, GI discomfort (most commonly nausea), epiphora secondary to bilateral nasolacrimal duct obstruction, bone marrow suppression, and over time a low risk of secondary malignancies and leukemia with high dose and repeat treatments. Clinicians should ensure the benefits outweigh risks in decision making of RAI treatment.

INITIAL TSH SUPPRESSION

The initial TSH suppression therapy has been proven to decrease the risk of recurrence and improve overall survival in high-risk patients if TSH was suppressed to undetectable level (56). According to 2009 ATA guideline, targeted initial TSH suppression level is less than 0.1 mU/L for high-risk and intermediate-risk patients and 0.1 to 0.5 mU/L for low-risk patients.

EXTERNAL BEAM RADIATION THERAPY (EBRT) AND SYSTEMIC THERAPY

Role of external beam radiation therapy (EBRT) is limited, and its survival benefit is uncertain. Current recommendations suggest EBRT is indicated for gross unresectable tumor in patients over 45 years old, none operable symptomatic metastases (pain, fracture, or neurologic symptoms), or as an adjuvant therapy with surgery for selective cases of bone or brain metastases with concomitant use of glucocorticoids (57,58).

Systemic therapy in WDTC is mostly reserved for distal metastases, especially in the situations with the evidence of progression, RAI refractory diseases, or compromising organ function. Doxorubicin remains the only FDA-approved agent for metastatic thyroid carcinoma. Paclitaxel ± doxorubicin and carboplatinum with rh TSH also demonstrated partial response. With recent advances in molecular basis of WDTC, many novel targeted agents (including multi-kinase inhibitors) are in clinical trials. Among them, sorafenib in a phase II clinical trial for DTC and vandetanib in a recent phase III clinical trial for MTC showed clinical benefit (59–61).

LONG-TERM MANAGEMENT OF DTC

Methods of Follow-Up

The goals for long-term follow-up for thyroid cancer are to detect recurrent and persistent disease as well as monitor thyroxine suppression therapy. Clinical examination, serum Tg level, neck ultrasound, diagnostic whole-body RAI scans (WBS), and TSH suppression all play roles in long-term follow-up. Serum Tg level is a sensitive and specific marker to detect PTC recurrence in the absence of Tg antibodies, especially post total thyroidectomy and/or RAI ablation. Initial Tg level is measured with either thyroid hormone withdrawal or rhTSH in low-risk patients. Tg should be measured along with Tg antibodies and neck ultrasound every 6 to 12 months for intermediate- to high-risk patients and every 12 months for low-risk patients. A rising Tg level raises the suspicion for possible recurrent disease and warrants a further workup to localize the recurrence. Thyroid and lateral neck ultrasound is sensitive to detect cervical metastases (62). Tg level can be measured in the needle washout fluid in US-guided FNA sample (63). WBS performed 6 to 12 months after remnant ablation may be beneficial in high- or intermediate-risk patients. ^{18}FDG-PET is indicated to localize Tg positive (greater than 5 to 10 ng/mL) and RAI scan-negative tumor (64). A recent study demonstrated that PET/CT has additional benefits to detect unrecognized distant metastases and to identify non–iodine-avid metastatic lesions (65).

Long-term TSH suppression has been reported to be associated with the reduction of adverse clinical outcomes in patients with thyroid cancer (66). Current guidelines suggest maintaining TSH less than 0.1 mU/L indefinitely, for those with persistent disease, between 0.1 and 0.5 mU/L for 5 to 10 years for high-risk patients, and low-normal for low-risk disease.

Locoregional Recurrent or Persistent Disease

Studies have reported that 5% to 20% of patients treated with total thyroidectomy developed local recurrence within 10 years, 60% to 75% of which localized in the neck lymph nodes with level VI being the most common site (37,67). In patients greater than 45 years old, local regional recurrence may be associated with more morbidity than those less than 45 years old. Maintaining the balance between controlling the recurrent diseases and minimizing treatment-related morbidity is an important principle for the management of recurrent or persistent diseases. High-resolution ultrasound of the thyroid bed and bilateral necks, Tg and its antibody level, and WBS remain the important modalities to detect and follow up recurrent disease. The clinical use of serial Tg level to detect and monitor recurrent DTC is well documented. The primary role for CT and MRI in recurrent/persistent disease is to detect suspicious recurrences in unusual locations, such as supraclavicular, or superior mediastinum, and optimize the surgical planning. The use of PET scanning has been widely accepted as a modality to detect recurrence of DTC post thyroidectomy ± RAI (68). A recent study demonstrated the additional benefit of PET/CT to detect unrecognized distant metastatic disease and non–iodine-avid lesion, which led to a change in treatment plan in up to 40% of the patients (65).

REOPERATION FOR RECURRENT/ PERSISTENT DIFFERENTIATED THYROID CANCER

For recurrent or persistent DTC, a systematic approach to the thyroid bed and/or defined compartment neck dissection was reported to render a better outcome after reoperation than "berry picking" or local lymph node dissection. External beam radiation and systemic therapy are reserved for gross disease and palliation (69). To evaluate a patient for potential reoperation for recurrent or persistent disease, a thorough preoperative evaluation should encompass a detailed history, physical examination, and review of previous operative reports to obtain information of extent of the surgery and integrity of parathyroid glands, ionized calcium level, and intact PTH for lab testing. It is also crucial to evaluate vocal cord function, because clinical symptoms alone are not reliable for documenting RLN palsy (70).

Reoperative surgery in level VI places the RLN and parathyroid glands at greater risk compared with primary surgery. Early intraoperative visualization of RLN is the key to protect the integrity of RLN, and nerve monitoring can assist in the identification of RLN in reoperative settings (71).

Various strategies to identify the RLN(s) should be considered by the surgeons to avoid a previously dissected area. A medial approach to the superior pole can be used only when this area was not dissected from the previous surgery. A lateral approach and medial anterior approach are also commonly used strategies to allow identification of the RLN in previously undissected areas. The incidence of permanent hypoparathyroidism after reoperative surgery is reported up to 3.5% (72). Preservation of parathyroid gland function requires solid knowledge of anatomy and meticulous surgical technique. Care should be taken to preserve parathyroid glands and their blood supply. The surgical specimen should be examined for parathyroid tissues. If identified, reimplantation of parathyroid glands outside of the central neck is recommended after histologic confirmation by frozen section particularly in aggressive or recurrent disease. Effort should be made to avoid inadvertent reimplant tumor or metastatic lymph nodes with the parathyroid tissue. A recent study demonstrated that permanent hypoparathyroidism can be minimized with careful preoperative planning and meticulous intraoperative dissection (73).

Distant Metastatic Disease

Unlike other malignancies, surgical treatment is not a contraindication for DTC. Better survival outcome has been associated with the responsiveness to reoperation and/or RAI (74). Prognosis depends on several factors including the histology of primary tumor, distribution of the metastases, tumor burden, age at diagnosis, and FDG avidity (75). The most common sites of metastases are pulmonary, bone, and brain. 2009 ATA guideline recommends RAI therapy for RAI-avid pulmonary metastases. There are insufficient data to suggest any specific systemic therapy for non–RAI-avid pulmonary metastases. The options then are minimal surgery ± EBRT for palliation, tyrosine kinase inhibitors, and clinical trials. For bone metastases, surgical resection, RAI therapy for iodine-avid lesions, EBRT with concomitant steroids, intra-arterial embolization, and periodic pamidronate remain the options for selected patients. Surgical resection and EBRT have been the mainstays for those patients with brain metastases. RAI therapy could be considered for iodine-avid lesions after EBRT and concomitant glucocorticoids.

MEDULLARY THYROID CARCINOMA

MTC arises from the calcitonin secreting parafollicular C cells of thyroid glands. They derive from the neural crest cells that locate mainly at posterior upper one-third of the thyroid glands. It accounts 4% of all thyroid malignancy in the United States (76). They can be either sporadic (75%) or inherited (25%) with the germline mutations of RET proto-oncogenes (77,78). Cervical lymph node involvement is common at presentation. Ten-year disease-specific survival of medullary carcinoma is 75% (76).

Genetics of MTC

Inherited MTC syndromes (multiple endocrine neoplasia II, MEN II) are autosomal dominant, consisting of MEN IIA, MEN IIB, and familial MTC (FMTC). The most common type of MENII is MENIIA, which is characterized by the triad of MTC, pheochromocytoma, and primary hyperparathyroidism. The typical age of onset is the third or fourth decade of life. FMTC is a variant of MENIIA without pheochromocytoma or primary hyperparathyroidism (79). The typical age of onset is older than MENIIA patients. MENIIB is the most aggressive type of MEN syndrome due to its very early onset of the disease. Majority of the cases are *de novo* germline RET mutations (80). MENIIB syndrome is defined as MTC, pheochromocytoma and musculoskeletal abnormalities (i.e., Marfanoid habitus), or neuromas of lips, conjunctiva, tongue, and GI system. The average age of onset is 10 years earlier than MENIIA (81). Germline RET testing plays an important role in diagnosis of MTC. It helps to distinguish sporadic cases from inherited cases. About 95% of MENIIA and IIB and 88% of FMTC have an identifiable RET mutation (81). In order to diagnose METIIA or MEN IIB for certain, a RET mutation from the patient or the clinical features of MENIIB or IIA in other first-degree relatives have to be identified. According to the 2009 ATA guidelines for MTC, the indications for germline RET testing include a personal medical history of C cell hyperplasia, MTC, MENIIA, or MENIIB (79). For MENIIB, RET testing should be done shortly after birth, due to its early onset and aggressive behavior. Prophylactic thyroidectomy is recommended within the first year of life. For MENIIA, the timing of RET testing is less than 3 to 5 years of age with recommended timing for prophylactic thyroidectomy before age of 5. Once a RET mutation is identified in a family, genetic counseling and RET testing should be offered to all first-degree relatives who might benefit from potential prophylactic surgical management before the recommended age (82).

Preoperative Workup

Preoperative testing for presumed MENIIA or IIB patients includes calcitonin level, CEA, neck ultrasound, and screening for primary hyperparathyroidism. Primary hyperparathyroidism and pheochromocytoma screening should begin by age of 8 by plasma or urine metanephrine. Abdominal CT or MRI for pheochromocytoma is only indicated if there are symptoms of excessive catecholamine or evidence of elevated metanephrine or normetanephrines. Pheochromocytoma should be surgically resected prior to surgery of MTC or primary hyperparathyroidism due to the high risk of anesthesia. Although FNA is indicated for any thyroid nodule, its sensitivity (63%) is lower than that of serum calcitonin (98%).

Extent of Surgery

MTC cells do not have the ability to take up iodine, and RAI therapy is ineffective in MTC patients. The role of adjunctive external bean RT in MTC patients is controversial. Surgical management is the main treatment modality of MTC. Lymph node involvement is up to 75% with palpable MTC. Current ATA guidelines (2009) recommend total thyroidectomy with central neck dissection for MTC patients with no evidence of lateral neck and distant metastatic disease, with or without central neck lymph node involvement. If lateral neck lymph nodes are involved, level IIa, III, IV, and V should be added to the previously mentioned surgery. The patients with distant metastatic disease are incurable, and less aggressive surgery may be appropriate to preserve the function of parathyroid, speech, and swallowing.

Postoperative Follow-Up

Serum calcitonin is a highly sensitive method to detect persistent or recurrent disease. Doubling time has proven to be a useful marker of disease burden and prognosis. Both calcitonin and CEA play important roles in the follow-up of MTC patients, used in conjunction with each other and clinical and radiographic evaluation. Serial measurements of calcitonin and CEA every 2 to 3 months were recommended in current ATA guidelines.

HIGHLIGHTS

- The annual incidence of pathologic thyroid cancer is increasing over the years, and the diagnosis and treatment of thyroid cancer are evolving in last decade, as risk stratification has been established.
- Recent advances in molecular genetics and signaling pathways in thyroid cancer provide better understanding of the biologic behavior of thyroid cancer, which allows potential clinical application in precise diagnosis and treatment.
- Knowledge of thyroid, parathyroid, and laryngeal nerve anatomy is essential to perform thyroid surgery safely. Preservation of nerve function and the parathyroid glands in thyroid surgery is key to maintain the quality of life of patients postoperatively.
- Indications for TSH suppression and RAI after total thyroidectomy for differentiated thyroid carcinoma are based on the risk of the recurrence.
- High-resolution ultrasound and serum Tg levels are two important tools for long-term follow-up of patients with PTC.

Hyperparathyroidism: Evaluation and Surgery

134

Maisie L. Shindo

ABSTRACT

Primary hyperparathyroidism is characterized by autonomous hypersecretion of one or more parathyroid glands. The incidence of primary hyperparathyroidism in the United States is approximately 100,000 patients per year. Causes of hyperparathyroidism can be classified as primary hyperthyroidism, secondary hyperparathyroidism, tertiary hyperparathyroidism, familial hypocalciuric hypercalcemia (FHH), and parathyroid carcinoma. Appropriate management of these patients with hyperparathyroidism requires a thorough understanding of the pathogenesis as well as typical and atypical presentations, knowledge of laboratory tests for proper workup, and interpretation of imaging studies for localization of parathyroid adenomas. The ability to rapidly measure parathyroid hormone (PTH) level has allowed parathyroid surgeons to assess biochemical cure intraoperatively. Thus, surgical treatment of primary hyperparathyroidism has evolved primarily into minimally invasive single-gland excision. However, bilateral exploration still plays an important role in treatment of secondary and tertiary hyperparathyroidism. This chapter discusses clinical, laboratory, and radiologic evaluation of the hyperparathyroid patient as well as surgical and postoperative management.

EMBRYOLOGY AND ANATOMICAL CONSIDERATIONS

The inferior parathyroid glands are derived from the third pharyngeal pouch and descend caudally with the thyroid and thymus. The superior parathyroid glands are derived from the fourth pharyngeal pouch, attach to the posterior surface of the superior or midportion thyroid and migrate caudally with it. This pattern of migration explains the variability in the final arrest of the parathyroid glands, resulting in many possible locations of ectopic or supernumerary parathyroid glands. The limited course of the superior glands leads to less variability in location compared to the inferior gland. The inferior parathyroid glands can typically be found inferior, lateral or posterior to the inferior pole of the thyroid, anterior to a plane drawn through the recurrent laryngeal nerve. They can be quite variable in location. The superior parathyroid glands are less variable in location, the vast majority of them typically located near the cricothyroid joint, just superior to where the recurrent laryngeal nerve courses medially to enter the larynx. The blood supply to the parathyroid glands is primarily from the inferior thyroid artery, and in some there is contribution from the superior thyroid artery.

Humans typically have four parathyroid glands, two superior and two inferior. Approximately 3% to 13% of adults have supernumerary glands, and 5% have fewer than four (1). Normal parathyroid glands vary considerably in shape, size, and color. They are usually 2 to 3 mm in width, 1 to 2 mm in thickness, and 4 to 6 mm in length. Each gland weighs an average of 30 mg.

CALCIUM HOMEOSTASIS

Maintenance of extracellular calcium homeostasis involves the interaction of calcium, PTH, calcitonin, and vitamin D upon several target organs (kidney, bone, intestines, and parathyroid). Parathyroid cells respond to minute changes in the extracellular ionized calcium concentration, such that a small change in calcium concentration results in a change in the release rate of PTH in the opposite direction. This calcium-sensing property of parathyroid cells allows for the precise regulation of the extracellular ionized calcium concentration within a narrow range, normally 1.2 to 1.3 mmol/L. The calcium-sensing ability of parathyroid cells is believed to be mediated by a G-protein–coupled receptor on the parathyroid cell surface, known as calcium-sensing receptor (CaSR) (2). Hypocalcemia

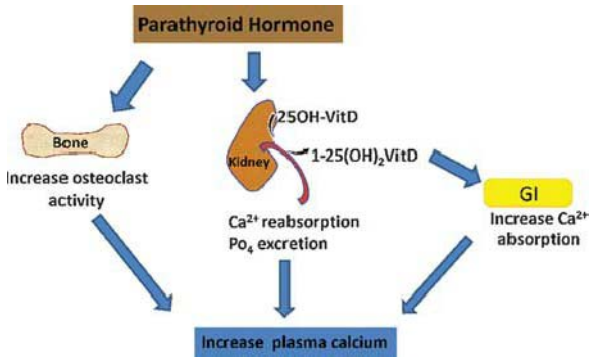

Figure 134.1 Actions of PTH.

induces PTH secretion, which raises the plasma calcium level toward normal by effecting the release of calcium from bone, increasing renal calcium reabsorption, and stimulating the production of 1,25-dihydroxyvitamin D. Vitamin D in turn increases intestinal absorption of calcium. Osteoclasts and certain cells of the renal tubule also exhibit calcium-sensing properties (Fig. 134.1).

PARATHYROID GLAND HISTOLOGY

The parenchyma of the parathyroid gland comprises primarily chief cells that are small, round, and light in color because of very weakly staining acidophilic cytoplasm. The nucleus is centrally placed. Chief cells synthesize PTH. Oxyphilic cells are less frequent, entirely lacking in small children under 6 years, and increase in number with age. Their cytoplasm is strongly acidophilic; the nucleus is small and uniformly intensely basophilic. They contain large amounts of mitochondria. These parenchymal cells are arranged in anastomosing chords surrounded by delicate connective tissue septa with abundant capillaries. A considerable number of fat cells infiltrate the gland beginning around puberty and may account for about half the weight of the parathyroid glands in adults (Fig. 134.2).

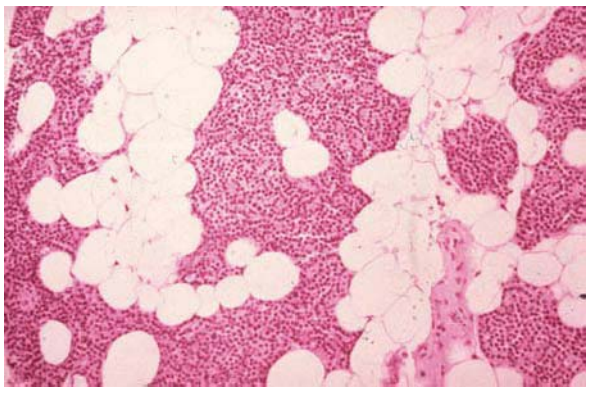

Figure 134.2 Histology of normal parathyroid gland showing chief cells and abundant fat cells.

HYPERPARATHYROIDISM

Hyperparathyroidism is classified into primary, secondary, and tertiary. Other rare causes of hyperparathyroidism include parathyroid carcinoma and FHH. It is important to understand the different causes of elevated PTH in surgical treatment considerations.

Primary Hyperparathyroidism

Primary hyperparathyroidism (1°HPT) is characterized by autonomous hypersecretion of one or more parathyroid glands. The incidence of 1°HPT in the United States is approximately 100,000 patients per year, and its prevalence is estimated to be between 0.2% and 1% (3). It predominantly affects those between the ages of 55 and 70 with a female-to-male ratio of 2:1. Recent reports from large series indicate that the etiology is a single parathyroid adenoma in 89% of cases, and hyperplasia or multiple adenomas in the remainder (4). The incidence of double adenomas ranges from 4% to 16% (5–7).

Secondary and Tertiary Hyperparathyroidism

Secondary hyperparathyroidism (2°HPT) is characterized by elevation of PTH level as a result of chronic hypocalcemia, most commonly from chronic renal failure, but it can also be caused by chronic vitamin D deficiency. In chronic renal failure, renal tubular excretion of phosphate is impaired, leading to hyperphosphatemia and binding with free calcium. In addition, renal hydroxylation of vitamin D is impaired leading to hypovitaminosis D. Vitamin D deficiency leads to decreased calcium absorption from both the gut and reabsorption of calcium in the renal tubules. The end effect is lower extracellular calcium, which in turn, stimulates the parathyroid glands to secrete PTH, resulting in hyperplasia of the parathyroid glands and elevation of PTH level. Other possible causes of elevated PTH associated with normal or low calcium are low calcium intake, inefficient calcium absorption from gastrointestinal disorders, and deficiency in intake of vitamin D; all these conditions result in low calcium and a compensatory rise in PTH level. In tertiary hyperparathyroidism, the chronically hyperplastic glands autonomously secrete PTH, which usually occurs after successful renal transplantation but can also occur after long-standing hypocalcemia of any other cause is corrected.

Parathyroid Carcinoma

Malignancy of the parathyroid gland is a very rare cause of hyperparathyroidism, representing less than 0.2% of patients with 1°HPT (7). It can rarely occur in association with hyperthyroid-jaw bone syndrome. Patients with this syndrome are carriers of the HRPT2 gene (8). This condition typically manifests with extremely high plasma calcium levels, usually greater than 13 mg/dL. Rarely a mass may be palpable (9).

Familial Hypocalciuric Hypercalcemia

FHH is an autosomal dominant genetic disorder characterized by mutations in the intracellular part of the CaSR (10,11). The result is a defect in the CaSR of the parathyroid cell resulting in a lack of PTH suppression in the setting of hypercalcemia. Genetic linkage studies have shown that chromosome 3q is the major, but not the sole, locus for FHH-causing gene (11,12). There are at least two other genetic loci, one linked to chromosome 19p and another family described in which linkage to 3q and 19q loci has been excluded but the FHH-causing gene has not yet been identified (13,14). While this condition is usually diagnosed at a younger age, it may manifest for the first time in older patients who have not sought medical attention throughout life. It typically has a benign course without the hypercalcemia-induced morbidities and is therefore generally not a surgical disease (15,16).

CLINICAL MANIFESTATIONS

The clinical presentation and complications of hyperparathyroidism depends on the degree of hypercalcemia and the rapidity in which the condition develops. The classic symptoms and manifestations of the disease are

1. Musculoskeletal: bone and joint pain, muscle pain, muscle weakness, osteopenia, osteoporosis, pseudogout, renal osteodystrophy
2. Genitourinary: nephrolithiasis, renal insufficiency, nocturia, polyuria
3. Gastrointestinal: constipation, peptic ulcers, heartburn, pancreatitis, abdominal pain, nausea
4. Neuropsychiatric: depression, anxiety, confusion, memory loss, impaired thinking or "brain fog"

A popular mnemonic for remembering these symptoms is "bones, stones, groans, and psychiatric overtones." Other manifestations that can also be seen are fatigue, calciphylaxis (soft tissue calcification), cardiocalcinosis, and band keratopathy.

EVALUATION

Evaluation of the hypercalcemic or hyperparathyroid patient starts with a good history and determination of what manifestations of the disease the patient has. Information on use of medications that can cause hypercalcemia should be elicited, specifically thiazide diuretics, lithium, dietary supplemental calcium, and vitamin D. Family history of hypercalcemia or hyperparathyroidism should be attained, as the patient may have familial hyperparathyroidism or FHH.

Laboratory Studies

The diagnosis of 1°HPT is made based on plasma calcium and PTH levels. Plasma calcium and PTH levels should be drawn on the same day. Normal range for plasma calcium in most laboratories is 8.5 to 10.2 mg/dL (or 2.2 to 2.5 mmol/L). Since most of the body's plasma calcium is bound to albumin, a decrease in plasma albumin will lower the plasma calcium level even though the free calcium remains the same. Therefore if the albumin level is low, the plasma calcium should be corrected such that 0.8 mg/dL should be added to the total calcium for every drop in albumin of 1.0 g/dL. Alternatively, one can measure ionized calcium, which represents free calcium. Normal range for ionized calcium in most labs is 1.14 to 1.28 mmol/L. PTH is an 84 amino acid peptide chain with a C-terminal and an N-terminal. Laboratories in the past measured PTH levels by measuring the N-terminal or C-terminal. Today, the most accurate assessment of PTH level is measurement of the entire chain, known as intact PTH. Normal range for PTH in most laboratories is 15 to 72 pg/mL. The classic laboratory findings of 1°HPT are elevated plasma calcium level and high intact PTH level. Some patients may present with elevated plasma calcium levels and PTH levels only in the midrange to upper limits of normal. In the absence of 1°HPT, elevated plasma calcium should suppress the PTH level. Therefore, unsuppressed PTH in the setting of elevated plasma calcium is "inappropriate" and indicates 1°HPT. In addition to plasma calcium and intact PTH levels, it is also helpful to look at 24-hour urine calcium and serum phosphate levels. Typically in 1°HPT, the serum phosphate is low, and the 24-hour urine calcium is normal or elevated. Some patients may present with only periodic elevations of plasma calcium. In patients with mildly elevated or normal calcium, if the PTH levels are persistently elevated, the serum phosphate is low and 24-hour urine calcium is high (greater than 350 mg), the diagnosis of 1°HPT is likely. In a patient with normal or occasional mildly elevated calcium levels, intermittent mild elevation of PTH, normal phosphate and low to normal 24-hour urine calcium, the diagnosis of 1°HPT is somewhat questionable. If the diagnosis is uncertain, it would be prudent to repeat calcium and intact PTH levels and follow the laboratory values. Other than 1°HPT, the differential diagnosis of hypercalcemia includes thiazide diuretics, immobilization, and hypercalcemia of malignancy and granulomatous diseases. Contrary to 1°HTP, the PTH level is generally low in these conditions.

Elevated plasma calcium and PTH with a *low* 24-hour urine calcium is suggestive of FHH. The diagnosis of FHH should be considered if there is a family history of hypercalcemia, PTH is not markedly elevated, or the 24-hour urinary calcium is low. In that setting 24-hour urine for calcium, plasma calcium, serum creatinine and 24-hour urine creatinine levels should be obtained to calculate calcium–creatinine clearance ratio. These tests should all be performed at the same time. FHH manifests with hypercalcemia and mildly elevated or normal PTH levels (17,18). In FHH, the 24-hour urine calcium is below normal range. The calcium–creatinine clearance ratio, calculated using

the following formula, is helpful in differentiating FHH from 1°HPT.

$$\frac{\text{24-hour urine calcium}}{\text{serum calcium}} \times \frac{\text{serum creatinine}}{\text{24-hour urine creatinine}}$$

A ratio that is greater than 0.01 is consistent with 1°HPT, though does not absolutely exclude FHH, and less than 0.01 is suggestive of FHH.

Some patients may also present with plasma calcium values in the mid to upper normal range but exhibit elevated ionized calcium. In recent years, a new entity known as normocalcemic hyperparathyroidism has been recognized where calcium level, including ionized calcium, is normal and PTH is elevated (19,20). It has been proposed that there is a generalized targeted tissue resistance to PTH in patients with this entity. A study by Maruani et al. (21) showed PTH-dependent functions of the kidney to be attenuated in the normocalcemic hyperparathyroid patients despite an identical primary hypersecretion of PTH. They concluded that: (a) PTH induces milder biologic bone effects than in hypercalcemic patients; (b) Calcium absorption in the renal tubular system is lower in patients with normocalcemic 1°HPT compared to that of patients with hypercalcemic form of the disease. (c) The ability of PTH to decrease tubular phosphate reabsorption and stimulate synthesis of 1,25-dihydroxyvitamin D is also blunted in the patients who remain normocalcemic, compared with those who are hypercalcemic. Normocalcemic 1°HPT can be difficult to diagnose, and 2°PTH from other conditions such as chronic vitamin D deficiency, renal insufficiency, and renal calcium leak need to be excluded first. In 2°HPT, the typical laboratory finding is elevated PTH but unlike 1°HPT, the plasma calcium level is low or normal. Those with 2°HPT from chronic renal failure also exhibit elevated blood urea nitrogen, serum creatinine, and phosphate.

Vitamin D levels should also be measured. In 1°HPT, the 25-hydroxy form will typically be low, and 1,25-hydroxy form is often elevated. Vitamin D levels are generally not used to make a diagnosis of 1°HPT but may be helpful in differentiating 2°HPT due to chronic vitamin D deficiency from "normocalcemic" 1°HPT. Since both conditions will present with normal calcium and elevated PTH, if the 25-hydroxyvitamin D level is low, one can correct the vitamin D deficiency and follow the calcium level. If the calcium level becomes elevated or the PTH level does not correct back down to normal range with vitamin D replacement, the diagnosis is likely to be 1°HPT.

Imaging Studies

While imaging studies are used primarily to localize parathyroid adenomas for surgical planning, they may also be helpful in confirming the diagnosis of 1°HPT. If the lab values are intermittently or only mildly elevated, the diagnosis of 1°HPT can be confirmed if the imaging study unequivocally detects a parathyroid adenoma. The two most commonly used imaging studies are parathyroid ultrasound and technetium-99m-sestamibi parathyroid (MIBI) scan. The sensitivity of each test varies considerably, depending on the equipment and more importantly how experienced is the individual performing or interpreting the study. In the hands of a highly experienced ultrasonographer, which can be radiologist, surgeon, or endocrinologist, the sensitivity is 80% to 85%. On ultrasound, parathyroid adenomas appear hypoechoic and hypervascular (Fig. 134.3). Generally ultrasound should be able to detect adenomas located dorsal to the esophagus. The limitation of ultrasound is detecting adenomas located retroesophageally or in the mediastinum. The principle of sestamibi parathyroid scanning is that ^{99}Tc MIBI tracer is taken up by both the thyroid and parathyroid adenoma but washes out of the thyroid faster than the parathyroid. Therefore early images at 20 minutes after injection are obtained, followed by delayed images typically at 2 hours (Fig. 134.4A). It is quite specific; however, its sensitivity

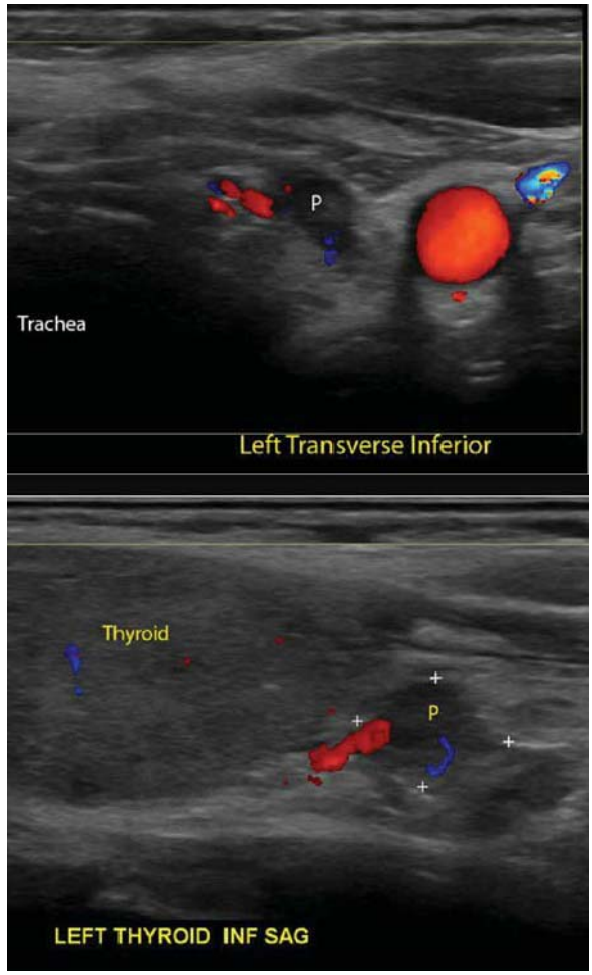

Figure 134.3 Ultrasound of left inferior parathyroid adenoma. **Top:** adenoma (P) between the trachea and carotid artery; **Bottom:** adenoma is at the inferior tip of the thyroid.

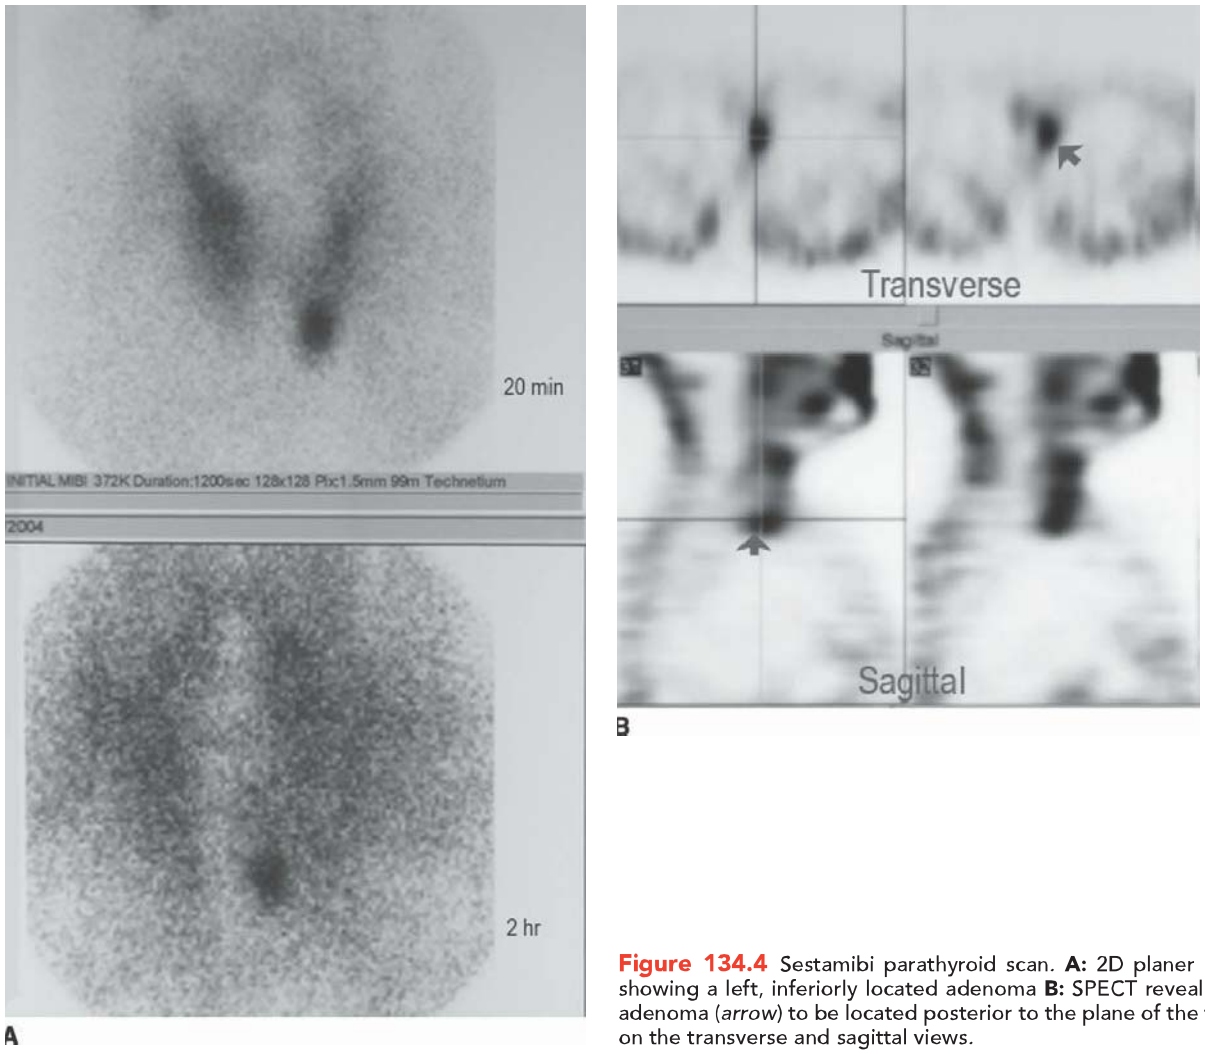

Figure 134.4 Sestamibi parathyroid scan. **A:** 2D planer images showing a left, inferiorly located adenoma **B:** SPECT revealing the adenoma (*arrow*) to be located posterior to the plane of the thyroid on the transverse and sagittal views.

can be low in detecting small glands. One of its limitations is that concurrent thyroid disease can result in a false-positive study. Another limitation is that the images are two-dimensional (2D) planer views and therefore do not provide information on the depth of the adenoma. This information is important for glands that are located inferior to the thyroid. On a 2D planer anterior–posterior view, without the information on the depth of the gland, a retroesophageal or paraesophageal gland can look virtually identical to an anteriorly located inferior gland. Oblique views or single photon emission computerized tomography (SPECT) obtained in conjunction with the 2D planer sestamibi scans can be helpful in providing information on the anterior–posterior location of the adenoma (Fig. 134.4B). Knowing this information obviates unnecessary extensive or missed exploration. If localization with sestamibi scan and ultrasound performed in experienced hands fail, thin-cut CT with intravenous contrast may be helpful. It is especially useful in detecting ectopic glands such as paraesophageal, retroesophageal, or mediastinal glands (Fig. 134.5).

INDICATIONS FOR SURGERY

Parathyroidectomy is indicated in patients with 1°HPT who have complications of the disease, such as nephrolithiasis, hypercalcemic crisis (calcium greater than 12.5 mg/dL), or are symptomatic with musculoskeletal pain, muscle weakness, or severe neuropsychiatric dysfunction (irritability, fatigue, confusion, or insomnia). However, since the gamut of muscular and neuropsychological symptoms is broad, it is often difficult to determine if the symptoms are truly due to 1°HPT. The indications for surgery in the asymptomatic patient were first established in 1990 by a NIH sponsored consensus panel and modified in 2002 (Table 134.1) (22). In 2009, the guidelines were rereviewed at the Third International Workshop on Asymptomatic Primary Hyperparathyroidism, and the recommendations basically remained the same except for three changes: (a) hypercalciuria (24-hour urine calcium greater than 400 mg) was eliminated, (b) creatinine clearance was changed from less than 30% to less than 60 mL/min, and (c) bone density T-score at any site less than −2.5 and/or previous fracture or

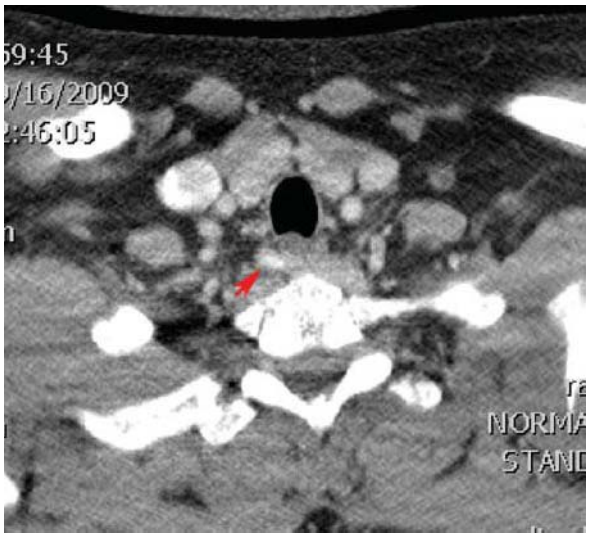

Figure 134.5 CT with contrast demonstrating a right paraesophageal adenoma (*arrow*).

bone fragility (Table 134.1) (23). Since parathyroidectomy traditionally has been performed under general anesthesia and required bilateral exploration, which has potential significant risks, many asymptomatic patients had generally been observed rather than treated surgically. However, in recent years, parathyroid surgery has evolved into minimally invasive focused exploration often under local anesthesia, with significantly lower surgical risks. Therefore, surgical consideration should be given to asymptomatic patients, even in healthy elderly patients with a reasonably long life expectancy, if they are appropriate candidates for minimally invasive parathyroidectomy (MIP).

Multiple studies in the last decade have proven the benefits of parathyroidectomy for 1°HPT. Studies on quality of life postparathyroidectomy have been performed using the SF-36 survey, a self-ranked 36-item survey that assesses general health, as well as the Parathyroidectomy Assessment of Symptoms survey. Both have been shown to improve quickly after surgery (24–27). Furthermore, these improvements are sustained long term (24,27,28). Bone density and hyperlipidemia have also been shown to improve with parathyroidectomy (29,30).

Indications for parathyroidectomy in 2°HPT have been based mostly on presence of musculoskeletal symptoms, such as bone and joint pain, muscle weakness, or radiologic evidence of renal osteodystrophy. In recent years treatment with vitamin D and its analogs have allowed the majority of these patients to be managed by medical treatment for many years without severe symptoms of high bone turnover. Nevertheless, chronic high values of phosphate, calcium, and PTH in renal failure patients have been shown to be associated with increased mortality, mainly due to cardiovascular complications induced by ectopic calcifications (31,32). Therefore, the main indication currently for parathyroidectomy in these patients is when serum phosphate, calcium, and PTH levels cannot be maintained within target ranges with vitamin D or D-analog therapy (32,33). The introduction of cinacalcet, a new allosteric modulator of the CaSR on parathyroid cells that reduces PTH secretion, has also reduced the need for parathyroidectomy by 90% (34). Surgery is indicated when cinacalcet cannot be continued due to adverse side effects or poor compliance, or if the condition is refractory to cinacalcet therapy. Several studies have shown that parathyroidectomy in dialysis patients with advanced 2°HPT is associated with reduced incidence of major cardiovascular events and overall lower mortality (35–38).

TABLE 134.1 INDICATIONS FOR PARATHYROIDECTOMY IN ASYMPTOMATIC PATIENTS

2002	2009
Ca^{2+} > 1 mg/dL above upper limit of normal	Ca^{2+} > 1 mg/dL above upper limit of normal
Creatinine clearance reduced by 30%	Creatinine clearance <60 mL/min
Reduction in bone density (hip, L Spine, Radius) T-score < −2.5	Reduction in bone density (hip, L Spine, Radius) T-score < −2.5; Previous fracture or bone fragility
Under 50 y of age	Under 50 y of age
Medical surveillance not feasible (e.g., coexistent illness) or not possible (e.g., poor follow-up)	Medical surveillance not feasible (e.g., coexistent illness) or not possible (e.g., poor follow-up)
24-h urine calcium >400 mg	

PARATHYROIDECTOMY

Bilateral Exploration

While the majority of parathyroid surgeries today are performed using a targeted approach exploring only a single gland (see next section), surgeons still need to be thoroughly familiar with the principles of 4-gland exploration, which is essential for treatment of hyperplasia, 2°HPT, and tertiary hyperparathyroidism. Knowledge of parathyroid gland locations is the key to successful 4-gland exploration. Embryologically, the inferior parathyroid glands arise from the dorsal wing of the third pharyngeal pouch, and the ventral wing of the third brachial pouch differentiates into the thymus. The thymus then migrates caudally, pulling the parathyroids with it. Descent of the inferior parathyroid glands usually stops at the dorsal (posterior) surface of the inferior thyroid outside of its fibrous capsule. At times the inferior parathyroids may not lose its connection to the thymus and thus descend into the anterior mediastinum with the thymus. The superior parathyroid glands arise from the dorsal wing of the fourth pharyngeal pouch and descend with the thyroid. The superior parathyroids

are generally located more posterior and medial than the inferior parathyroids, and their final resting point is usually on the dorsal surface of the mid or superior pole of the thyroid. However, they may also be ectopically located lateral or posterior to the esophagus. Rarely can they be located superior to the superior pole. Parathyroid glands can also be located in the carotid sheath or inside the fibrous capsule of the thyroid (intrathyroid).

When performing 4-gland exploration, it is important to search for each gland systematically moving from one quadrant to the next in the expected locations of the parathyroid glands. If the glands are not identified in the expected locations, the ectopic locations of the missing gland should then be systematically explored. For example, if a superior gland is missing, the paraesophageal and retroesophageal areas should be explored. If an inferior parathyroid is missing, exploration should be directed first at the most common ectopic location for the inferior glands—the thymus and superior mediastinum. If the missing parathyroid is not found in these locations the carotid sheath should be explored. The last location to consider is intrathyroid, in which case a hemithyroidectomy on the side of the missing gland may be necessary. An alternative to hemithyroidectomy for identifying an intrathyroid adenoma is to perform intraoperative thyroid ultrasound with a small probe. If a hypoechoic nodule adjacent to the posterior capsule is found (Fig. 134.6), needle aspiration of the lesion can be performed. The sample can be rinsed with approximately 2 mL of normal saline and a rapid PTH assay can be performed intraoperatively. The PTH level will be high if the lesion is a parathyroid adenoma.

When performing subtotal parathyroidectomy, it is important to not completely excise or devascularize each parathyroid gland as soon as it is identified. As each one is identified, it is best to biopsy part of the gland for confirmation and temporarily keep a portion *in situ*. Once all four glands are histologically confirmed, the most viable residual gland should be selected for preservation *in situ*, and then excision of the other glands can be performed. Some of the excised parathyroid glands should be cryopreserved for possible future use. Approximately 30 to 40 g of parathyroid tissue should be prepared for reimplantation. It is preferable to reimplant into the brachioradialis muscle of the patient's nondominant hand. The parathyroid tissue is incised into approximately 1 × 1 × 3 mm pieces (Fig. 134.7A) and each piece is microsurgically reimplanted into the brachioradialis muscle. Each reimplantation site should be marked with hemoclip and/or colored permanent suture for ease of identification if the need arises to someday excise hyperplastic reimplanted tissue (Fig. 134.7B).

The decision to perform subtotal versus total parathyroidectomy depends on the disease and to some extent surgeon's preference. Those with hyperplasia due to 1°HPT should undergo subtotal parathyroidectomy, with the goal for the intraoperative rapid parathyroid hormone (IOPTH) to return to the mid-normal range. Most would also

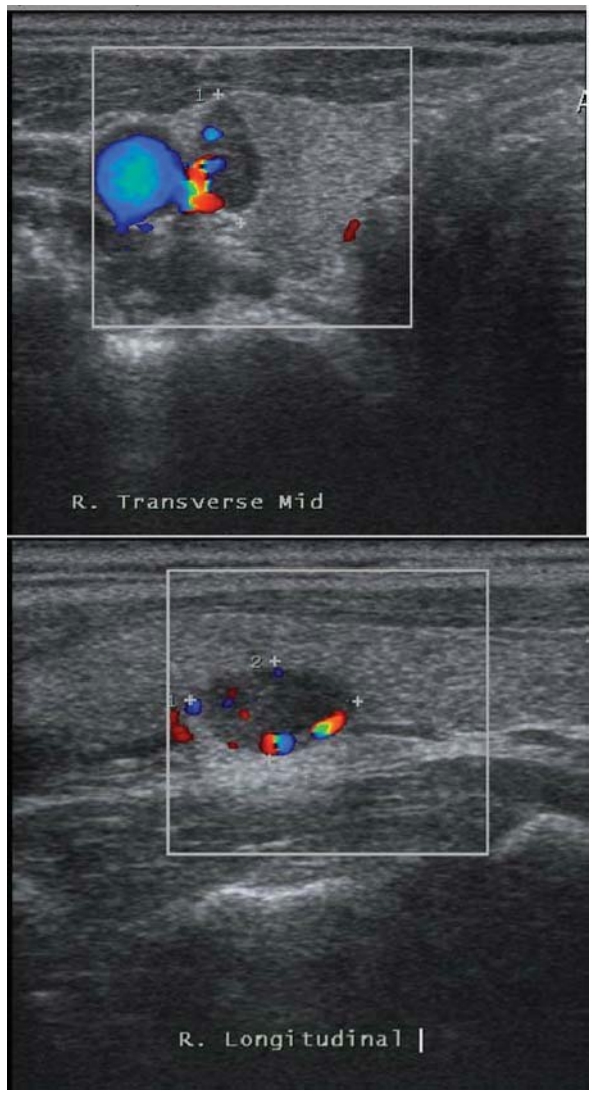

Figure 134.6 Ultrasound showing intrathyroid parathyroid.

reimplant some of the excised parathyroid tissue in the forearm, although one could argue that if the IOPTH at the end of the exploration is in midnormal range, reimplantation may not be necessary. Regardless, some of the tissue should be cryopreserved. Extent of parathyroidectomy is more controversial for 2°HPT or tertiary hyperparathyroidism. Unlike 1°HPT, chronic renal failure with hypocalcemia is a strong stimulus for parathyroid hyperplasia. Therefore, if subtotal parathyroidectomy is performed, any glandular tissue left behind can become hyperplastic again in the future in these patients. Consequently, some argue that total parathyroidectomy with reimplantation in the forearm is preferred in these patients to obviate the need for neck reexploration. Elevated preoperative calcium and post-op IOPTH levels were significant predictors for recurrent disease, while postoperative PTH less than 10 pmol/L had a positive predictive value of 97.5% for cure (39). For those who are younger patients, post kidney transplants, or candidates for kidney transplantation,

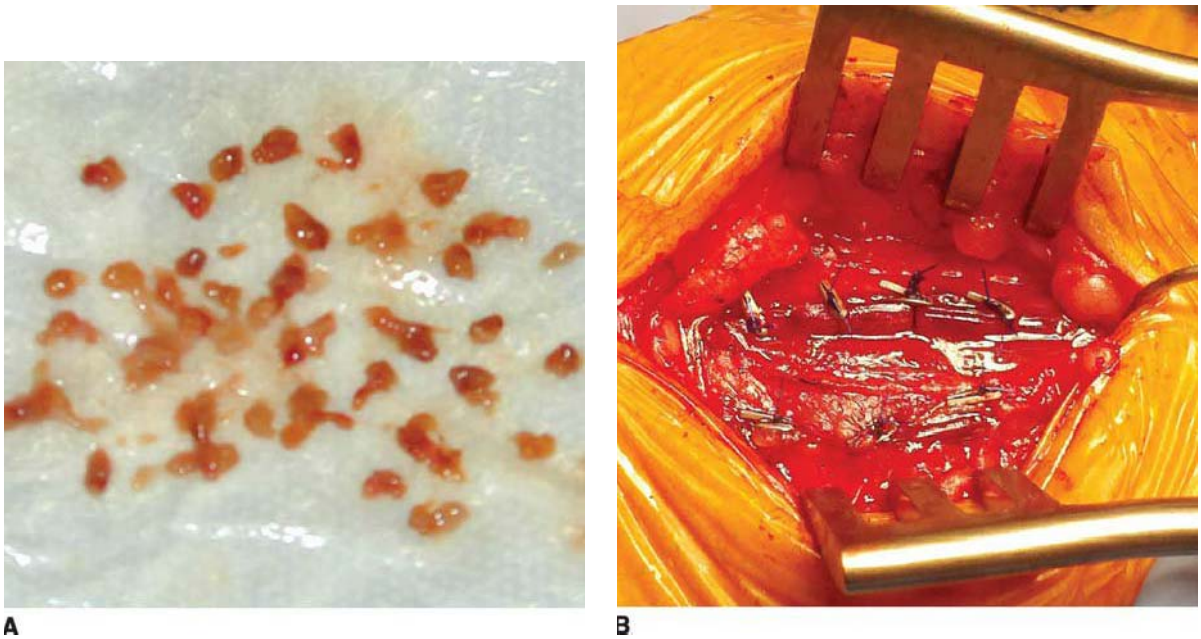

Figure 134.7 **A:** Parathyroid gland cut and prepared for reimplantation. **B:** Reimplanted sites in brachioradialis muscle marked with hemoclips.

subtotal parathyroidectomy may be appropriate, whereas total parathyroidectomy with autotransplantation may be recommended for patients expected to undergo long-term dialysis who are not candidates for transplantation (33).

Minimally Invasive Parathyroidectomy

The traditional approach for years in parathyroid surgery has been to perform bilateral exploration and examine all four parathyroid glands. With the ability to preoperatively localize an adenoma with imaging modalities unilateral exploration became acceptable, where the localized adenoma is excised and presence of another normal gland on the same side is confirmed. The limitation of this approach is that a second adenoma (double adenoma) on the contralateral side can be missed. In 1991, Irvin et al. introduced the concept of rapid measurement of intact PTH intraoperatively. The intact PTH has a very short half-life of approximately 2 to 4 minutes. Therefore, following successful removal of a single parathyroid adenoma, measurement of intact PTH level shortly after removal of an adenoma can be used to predict success of surgery. Several studies have shown that following excision of a localized adenoma, IOPTH accurately predicts presence or absence of other functioning glands (40–43). With this approach, it is no longer necessary to explore multiple glands, and the risk of missing multiglandular disease is reduced. With the ability to preoperatively localize an adenoma and use IOPTH assay, parathyroid surgery has evolved into focused exploration with single-gland excision. A 2002 study on worldwide trends in parathyroid surgery reported that 60% of surgeons perform minimally invasive single-gland excision rather than bilateral exploration (44). Minimally invasive focused parathyroidectomy begins with a small incision in the area of a suspected adenoma. Most centers use IOPTH to confirm absence of other hyperfunctioning glands. A preexcision level is typically drawn at the time of anesthetic induction and/or right after the parathyroid adenoma is mobilized for excision. A postexcision level is then drawn 10 to 15 minutes after the adenoma is excised. A drop of more than 50% from the preexcision value is the most commonly used criteria for successful parathyroidectomy.

Pitfalls of IOPTH

Several validation studies evaluated IOPTH levels pre- and postexcision of abnormal gland(s) during conventional bilateral exploration (45–48). One pitfall of IOPTH is that the postexcision may fall below 50% of baseline yet one or more enlarged gland still remains. This is defined as a *false-positive* result. Gauger et al. (45) reported 55% false-positive rate in 20 patients during conventional bilateral exploration, all due to double adenomas. Similarly, Jaskowiak et al. (46) reported 50% false-positive and 50% true-negative rates for IOPTH when double adenomas are present. To explain this false-positive phenomenon with double adenomas, some hypothesize that the second adenoma, which is usually the smaller one, may not be hypersecretory. Therefore, if the second gland is not biochemically significant, the IOPTH value will actually drop below 50% after excision of the "active" one. Even with 4-gland hyperplasia, IOPTH may exhibit kinetics similar to that of single adenomas. For example, one study reported that in

12.5% of patients who were undergoing surgery for known hyperplasia from MEN1 syndrome, the kinetics of IOPTH was similar to that seen with a single adenoma (49).

False-positive rates have been reported to range from 2% to 13%, giving an overall specificity rate of approximately 90% (48,50,51). Thus while IOPTH significantly reduces the chances of missing multiglandular disease, operative morbidity, and length of hospital stay, it can still potentially miss multiple gland pathology, which may result in need for reoperation. Hallfeldt et al. reported that in 2 of 36 patients in whom they used the 50% criteria, but the absolute IOPTH value remained above normal range, the IOPTH levels began to elevate again postoperatively. One of these two patients were reexplored and found to have hyperplasia (48). Karakousis et al. (51) also reported that in their patients with multiglandular disease, IOPTH had a false-positive rate of 29% if the IOPTH drops by 50% but does not return to normal range, and that this would be lower if a more stringent criteria was used (51). To reduce false-positive rates, the use of a more stringent criteria has been proposed, such as postexcision level less than 50% of preexcision level and must also return within normal range (52). Therefore, if the postexcision level does not meet both of these criteria, one or more hyperfunctioning glands remain in the patient and the remaining glands should be explored systematically.

Conversely, a *false-negative* result is defined as IOPTH failing to fall below 50% when no additional enlarged glands remain. One possible mechanism for such false-negative values is that there can be a sudden rise in circulating PTH during manipulation of the adenoma; therefore, if the 5-minute postexcision value is compared to a baseline drawn before manipulation, it may not be less than 50% of baseline or sometimes can actually be higher than the baseline. For example, if the PTH level is 110 pg/dL at the time of induction and surges to 300 pg/dL after manipulation of the adenoma, a postexcision level drawn 5 minutes after removal may drop to 60 pg/dL, which is not less than 50% when compared to the 110 pg/dL preexcision level, yet it is certainly greater than a 50% drop in relation to the second level drawn. Therefore, if only the first prelevel is available for comparison, it may lead to unnecessary further exploration because technically the patient has not met the criteria for biochemical cure. Because of this some surgeons draw a second "pre" level just before excision of the adenoma and compare the postexcision level to the higher of the two preexcision levels. Another reason for false-negative results is slower kinetics for PTH clearance. To get around this problem one can delay the first postexcision draw until 10 or 15 minutes after excision of the adenoma. Another option would be to draw the IOPTH at either 10 minutes or 15 minutes after excision, at which time the values may be close to 50% of baseline. The false-negative rate ranges from 3% to 8% in the literature, giving an overall sensitivity rate of approximately 95% (50,53–55). A false-negative result potentially can subject the patient to unnecessary additional neck exploration at the time of primary surgery.

To date, no uniform guidelines have been formulated to interpret IOPTH values. The goal is to achieve a high sensitivity and specificity. One achieves high specificity by reducing false-positive rate, and high sensitivity by lowering false-negative rate. Attempts to reduce the failure rate by adding a more stringent criterion minimizes the incidence of false-positives and increase specificity. However, this is at the expense of raising false-negative rate and thus a lower sensitivity, which results in unnecessary further explorations. Reported specificity and sensitivity rates in the literature are somewhat inconsistent, which makes it difficult to find the right balance. Lombardi proposed more than a 50% decrease from the highest preexcision level and/or an IOPTH level within the normal range 20 minutes after excision to predict surgical cure and postoperative normocalcemia. Ozimek et al. (42) also proposed more than a 50% decrease from the highest PTH level plus a decrease to the normal range within 15 minutes and reporting 97% sensitivity but reducing the specificity to 88% (42). The need for IOPTH has also been questioned in recent years (56–60). A number of authors have reported failure rates of only 1% to 3% when IOPTH was not used during MIP (57,60,61). Based on these results, a viable option when preoperative ultrasound and sestamibi studies are concordant would be *not* to measure PTH intraoperatively but to delay it until later the same day or next day in order to avoid unnecessary conversion to more extensive neck exploration. A cost analysis by Aggarwal et al. (61) showed that this approach could theoretically reduce the cost by one-third, factoring in the risk of unnecessary conversion exploration (61).

Minimally Invasive Radioguided Parathyroidectomy

Radioguided parathyroidectomy, in which technetium sestamibi is injected prior to surgery and a gamma probe is then used to compare the radioactive level before and after excision adenoma, has also been described as another way to accomplish minimally invasive targeted parathyroidectomy. Following excision of the adenoma, the radioactive counts of the adenoma as well as the background are obtained. If the *ex vivo* count on the adenoma is greater than 20% of background count, the patient is considered to have only one adenoma and surgery is deemed successful. This minimally invasive radioguided parathyroidectomy is referred to as MIRP. It should be cautioned that *ex vivo* radioactivity percentages can differentiate hyperactive parathyroid tissue from any other tissue, but they cannot differentiate adenoma from hyperplasia and thus are not helpful in ruling out multiglandular disease (62). Some surgeons also combine MIRP with the use of IOPTH to confirm biochemical cure. The cure rate with radioguided parathyroidectomy has been reported to be as high as 98% (63–65).

Outcome of Minimally Invasive Parathyroidectomy versus Bilateral Exploration

Several retrospective studies comparing the outcome of MIP with IOPTH to that of conventional bilateral exploration have shown that the success rates of the MIP were similar to or better than that of bilateral exploration (24,43,47,66–68). Furthermore complication rates tend to be lower. Burkey et al. compared the outcome of three different approaches, gamma probe ($n = 50$), IOPTH ($n = 50$), and bilateral exploration ($n = 50$). The cure rates were 98%, 100%, and 96%, respectively, and the complication rate was higher in the bilateral exploration group compared to the other two (66). Similarly, Boggs et al. (67) reported a failure rate of 1.5% when Sestamibi and IOPTH were used versus 5% when bilateral exploration was performed without IOPTH. In a study to evaluate whether or not IOPTH improves the results of parathyroidectomy, Miura et al. (43) showed that by adding IOPTH to the operation, the accuracy of Sestamibi scan improved from 83% to 92%, and the accuracy of ultrasound improved from 71% to 86%. These results were validated by Udelsman et al. (68) recently in a comparison study of a large cohort of 1,650 patients undergoing parathyroidectomy that demonstrated the superiority of MIP to bilateral exploration. The cure rate was 99.4% with a complication rate of 1.45% in the MIP group compared to conventional exploration with a cure rate of 97.1% and a complication rate of 3.10%. A prospective blinded randomized study also showed that the cure rates were similar between MIP and bilateral exploration, but MIP had lower postoperative pain, lower analgesic request rate, lower analgesic consumption, shorter scar length, better cosmetic satisfaction rate in a short time period (69).

Surgical Techniques

MIP can be performed under local anesthesia with intravenous sedation or under general anesthesia. Two approaches can be used—anterior and lateral. Most surgeons utilize the anterior approach because of familiarity from performing thyroidectomy; however, the lateral approach can also be useful.

Anterior Approach

The patient is placed in supine position and a midline curvilinear 2 to 3 cm incision is drawn at the level of the adenoma. An ultrasound can also be performed prior to marking the patient to assist in placement of the incision. The strap muscles are separated along the median raphae laterally on the side of the adenoma. When excising glands that are located inferior to the thyroid lobe or just posterior to the inferior pole the trachea or inferior thyroid pole is retracted medially and the gland should be easily identified (Fig. 134.8). For more superiorly located adenomas the thyroid lobe is retracted medially and rotated to expose the posterior surface. Blunt dissect is then used to search for the adenoma. One should be cognizant of the location of the recurrent laryngeal nerve in dissecting these glands. Especially for glands located lateral or posterior to the esophagus, it is important to look for the recurrent laryngeal nerve, which often may course anterior to the adenoma. After identification of the adenoma, it is removed using blunt dissection. Small feeding vessels can be isolated and cauterized on the capsule of the parathyroid gland. Hemostasis is achieved and the incision is closed in two layers.

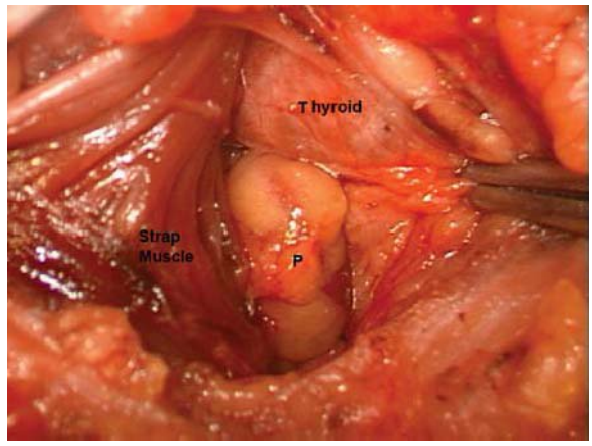

Figure 134.8 Minimally invasive parathyroidectomy using anterior approach: Right inferior parathyroid adenoma (P) identified posterior to the inferior pole of thyroid. Top of photo is cephalad.

Lateral Approach

This approach allows better exposure to posteriorly located adenomas without having to extensively retract the thyroid lobe, thus allowing the performance of the procedure local/sedation (70). The incision is placed more laterally between the midline and the anterior border of the sternocleidomastoid muscle. The sternocleidomastoid muscle is retracted laterally to expose the strap muscles (Fig. 134.9A). The ansa hypoglossi nerve is identified coursing along the posterior edge of the strap muscles. The muscle is then retracted medially, exposing the internal jugular vein and carotid artery (Fig. 134.9B and C). The vagus nerve may also be encountered during the dissection. The vein, artery, and vagus nerve are retracted laterally, exposing the thyroid capsule (Fig. 134.9C). Again, using the ultrasound images or intraoperative ultrasound, dissection is targeted at the exact location of the adenoma (Fig. 134.9D).

Once identified, the same steps are carried out for excision and closure as described in the anterior approach. When excising adenomas located posteriorly on the prevertebral fascia, it is important to be cognizant of the recurrent laryngeal nerve (Fig. 134.10), which can course right over the adenoma or just medial to it.

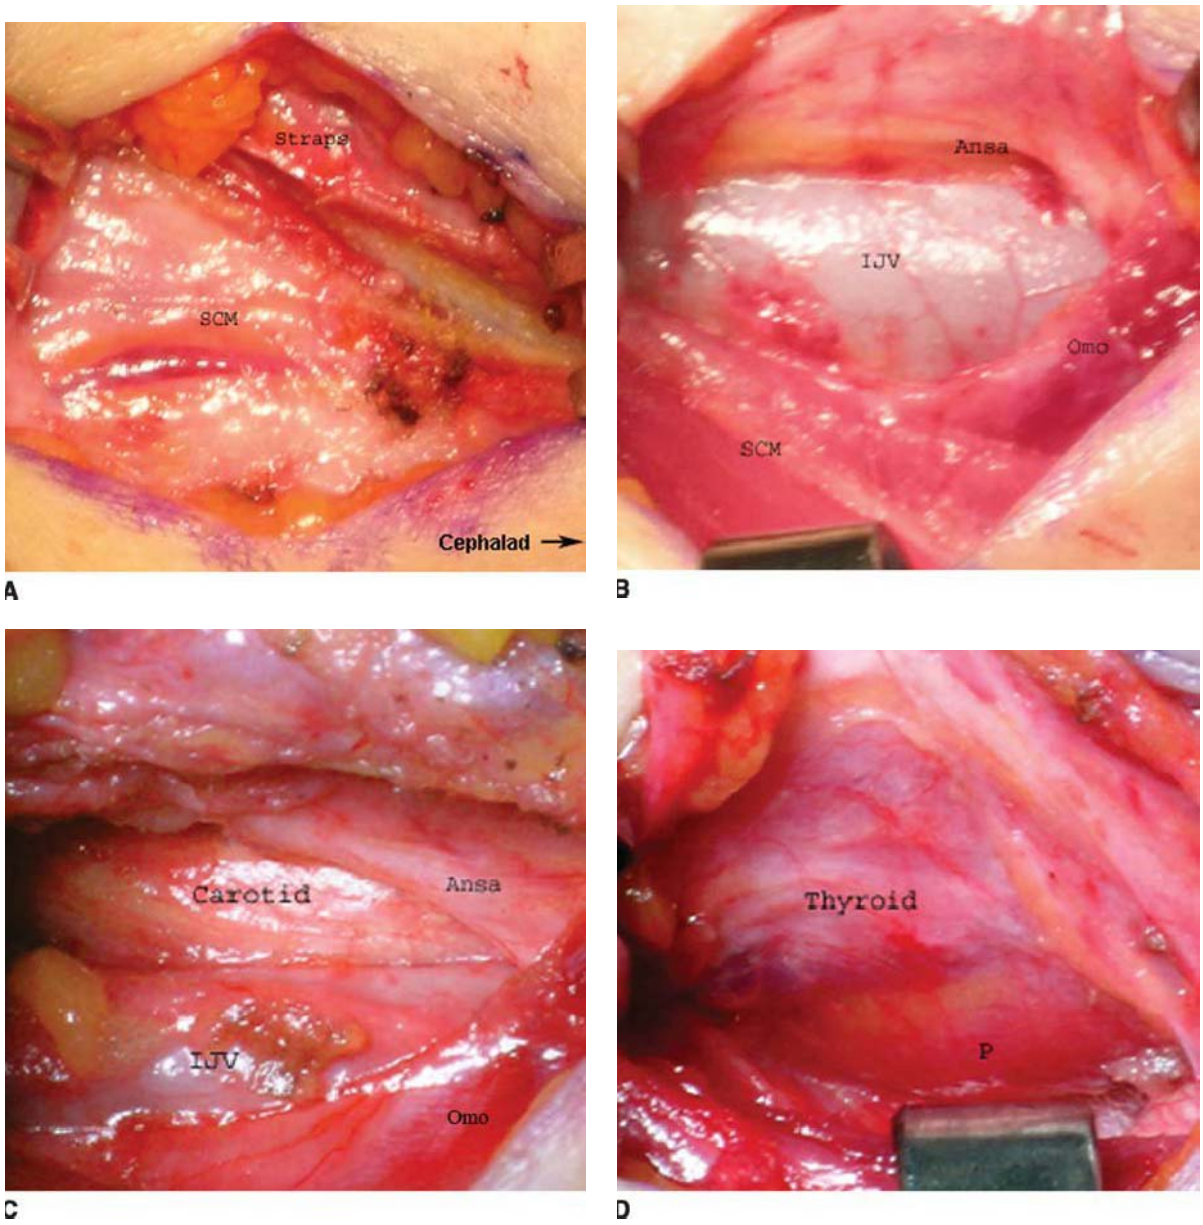

Figure 134.9 Minimally invasive parathyroidectomy using lateral approach for left superior adenoma. **A:** The sternocleidomastoid muscle (SCM) is retracted laterally and strap muscles are retracted medially; **B:** The internal jugular vein (IJV), omohyoid (OMO), and ansa hypoglossi are exposed; **C:** The carotid artery is exposed, which will be retracted laterally; **D:** After the strap muscles with the ansa are retracted medially, the thyroid is exposed with parathyroid adenoma (P) posterior to it.

MEDIASTINAL ADENOMA

Approximately 1% to 2% of parathyroid adenomas are located in the upper mediastinum. Once identified on sestamibi scan (Fig. 134.11), CT with contrast or MRI should be obtained for surgical planning. Traditionally surgical treatment required sternotomy or thoracotomy (71,72). In recent years, resection of these adenomas can be accomplished via mediastinoscopy using a suspension scope, or thorascopically through intercostals space depending on its location (73,74). Recovery and post-op complications with these minimally invasive approaches are lower than that of traditional thoracotomy.

PARATHYROID CARCINOMA

Parathyroid carcinoma should be suspected if the patient presents with very high plasma calcium (greater than 13 mg/dL) or PTH levels, a palpable mass in the area of localized adenoma, suspicious lymphadenopathy, or high depth–width ratio of the mass on ultrasound. Intraoperatively the diagnosis of carcinoma should be

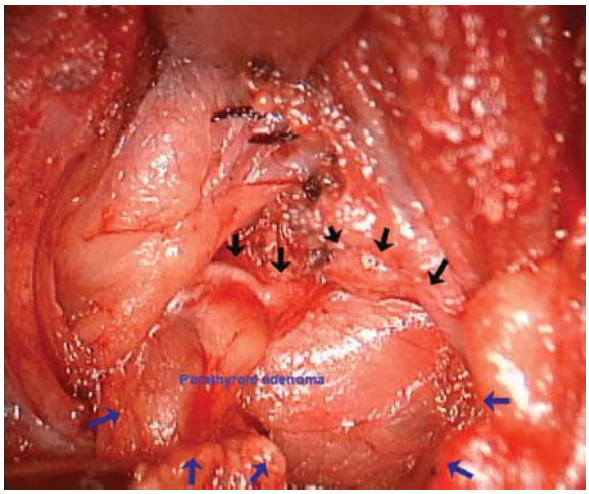

Figure 134.10 Left inferior paraesophageal adenoma (outlined by *blue arrows*) with recurrent laryngeal nerve (*black arrows*) coursing over it.

entertained if the mass is adherent to surrounding tissues, since benign parathyroid adenomas typically "shell out" easily with blunt dissection. If any of the above is present, frozen section should be performed. Making a definitive diagnosis of parathyroid carcinoma intraoperatively is extremely difficult, since the main criteria for such diagnosis are vascular invasion, perineural space invasion, capsular penetration with growth into adjacent structures, or metastases. High mitotic rate and considerable thick fibrous bands coursing throughout the gland can be seen on frozen section, but they are not diagnostic (Fig. 134.12). If the diagnosis is either confirmed or highly suspicious, complete en bloc resection, including hemithyroidectomy and paratracheal dissection, should

Figure 134.11 Sestamibi scan showing right superior mediastinal adenoma (*arrow*).

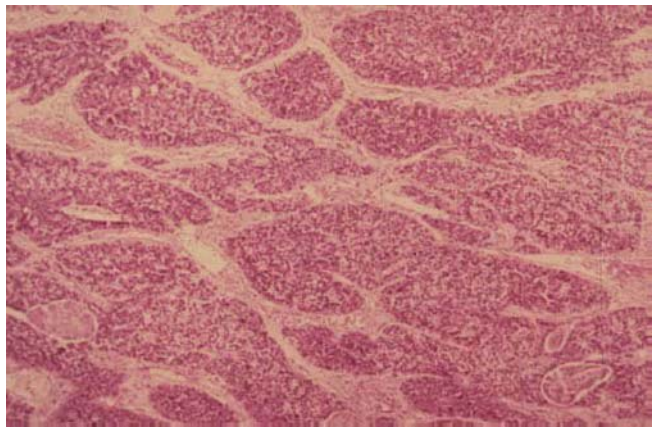

Figure 134.12 Histology of parathyroid carcinoma—Atypical chief cells with extensive fibrous bands.

be performed. Recurrence is usually in cervical nodes. The most common site of distant metastasis is lungs. Morbidity and mortality of recurrent parathyroid carcinoma usually result from unremitting hypercalcemia and its complications rather than mass effect of tumor burden. Treatment of locoregional recurrent parathyroid carcinoma is primarily surgery, since it generally responds poorly to radiation or chemotherapy. Treatment of advanced disease is primarily targeted at controlling hypercalcemia with bisphosphonate and calcimimetic agents.

POSTOPERATIVE CARE

Patients undergoing bilateral exploration may be at risk of developing hypocalcemia postoperatively and therefore have traditionally been admitted for overnight observation. Potential causes of post-op hypocalcemia after bilateral exploration and parathyroidectomy include injury and devascularization of remaining glands, calciuretic effect of intravenous fluid, decreased PTH production from the remaining suppressed parathyroids, and hungry bones syndrome. Patients who have undergone subtotal parathyroidectomy for hyperplasia are even more at risk, since the small volume of parathyroid left *in situ* may become devascularized. Virtually all who are treated with total parathyroidectomy and reimplantation for 2°HPT or tertiary hyperparathyroidism will be hypocalcemic post-op until the reimplanted tissue establishes a blood supply and regains normal function.

Those admitted for observation following 4-gland bilateral exploration should be assessed for symptoms of hypocalcemia such as paresthesias of hands, feet, or perioral region as well as muscle spasms. Early signs of hypocalcemia include: (a) Chovstek sign where tapping preauricularly elicits twitching of the ipsilateral face, and (b) Trussou sign where inflation of a blood pressure cuff elicits cramping in the extremity. Severe hypocalcemia can induce muscle cramping, tetany, seizures, and cardiac

arrhythmias. Calcium levels should be checked starting the next morning, and two levels should be drawn 6 to 8 hours apart since the calcium may not drop until well beyond 24 hours after surgery. The patient can be discharged if the sequential calcium levels are stable or demonstrate an upward trend.

Another approach to facilitating safe and early discharge after bilateral exploration is routine empiric supplementation of calcium with or without calcitriol (vitamin D). Patients would then be discharged on supplementation if the plasma calcium is normal the following morning. If this approach is to be taken, the patient should be educated on symptoms of hypocalcemia and instructed to call should symptoms develop. The disadvantage of this approach with routine administration of calcium and vitamin D replacement is that measurement of postoperative calcium to ensure biochemical cure of disease may be inaccurate.

In recent years IOPTH following total thyroidectomy has been used to predict the risk of developing hypocalcemia and plan early discharge. The same concept can also be applied to management of patients following 4-gland exploration. Noordzij et al. (75) pooled results of post-thyroidectomy PTH measurements in 457 patients from 9 studies and found that the immediate post-op PTH was less than 10 pg/mL in those who became hypocalcemic. Other studies have found that the absolute value of IOPTH level at which the patient is at risk of becoming hypocalcemic ranged from 8 to 16 pg/mL (or 1.7 to 3.7 pmol/L) (76–81). Based on these studies, one can extrapolate that if the post-op PTH is greater than 16 pg/mL the patient can be safely discharged without supplements. There is no concrete algorithm for managing post-op calcium utilizing post-op IOPTH level. Figure 134.9 outlines a suggested algorithm. If post-op IOPTH is above 10 pg/mL and the morning calcium is within normal range, the patient can be discharged. If post-op IOPTH is below normal range (i.e., less than 5 pg/dL), oral calcium supplement (see below for dosage) should be initiated along with calcitriol 0.5 mcg daily. Two sequential calcium levels should be drawn 6 to 8 hours apart the next day since. The patient can be discharged if sequential calcium levels demonstrate an upward trend. If IOPTH is between 5 and 10 pg/mL, and the morning calcium level is below normal range, oral calcium supplementation should be initiated. The calcium level should be rechecked in 6 hours and monitored as described above. If the calcium is less than 7 mg/dL, or the patient experiences cramps, calcium gluconate should be administered intravenously as outlined below.

Surgeons and endocrinologists employ a variety of different postoperative regimens for treatment of hypocalcemia. While there is no consensus on this issue, there are some general principles which can guide medical management of hypocalcemic patients after parathyroidectomy. Should symptoms develop or serum calcium values corrected for albumin drop below 8.0 mg/dL, oral calcium carbonate should be initiated at a dose of 1.5 to 4 g/d. Patients with severe hypocalcemia, that is, less than 7.0 mg/dL, or severe symptoms such as cramps and tetany require replacement with intravenous calcium gluconate. Calcium gluconate is preferred over calcium chloride for intravenous administration, as the latter is associated with increased risk of tissue necrosis. If only the chloride form is available and must be used, it should be administered via a central venous line. The initial dose for infusion is 1 g (93 mg of elemental calcium) to 2 g diluted in 250 mL of dextrose solution given over 10 to 20 minutes. If the calcium persistently remains below 7 mg/dL, a continuous intravenous infusion should be initiated. Continuous infusion is typically given as 10 g/L solution infused at a rate of 1 to 3 mg of elemental calcium/kg/h. These patients should be monitored since they can potentially develop electrocardiogram (EKG) changes. Vitamin D should be administered, as it is the mainstay of therapy in the treatment of hypoparathyroidism. A variety of vitamin D preparations are available, including ergocalciferol (vitamin D_2), cholecalciferol (vitamin D_3), and calcitriol, which is the biologically active form of vitamin D (1,25-dihydroxyvitamin D_3). Calcitriol should be used instead of the inactive forms (D_2, D_3) in hypoparathyroid patients, since there is a lack of PTH to convert the inactive form to active form. The typical dose of calcitriol is 0.25 to 0.5 mcg daily.

Special consideration should be given to management of hypocalcemia in patients with 2°HPT or tertiary hyperparathyroidism who undergo subtotal/total parathyroidectomy with reimplantation. They can develop profound hypocalcemia post-op as a result of the total parathyroidectomy and/or severe hungry bone. These patients require continuous intravenous calcium infusion with titration to maintain ionized calcium above 1.0 mmol/L. Ionized calcium levels should be monitored every 6 hours along with daily magnesium and phosphorous levels. Oral calcium and calcitriol should also be initiated simultaneously in maximum dose and then tapered when the reimplanted tissue starts to produce PTH. It is optimal to manage these patients jointly with nephrology or transplant team.

Patients undergoing minimally invasive parathyroidectomy can be discharged on the same day, since their risk of hypocalcemia is low. They may develop delayed hypocalcemia due to hungry bone syndrome, which if does occur typically will be after 2 to 3 days post-op. Therefore, patients should be instructed to call if they experience symptoms of hypocalcemia. In that setting they should be treated with oral calcium supplements and a calcium level should be checked as previously described. Some patients who have had chronically very high calcium levels in the 11 to 12 mg/dL range may experience these symptoms even though their post-op calcium is within normal range.

HIGHLIGHTS

- The most common cause of primary hyperparathyroidism is a single adenoma
- Secondary hyperparathyroidism is associated with chronic renal disease and 4-gland hypertrophy
- Serum calcium over 13 mg/dL suggests malignancy
- Symptoms of hyperparathyroidism include musculoskeletal pain, nephrolithiasis, gastrointestinal upset, and neuropsychiatric conditions ("bones, stones, groans, and psychiatric overtones")
- Hypercalcemia may be due to thiazide diuresis, immobilization, malignancy, and granulomatous diseases
- Elevate serum calcium and PTH with low 24-hour urine calcium suggests FHH
- Failure of 10 PTH to fall by over 50% into the normal range after excision of an adenoma may indicate a double adenoma
- Very low 10 PTH (below 16 pg/mL) often predicts postoperative hypocalcemia

Sleep Medicine for the Otolaryngologist

135

Pell Ann Wardrop *Kathleen L. Yaremchuk*

Otolaryngologists are frequently the portal for diagnosis and treatment of sleep disorders for patients with snoring or other airway complaints. Although sleep apnea is the most common sleep disorder encountered in an otolaryngology practice, most patients have a combination of several sleep disorders contributing to their symptomatology. Sleep affects every aspect of life from the feeling of general well-being to insulin metabolism, cardiovascular health, and cognitive functioning. Because of this gateway role, an awareness and expertise in the diagnosis and management of all sleep disorders are necessary for otolaryngologists.

OVERVIEW OF NORMAL SLEEP

The average adult needs 8.25 hours of sleep to feel rested. Normal sleep is divided into non–rapid eye movement (NREM) and rapid eye movement (REM) sleep. NREM sleep accounts for 75% to 80% of sleep time in normal sleep. NREM sleep is further divided into progressively deeper stages of sleep: stage N1, stage N2, and stage N3 (deep or delta-wave sleep) (Table 135.1). Each of these four stages of sleep has identifying patterns on electroencephalography (EEG) tracings. Sleep is entered through NREM sleep, and the normal sleep cycle is generally approximately 90 minutes in length with a period of REM sleep. Delta- or slow-wave sleep, stage N3, usually dominates the first third of the night's sleep, while REM sleep dominates the last third (Fig. 135.1). After age 55, stage N3 or slow-wave sleep decreases, and wake after sleep onset (WASO), arousals, and awakenings increase (Fig. 135.2).

OVERVIEW OF SLEEP DISORDERS—THE SLEEPY PATIENT

The International Classification of Sleep Disorders (ICSD-2) lists more than 80 specific sleep disorder diagnoses within eight major categories (Table 135.2) (1). The list demonstrates the complexity involved in making an accurate diagnosis. Review of the differential diagnosis and evaluation of the sleepy patient serve to highlight many of the common sleep disorders encountered in an otolaryngologic practice. Fatigue or excessive daytime sleepiness (EDS), defined as an Epworth Sleepiness Scale (ESS) ≥10, is one of the most common complaints among patients who present to an otolaryngologist with snoring. EDS affects approximately 12% of the general adult population. The number of affected patients climbs to 20% to 25% in the primary care physicians' practice (2). The 2008 National Sleep Foundation (NSF) survey revealed that 36% of Americans drive drowsy or have fallen asleep while driving. Sleepiness and fatigue are usually caused by voluntary sleep deprivation or by an underlying sleep disorder. Anything that disturbs or disrupts sleep can lead to sleepiness or fatigue.

Sleepiness is a presenting complaint in a wide range of sleep disorders including obstructive sleep apnea (OSA), obesity–hypoventilation syndrome (OHS), central sleep apnea (CSA), voluntary sleep restriction, poor sleep hygiene, restless legs syndrome (RLS), periodic limb movement disorder, narcolepsy, circadian rhythm disorders, and insomnia (Table 135.3). The sleepy patient can even be difficult to identify with the standard questionnaires, such as the ESS. Many patients with obstructive sleep apnea syndrome (OSAS) and other sleep disorders will complain of tiredness, fatigue, and lack of energy rather than sleepiness (3). Failure to ask about these additional symptoms may lead to a failure to diagnose a significant, treatable sleep disorder. Some sleep disorders, particularly OSAS and RLS, disrupt sleep and cause functional sleep deprivation. These patients have manifestations of sleep deprivation even if they spend adequate time in bed. Medical problems including fibromyalgia, genitourinary disorders, gastrointestinal disorders, and chronic pain may disrupt sleep. The sleep disruption may manifest in an increased arousal index in the polysomnogram (PSG). The arousal

TABLE 135.1 NORMAL SLEEP ARCHITECTURE

Sleep Stage	Arousal Threshold	Identifying Characteristics in EEG/PSG Tracings	% of Total Sleep Time
Stage N1	Low	Theta waves on EEG Slow rolling eye movement, vertex sharp waves	1%–5%
Stage N2	High	K complexes Sleep spindles	45%–55%
Stage N3	Highest	Delta waves	20%–25%
REM or Stage R	Variable	Sawtooth waves or EEG activation, REMs and muscle atonia	20%–25%

index represents the number of EEG arousals or partial awakenings per hour of sleep.

Sleep-Disordered Breathing

Obstructive Sleep Apnea

Sleep-disordered breathing (SDB) describes a group of disorders characterized by abnormalities of respiratory pattern (pauses in breathing) or the rate of ventilation during sleep. The spectrum of SDB includes OSA, OHS, and CSA. OSA is a common medical condition with significant adverse consequences, but OSA remains undiagnosed in many individuals. The prevalence of OSA in the United States is currently estimated to be between 5% and 10% (4). Higher prevalence rates are found among specific population subsets, such as individuals who are older, overweight, or have concomitant medical comorbidities (5). It is estimated that only 10% of the population has been adequately screened for appropriate diagnosis (6). Risk factors for the diagnosis of OSA include male gender, obesity, age over 40, history of hypertension, smoking, alcohol use, anatomic characteristics that narrow the upper airway, and a family history of sleep apnea (7).

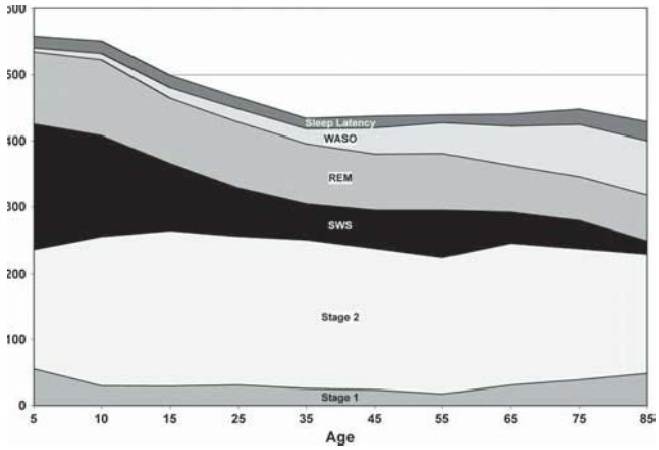

Figure 135.2 Changes in sleep with age in normal humans. (Reprinted with permission from Ohayon MM, Carskadon MA, Guilleminault C, et al. Meta-analysis of quantitative sleep parameters from childhood to old age in healthy individuals: developing normative sleep values across the human lifespan. *Sleep* 2004; 27:1255–1273.)

The typical patient with OSA complains of snoring, EDS, witnessed apneas, and disrupted sleep. However, up to 75% of patients with OSA present with fatigue, tiredness, or lack of energy as their primary complaint rather than sleepiness (8). Many patients with OSA do not have a history of witnessed apneas. Younger, leaner patients and women tend to experience sleep disruptions or arousals instead of apneas during sleep (9). Patients may also present with cognitive complaints such as memory deficits or mood disorders.

Women with OSA may have different presenting symptoms than those typically described in the male population (10). Women are more likely to complain of insomnia and are more likely to have a history of depression and hypothyroid disease. They drink fewer caffeinated and alcoholic beverages than their male counterparts with OSA. Awareness of the variety of presenting complaints of patients with sleep apnea assists in timely diagnosis and treatment.

The association of cardiovascular sequelae and OSA is well documented. There is an increased risk of hypertension,

TABLE 135.2 INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS-2

I. Insomnia	
Adjustment insomnia	307.41
Psychophysiologic insomnia	307.42
Paradoxical insomnia	307.42
Idiopathic insomnia	307.42
Insomnia due to mental disorder	327.02
Inadequate sleep hygiene	v69.4
Insomnia due to drug or substance	292.85
For alcohol use	291.82
Insomnia due to medical condition	327.01
Insomnia not due to substance or known physiologic condition, unspecified (*nonorganic insomnia, NOS*)	780.52
Physiologic (*organic*) insomnia, unspecified	327.00
II. Sleep-related breathing disorders	
Primary CSA	327.21
Cheyne-Stokes breathing pattern	786.04
High-altitude periodic breathing	327.22
CSA due to medical condition not Cheyne-Stokes	327.27
CSA due to drug or substance	327.29
OSA, adult	327.23
Sleep-related nonobstructive alveolar hypoventilation, idiopathic	327.24
Sleep-related hypoventilation/hypoxemia Due to pulmonary parenchymal or vascular pathology	327.26
Sleep-related hypoventilation/hypoxemia Due to lower airways obstruction	327.26
Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders	327.26
Other sleep-related breathing disorders	327.20
III. Hypersomnias of central origin not due to a circadian rhythm sleep disorder, sleep-related breathing disorder, or other cause of disturbed nocturnal sleep	
Narcolepsy with cataplexy	347.01
Narcolepsy without cataplexy	347.00
Narcolepsy due to medical condition without cataplexy	347.10
With cataplexy	347.11
Narcolepsy, unspecified	
Recurrent hypersomnia (*including Kleine-Levin syndrome & menstrual-related hypersomnia*)	327.13
Idiopathic hypersomnia with long sleep time	327.11
Idiopathic hypersomnia without long sleep time	327.12
Behaviorally induced insufficient sleep syndrome	307.44
Hypersomnia due to medical condition	327.14
Hypersomnia due to drug or substance (*abuse*)	292.85
For alcohol use	291.82
Hypersomnia due to drug or substance (*medications*)	292.85
Hypersomnia not due to substance or known physiologic condition	327.15
Physiologic (*organic*) hypersomnia, unspecified (*organic hypersomnia, NOS*)	327.10
IV. Circadian rhythm sleep disorders	
Circadian rhythm sleep disorder, delayed sleep phase type (*delayed sleep phase disorder*)	327.31
Circadian rhythm sleep disorder, advanced sleep phase type (*advanced sleep phase disorder*)	327.32
Circadian rhythm sleep disorder, irregular sleep–wake type (*irregular sleep–wake rhythm*)	327.33
Circadian rhythm sleep disorder, free-running type (*nonentrained type*)	327.34
Circadian rhythm sleep disorder, jet lag type (*jet lag disorder*)	327.35
Circadian rhythm sleep disorder, shift work type (*shift work disorder*)	327.36
Circadian rhythm sleep disorder due to medical condition	327.37
Other circadian rhythm sleep disorder (*circadian rhythm disorder, NOS*)	327.39
Other circadian rhythm sleep disorder due to drug or substance	292.85
For alcohol use	291.82
V. Parasomnias	
Confusional arousals	327.41
Sleepwalking	307.46
Sleep terrors	307.46
REM sleep behavior disorder (*Including parasomnia overlap disorder and status dissociatus*)	327.42
Recurrent isolated sleep paralysis	327.43
Nightmare disorder	307.47
Sleep-related dissociative disorders	300.15
Sleep-related groaning (*catathrenia*)	327.49
Exploding head syndrome	327.49
Sleep-related hallucinations	368.16
Sleep-related eating disorder	327.49
VI. Sleep-related movement disorders	
RLS	333.99
Periodic limb movement disorder	327.51
Sleep-related leg cramps	327.52
Sleep-related bruxism	327.53
VIII. Other sleep disorders	
Other physiologic (*organic*) sleep disorder	327.80
Other sleep disorder not due to substance or known physiologic condition	307.40
Environmental sleep disorder	307.48

Index of the ICSD-2 reprinted with permission.

myocardial infarction (MI), and cardiovascular accident in those with moderate to severe OSA (11). OSA syndrome significantly increases the risk of stroke or death from any cause, and the increase is independent of other risk factors, including hypertension (12). OSA is also associated with an increase in insulin resistance and metabolic syndrome (13). This association seems to be dose-related, more severe OSA, as defined by the apnea–hypopnea index (AHI), associated with more severe metabolic syndrome, and it is independent of the body mass index (BMI) (14). Physical characteristics including a BMI > 30, neck circumference greater than 17 inches in men and a BMI > 30,

TABLE 135.3 COMMON CAUSES OF EDS

Inadequate Sleep	Poor-Quality Sleep	Central Etiology	Other
Voluntary sleep restriction	SDB	Narcolepsy	Metabolic
Insomnia	RLS/periodic limb movement disorder	Idiopathic hypersomnia	Neurologic
Circadian rhythm disorder	Pain/fibromyalgia	Posttraumatic hypersomnia	Mood disorders
Poor sleep hygiene			Infection

neck circumference greater than 14½ inches in women, retrognathia, and tonsillar hypertrophy are associated with an increased risk of OSA.

The diagnosis of OSA is made with either in-lab polysomnography or a home sleep study.

The frequency of apneas and hypopneas per hour of sleep is expressed as the "apnea–hypopnea index" or the AHI (number of apneas plus hypopneas per hour of sleep). The respiratory disturbance index (RDI) includes the total of apneas, hypopneas, and respiratory effort–related arousals (RERAs) per hour of sleep. When a portable monitor is used that does not record EEG or measure sleep, the RDI refers to the number of apneas plus hypopneas per hour of recording (15). OSA severity is defined by the AHI or the RDI as measured by a PSG or cardiorespiratory sleep study (Table 135.4).

Obesity–Hypoventilation Syndrome

OHS, historically known as the Pickwickian syndrome (16), consists of the triad of obesity, SDB, and chronic hypercapnia during wakefulness in the absence of other known causes of hypercapnia (17). Its exact prevalence is unknown, but it has been estimated that 10% to 20% of obese patients with OSA have hypercapnia (18). Of the patients with OHS, 90% have OSA, but 10% have nonobstructive hypoventilation with an AHI < 5 on polysomnography. This disorder is diagnosed in patients with an elevated body mass index (BMI > 30 kg/m^2), arterial carbon dioxide level over 45 mm Hg, an increase in 10 mm Hg in the $PaCO_2$ during sleep, and hypoxemia. Over the past 20 years, the epidemic of obesity has increased exponentially in the United States. The prevalence of BMI ≥ 40 kg/m^2 has increased by fivefold, and the prevalence of BMI ≥ 50 has increased 10-fold. This marked increase in extreme obesity will likely result in the increase of OHS in OSA patients.

Patients with OHS have a blunted central response to hypercapnia and hypoxia and decreased lung compliance coupled with increased lung resistance, resulting in a threefold increase in the work of breathing. They have significantly increased morbidity and mortality when compared to eucapnic OSA patients; therefore, identification and prompt treatment are imperative (19).

TABLE 135.4 CLASSIFICATION OF SLEEP APNEA SEVERITY

Classification	AHI
Mild	5–14
Moderate	15–29
Severe	≥30

AHI, apnea–hypopnea index (mean number of apneas plus hypopneas/hour of sleep).

Central Sleep Apnea/Complex Sleep Apnea

CSA is characterized by recurrent episodes of breathing cessation in sleep associated with the lack of respiratory effort. It is not a single disorder, but rather a manifestation of breathing instability that can be caused by many disorders. A form of CSA, Cheyne-Stokes breathing is a cyclical crescendo–decrescendo pattern of central apneas and hyperpneas that is seen in congestive heart failure, stroke, and renal failure. Other causes of CSA include opioid-associated central apnea, neuromuscular disorders, high-altitude periodic breathing, and brainstem lesions. Occasionally, treatment of OSA with positive airway pressure (PAP) can precipitate the emergence of central apneas or a Cheyne-Stokes pattern of breathing. This phenomenon has termed complex sleep apnea syndrome (CompSAS). Patients with CompSAS can have very disrupted breathing and fragmented sleep on continuous positive airway pressure (CPAP), with respiratory disturbances in the range typically found in patients with moderately severe sleep apnea (20).

Inadequate Sleep

The number one cause of sleepiness is self-imposed sleep restriction or inadequate time in bed. The 2008 NSF "Sleep in America" poll (21) reported that 16% of individuals obtained less than 6 hours of sleep per night on weekdays. Only 26% reported sleeping 8 hours or more per night despite the fact that this is the amount of sleep that the average individual needs to be adequately rested. This is a societal problem which, based upon the NSF annual sleep polls, appears to be increasing in prevalence.

Sleep deprivation has been shown to negatively impact cognitive functioning and performance and to increase the rate of automobile accidents and accidents in the workplace. On tests of reaction time, concentration, and memory, subjects who are experimentally sleep deprived or sleepy due to a sleep disorder perform poorly compared

to subjects who are not sleep deprived or have normal sleep. To put the degree of psychomotor impairment associated with sleep deprivation in perspective, studies that compared the effects of alcohol with sleep deprivation have been conducted. In one study, sleep-deprived subjects scored similarly to those subjects with a blood alcohol level of 0.08% (22).

The cardiovascular system also is adversely affected by sleep deprivation. There are increases in inflammatory markers including C-reactive protein and an increased risk of cardiovascular events and morbidity (23). Physiologic effects of sleep deprivation include changes in circulating levels of many hormones including growth hormone, thyroid-stimulating hormone, leptin, thyroxine, cortisol, prolactin, estradiol, luteinizing hormone, adrenaline, and noradrenaline (24). Short sleep time is associated with impaired glucose tolerance and obesity (25). Alterations in immune function occur with sleep deprivation including changes in natural killer cell activity, levels of interleukin-6, antibody titers, and increased rates of some cancers (26).

Sleep deprivation or voluntary sleep restriction has significance for physicians as well as patients. There is an extensive research relative to sleep deprivation and performance relevant to resident education (27–29). This literature demonstrates decrements in cognitive function, fine motor skills, learning, judgment, and reaction time. As a result of concern about the negative effects of sleep deprivation on residents and their patients, the Accreditation Council for Graduate Medical Education began limiting work hours for residents in 1990 and implemented mandatory standards to limit work hours for resident physicians in 2003. These standards are revised intermittently, most recently in 2011, as more research on the effects of sleep deprivation on performance becomes available (30).

This issue affects attending physicians as well. Although studies have shown that older and more experienced physicians have some resistance to the effects of sleep deprivation, all physicians are susceptible to the performance and judgment decrements caused by sleep deprivation. There is a growing movement to restrict all physician work hours given the prevalence of sleep disorders in our society overall and the increase in this incidence with age (31).

Insomnia

Chronic insomnia, defined as difficulty initiating or maintaining sleep or nonrestorative sleep lasting for over a month, affects 10% to 15% of the adult population. Chronic insomnia is associated with decreased quality of life and adverse health effects, particularly an increased risk of depression. Insomnia can be the result of another sleep disorder such as sleep apnea or RLS. It can also result from poor sleep hygiene such as caffeine or alcohol intake at night, irregular sleep/wake habits, exposure to light from a computer monitor before bed, medications, other medical comorbidities, or psychiatric disorders. Patients with insomnia may complain of excessive sleepiness, feeling tired or fatigued, or an uncomfortable feeling of hyperarousal. Treatment of insomnia is important for overall patient well-being. Cognitive behavioral therapy for insomnia (CBT-I) is a specific, highly practical therapeutic approach for chronic insomnia. This is usually performed by a medical psychologist or trained therapist. CBT-I is recognized as the most effective long-term therapy of chronic insomnia (32). If the insomnia is due to a medical or psychiatric condition, treatment of the underlying cause may be beneficial. The use of hypnotics has been found to be useful only as a short-term therapeutic measure.

Circadian Rhythm Disorders

Circadian rhythm sleep disorder is a persistent or recurring pattern of sleep disruption resulting either from an altered sleep–wake schedule or a misalignment between a person's natural sleep–wake cycle and the sleep-related demands placed on him or her. These disorders, frequently overlooked by clinicians as a cause of sleep disorders, can result in excessive sleepiness, poor sleep quality, or insomnia. Frequently encountered types of circadian rhythm disorders include the following:

- Shift work type—Shift work sleep disorder involves sleepiness or insomnia that occurs when the work schedule overlaps the usual wake time. There are over 6 million people in the United States working night or rotation shifts, so this is a common sleep disorder.
- Delayed sleep phase type—Delayed sleep phase syndrome (DSPS) is a disorder in which the person's sleep–wake cycle is delayed by two or more hours. Patients with DSPS generally fall asleep late at night, often in the predawn hours, and wake in the late morning or in the afternoon. Furthermore, there is a striking inability to fall asleep at an earlier, more typical bedtime. This disorder, which often develops during puberty, is estimated to affect 7% to 16% of adolescents.
- Jet lag type—This is caused by a mismatch of the patient's sleep–wake cycle and the time zone. The more time zones that are traveled, the greater the disruption. Eastbound travel, in which sleep–wake hours are advanced, typically causes more problems than westbound travel, in which sleep–wake hours are delayed. People who travel often and cross many time zones when they travel are most susceptible to this type.

Narcolepsy

Narcolepsy is a neurologic disorder affecting 0.05% of the US population that is characterized by EDS and abnormal manifestations of REM sleep such as cataplexy. The classic tetrad of narcolepsy, present in only 20% to 30% of patients

with narcolepsy, includes EDS, cataplexy, hypnagogic hallucinations, and sleep paralysis. Patients with narcolepsy experience EDS with ESS > 14 and intermittent, uncontrollable episodes of falling asleep during the daytime. Cataplexy, a loss of muscle tone without loss of consciousness elicited by an emotional stimulus, is present in 60% of patients with narcolepsy (33). These sudden sleep attacks may occur during any type of activity at any time of the day. Symptoms generally present in the second decade of life, but the diagnosis of narcolepsy is often delayed by more than 10 years after onset of symptoms (34).

While the presence of severe EDS and cataplexy strongly supports the diagnosis of narcolepsy, diagnosis is usually made with the multiple sleep latency test (MSLT) that demonstrates two or more episodes of sleep onset REM during the five-nap study.

REM Behavior Disorder

While patients with REM behavior disorder (RBD) do have disrupted sleep and daytime sleepiness, they will usually present with the complaint of dream-enacting behavior and violent dreams. These patients can harm themselves or their bed partners during these episodes. RBD is neurologic disorder with a lack of atonia during REM sleep. The majority of patients with RBD have Parkinson disease or a related synucleinopathy; however, RBD can precede the onset of Parkinson disease by over a decade.

Restless Legs Syndrome

Patients with RLS will often complain of difficulty initiating sleep and nonrestorative sleep with daytime sleepiness. RLS is defined as an urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs, worse at rest, and in the evenings and relieved by movement. Eighty percent of people who have RLS also have periodic limb movements of sleep (PLMS). These are jerks of the legs or arms that occur every 20 to 30 seconds on and off throughout the night. This can cause partial awakenings or arousals that disrupt sleep. RLS is diagnosed by history. The four basic criteria for diagnosis are listed in Table 135.5 (35).

Patients with a history of nocturnal limb movements, daytime somnolence, and a lack of daytime symptoms of RLS should be studied with a full PSG to identify any leg movements leading to arousals and sleep disruption. These patients may have periodic limb movement disorder leading to daytime sleepiness, sleep maintenance insomnia, and nonrestorative sleep.

The majority of patients with sleep apnea who kick at night do not have RLS or PLMS. Their kicking is a response to their airway obstruction and is relieved by resolution of the airway obstruction. A CPAP titration study in these patients will show that the leg movements resolve with adequate CPAP pressure.

TABLE 135.5 ESSENTIAL DIAGNOSTIC CRITERIA FOR RLS

1. An urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs. (Sometimes the urge to move is present without the uncomfortable sensations, and sometimes the arms or other body parts are involved in addition to the legs).
2. The urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting.
3. The urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues.
4. The urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night. (When symptoms are very severe, the worsening at night may not be noticeable but must have been previously present).

Restless legs syndrome: diagnostic criteria, special considerations, and epidemiology: a report from the restless legs syndrome diagnosis and epidemiology workshop at the National Institutes of Health. *Sleep Med* 2003;4:101–111, with permission.

EVALUATION OF THE PATIENT WITH A SLEEP DISORDER

Although OSA is the most common sleep disorder, many of the symptoms overlap with other sleep disorders, and many patients have more than one sleep diagnosis. To make a diagnosis, it is important to spend an adequate amount of time with the patient and bed partner to ensure the right questions are being asked to ascertain the nature of a patient's particular sleep disorder (Table 135.6). It is often helpful to have a bed partner present who will be able to describe movements that occur while the patient is asleep and, may have no independent recollection of their own activities or behavior.

The evaluation of a patient with sleep apnea begins with the chief complaint that has brought the patient to the physician's office. More often than not, the patient is in the office at the direction of a bed partner who has witnessed apneas, episodes of choking, restless sleep, and/or snoring. While the condition may have been occurring for some time, it is when the patient's bed partner issues an ultimatum and ends up moving to another room to sleep that the patient seeks medical advice.

The history should include a clear description of the sleep disturbance that is bringing the patient to the office. If the problem is snoring, frequency (most nights of the week), duration (all night), and volume (can be heard outside the bedroom) should be determined. Snoring is common in the general population, with 25% of women and 45% of men reporting habitual snoring.

There is poor validity on the self-perception of snoring. A sleeping patient is often unaware of his or her snoring, with 77% unable to decide whether they snored or not.

   d. Time in bed to go to sleep, time of awakening, or total sleep time
   e. Naps during the day

Of the 23% who reported that they did not snore, more than half during polysomnographic objective measurements demonstrated appreciable snoring (36). The reports of snoring from bed partners are usually gathered over a longer period of time.

There is a significant positive correlation between severity of OSA and snoring intensity (37). Maimon et al. demonstrated that snoring intensity increased progressively across categories of OSA and sound levels ranged from 46 ± 3.6 dB in mild to 60 ± 6.4 dB in severe sleep apnea. Snoring intensity has also been shown to be an independent variable related to sleepiness in OSA. Snoring may explain part of sleepiness that cannot be explained by polysomnography alone (38).

Reports of apnea can also be gathered from the patient and bed partner. Often patients will have an arousal that they are aware of and can self-report the apneas. Similarly, bed partners relate stories of how they need to shake the patients to get them to breathe during prolonged periods of apnea.

Nocturnal awakening may or may not be due to an apnea, so further questioning is necessary to better delineate the problem. The second most common sleep disorder after OSA is insomnia, which can also have the symptom of EDS. Individuals with insomnia will awaken at night but will be unable to fall back asleep, which is termed sleep maintenance insomnia. The patient with OSA will awaken but return to sleep without difficulty. Either of these awakenings will, however, result in EDS but for completely different reasons.

EDS is a very common symptom of patients presenting with a sleep disorder. Although it is associated with OSA, it is also present in multiple other sleep disorders such as obesity/hypoventilation syndrome, insufficient sleep, narcolepsy, and hypersomnias.

To help differentiate between feeling tired and true sleepiness, there are multiple self-administered tools that can be used. The ESS is a subjective measurement of sleepiness completed by the patient. It has been validated in clinical populations and asks about the likelihood of falling asleep in common settings. A score greater than or equal to 10 is indicative of EDS (39) (Table 135.7).

The patient's daily schedule must be reviewed, including the time the patient gets in bed to go to sleep, an estimate of how long it takes to fall asleep, the number of awakenings during the night, and the time the patient wakes up and gets out of bed. It is important to obtain detailed sleep–wake schedules in shift workers. If the patient indicates there is great variation in the sleep–wake schedule, this may be part of the problem and causing EDS. To document, the previous day's sleep–wake activity may be sufficient to determine the usual total sleep time and assess if it is adequate in duration.

A sleep diary can be used with patients who are unable to give an accurate description of their sleep–wake habits and have symptoms of EDS (Fig. 135.3). It can be given to the patient and may be used for a week or two to determine sleep habits. It is invaluable in recognizing and documenting insufficient sleep.

It is important to determine the duration of symptoms that are causing the patient to seek treatment. If the issue is of long duration, further evaluation with clinical testing may be done sooner than if the problem is of recent onset. If the problem has been present for some time, there may be a new symptom that is causing the patient to seek help at this point in time.

If the symptoms have been present for a short amount of time, questions may be raised regarding what has changed recently in the patient's life. Sometimes a change in job or the family situation can result in changes in sleep habits that are problematic.

Because of increased access to audio and video recordings, it is not uncommon for patients and their families to bring in

TABLE 135.7 THE ESS IS A SIMPLE QUESTIONNAIRE MEASURING THE LIKELIHOOD OF FALLING ASLEEP IN DIFFERENT SITUATIONS. SCORES GREATER OR EQUAL TO 10 ARE ABNORMAL AND CORRELATE WITH EDS

The ESS—A score >10 indicates EDS

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to our usual way of life in recent times. Even if you have not done some of the things recently, try to work how they would have affected you. Use the following scale to choose the most appropriate number for each situation:

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation	Chance of dozing
1. Sitting and reading	_____
2. Watching TV	_____
3. Sitting, inactive in public place (theater or meeting)	_____
4. As a passenger in a car without a break	_____
5. Lying down to rest in the afternoon when circumstances permit	_____
6. Sitting and talking to someone	_____
7. In a car, while stopped for a few minutes in traffic	_____
8. Sitting quietly after a lunch without alcohol	_____

Diego Head and Neck Surgery Sleep Medicine Clinic and is comprehensive in scope (40).

Review of Systems

Many medical conditions can cause or exacerbate problems with sleep. A complete 14-point review of systems is important and should be included as part of the initial encounter with the patient (Fig. 135.5).

General—Weight loss/gain, fatigue, fever or chills, weakness, or chronic pain can lead to difficult with restorative sleep. Weight gain may exacerbate or cause OSA. Fatigue and weakness may be a symptom of a sleep disorder. There is a decreased threshold for pain when sleep is disrupted.

Nose—Nasal congestion results in increased effort for respiration. Some individuals have difficulty only at night resulting in sleep disruption. Mouth breathing causes the tongue to fall posteriorly, which results in a narrowed hypopharyngeal airway and possible obstruction. Snoring is more common in the supine position with the mouth open.

Throat—Patients with chronic mouth breathing often wake up with dryness of the throat and sometimes a swollen uvula from turbulent airflow during sleep. This can be associated with SDB and OSA.

Neck—History of a goiter, neck mass, previous tracheotomy, or radiation therapy can result in tracheal abnormalities that are manifested during sleep. Tracheomalacia is a rather uncommon site for OSA.

Checklist: Review of Symptoms

General:
- ☐ Weight loss or gain
- ☐ Fatigue
- ☐ Fever or chills
- ☐ Weakness
- ☐ Trouble sleeping

Skin:
- ☐ Rashes
- ☐ Lumps
- ☐ Itching
- ☐ Dryness
- ☐ Color changes
- ☐ Hair and nail changes

Head:
- ☐ Headache
- ☐ Head injury

Ears:
- ☐ Decreased hearing
- ☐ Ringing in ears (tinnitus)
- ☐ Earache
- ☐ Drainage

Nose:
- ☐ Stuffiness
- ☐ Discharge
- ☐ Itching
- ☐ Hay fever
- ☐ Nosebleeds
- ☐ Sinus pain

Throat:
- ☐ Teeth
- ☐ Gums
- ☐ Bleeding
- ☐ Dentures
- ☐ Sore tongue
- ☐ Hoarseness
- ☐ Thrush
- ☐ Non-healing sores
- ☐ Last dental exam

Neck:
- ☐ Lumps
- ☐ Swollen glands
- ☐ Pain
- ☐ Stiffness

Respiratory:
- ☐ Cough (dry or wet, productive)
- ☐ Sputum (color and amount)
- ☐ Coughing up blood (hemoptysis)
- ☐ Shortness of breath (dyspnea)
- ☐ Wheezing
- ☐ Painful breathing

Cardiovascular:
- ☐ Chest pain or discomfort
- ☐ Tightness
- ☐ Palpitations
- ☐ Shortness of breath with activity (dyspnea)
- ☐ Difficulty breathing lying down (orthopnea)
- ☐ Swelling (edema)
- ☐ Sudden awakening from sleep with shortness of breath (paroxysmal noctural dyspnea)

Gastrointestinal:
- ☐ Swallowing difficulties
- ☐ Heartburn
- ☐ Change in appetite
- ☐ Nausea
- ☐ Change in bowel ha
- ☐ Rectal bleeding
- ☐ Constipation
- ☐ Diarrhea
- ☐ Yellow eyes or skin (jaundice)

Urinary:
- ☐ Frequency
- ☐ Urgency
- ☐ Burning or pain
- ☐ Blood in urine (hematuria)
- ☐ Incontinence
- ☐ Change in urinary strength

Vascular:
- ☐ Calf pain with walking (claudication)
- ☐ Leg cramping

Musculoskeletal:
- ☐ Muscle or joint pain
- ☐ Stiffness
- ☐ Back pain
- ☐ Redness of joints
- ☐ Swelling of joints
- ☐ Trauma

Neurologic:
- ☐ Dizziness
- ☐ Fainting
- ☐ Seizures
- ☐ Weakness
- ☐ Numbness
- ☐ Tingling
- ☐ Tremor

Endocrine:
- ☐ Head or cold intolerance
- ☐ Sweating
- ☐ Frequent urination (polyuria)
- ☐ Thirst (polydypsia)
- ☐ Change in appetite (polyphagia)

Psychiatric:
- ☐ Nervousness
- ☐ Depression
- ☐ Memory loss
- ☐ Stress

Figure 135.5 A standardized review of systems assists in identifying comorbidities that can contribute to or exacerbate sleep disorders.

Respiratory—Coughing, choking, or wheezing can be seen in OSA as well as in individuals with gastroesophageal reflux, asthma, and chronic obstructive pulmonary disease (COPD). Recent data suggest that OSAS is an independent risk factor for asthma exacerbations (41).

Gastrointestinal—Gastroesophageal reflux has been reported to occur in 62% to 74% of patients with OSA (42). Gastroesophageal reflux, as previously mentioned, is common in OSA. The increased negative thoracic pressure results in reflux and increased complaints upon awakening.

Genitourinary—Urinary frequency is a significant issue for men, more so than women, as they grow older. Benign prostatic hypertrophy can result in men awakening multiple times a night, which prevents them from getting a good night's sleep. The sample population had a mean age of 45.8 years and was 52.6% female and 80% Caucasian. In the community sample, 31% reported greater than one void per night, and 14.2% reported greater than two voids per night. The prevalence of nocturia increased with age, with no gender differences. For over active bladder cases, 66.8% reported greater than one void per night, and 42.2% reported greater than two (43). An increase in intra-abdominal pressure, confusion associated with arousals, and increased levels of atrial natriuretic peptide have been associated with nocturia in patients with OSA. Treatment of OSA has been shown to significantly decrease nocturia.

Neurologic—About 50% of people who have had a stroke have sleep apnea (44). Sixty percent of patients with Parkinson disease have sleep problems such as sleep fragmentation, insomnia, nightmares/night terrors/nocturnal vocalizations, hallucinations, and EDS (45).

Musculoskeletal—Musculoskeletal pain syndromes such as chronic arthritis and fibromyalgia can result in poor-quality sleep and are correlated with an increase in depression, pain intensity, activity levels, and hypochondriasis (46).

Endocrine—Diabetes can result in polyuria with disruption of sleep. Any disruption of the hypothalamic–pituitary–adrenal axis will disrupt the circadian rhythm. Insomnia and OSA are associated with hypothalamic–pituitary–adrenal axis abnormalities (47). Sleep difficulty is one of the hallmarks of menopause with the primary predictor of disturbed sleep architecture being the presence of vasomotor symptoms (48).

Psychiatric—Primary psychiatric diagnoses of depression, anxiety, bipolar disease, or attention deficit disorder can contribute to sleep disturbances or daytime impairment. Many of the medications used for treatment also impact normal sleep patterns (49).

Medications—Prescription and over-the-counter medications can impact sleep and should be thoroughly covered during the visit. There are many medications which have an impact on the sleep–wake cycle. Some of the medications can induce pain (statins), cough (angiotensin converting enzyme inhibitors), restless legs symptoms (antidepressants, neuroleptics, and antihistamines), or REM sleep behavior disorder (antidepressants, monoamine oxidase type B inhibitors) and subsequently cause sleep disruptions. Tables 135.8 and 135.9 demonstrate medications that disrupt sleep and wake, respectively.

Caffeine works as a central nervous stimulant that temporarily decreases drowsiness and improves alertness. It occurs naturally in coffee, tea, and chocolate and is present in soft drinks and most energy drinks. In North America, 90% of the population consumes caffeine daily (50). Two hundred milligrams or more of caffeine, the approximate caffeine content in two cups of coffee, has been shown to improve tests of vigilance, alertness, and reaction time in US Navy SEALs after 72 hours of sleep deprivation (51). The caffeine content of some common food and beverages is listed in Table 135.10.

The nicotine in cigarettes acts as a stimulant with an average cigarette delivering 1 mg. It is distributed quickly through the bloodstream and crosses the blood–brain barrier reaching the brain within 1 to 20 seconds after inhalation. The elimination half-life of nicotine in the body is about 2 hours. Nicotine reduces total sleep time and REM sleep time in healthy control subjects. There is an increase in sleep latency and increased arousals with fragmented sleep in active smokers versus nonsmokers. About 20% of smokers experience nocturnal sleep disturbing nicotine craving that occurs with patients waking up once or more a night and are unable to fall back asleep without smoking a cigarette (52).

Alcohol has a transient sedative effect in sleepy or anxious individuals. It is the most commonly used sleeping aid by the population at large. A survey of 18- to 45-year-olds reported that 13% use alcohol to induce sleep. When taken before bedtime, it shortens sleep latency. Alcohol is metabolized rapidly at the rate of one glass of wine or beer per hour. If an individual has had several drinks before sleep, alcohol concentrations in the blood approaches zero halfway through the night. Withdrawal tends to occur at that time and causes disrupted sleep and a sympathetic arousal, which includes tachycardia and sweating (53).

Physical Examination

The age and gender of a patient are important pieces of demographic information for patients with sleep disorders. Sleep disturbances are more common in men than women until menopause when the incidence of sleep apnea in women increases.

The height and weight of a patient should be accurately measured in the office. These measurements should not be self-reported because, as a patient ages, height can decrease due to osteoporosis or because the previous height measurement was taken with the shoes on.

TABLE 135.8 SELECTED COMMON MEDICATIONS THAT DISRUPT SLEEP

Drug Class	Examples	Typical Indications	Patient Complaints	Mechanism	Potential Solution
Selective serotonin reuptake inhibitors	sertraline, fluoxetine, citalopram	Major depression, anxiety disorders, postmenopausal hot flashes	Restless legs symptoms, sleep-onset insomnia, nonrestorative sleep, dream enactment behavior or "sleepwalking"	Drugs may have alerting side effects.[1] Increases restless legs symptoms and periodic limb movements of sleep,[2,3] increases likelihood of REM without atonia (may lead to clinical REM behavior disorder)[4]	Reassess original indication, consider alternate agent (bupropion not associated with increased RLS symptoms)
Tricyclic antidepressants	amitriptyline, imipramine, protriptyline	Major depression, anxiety, insomnia, neuropathic pain	Restless legs symptoms, sleep-onset insomnia, nonrestorative sleep	Increases restless legs symptoms and periodic limb movements of sleep,[2] protriptyline is strongly adrenergic and has an alerting side effect profile[5,6]	Reassess original indication, consider alternate agent
ACE Inhibitors	lisinopril, enalapril	Hypertension, diabetic proteinuria, congestive heart failure	Nocturnal cough Worsening sleep apnea	Increased bradykinin production leads to airway irritation, possible increased airway edema[7]	Consider substitution with angiotensin receptor blocker or other drug class
Norepinephrine and dopamine reuptake inhibitors	venlafaxine, desvenlafaxine, bupropion	Major depression, anxiety, postmenopausal hot flashes	Sleep-onset insomnia	Increased activity of alerting neurotransmitters[8]	Reassess original indication, consider alternate agent
Beta-2 agonists	albuterol, salmeterol	Asthma, COPD	Sleep-onset insomnia Sleep maintenance insomnia	Alerting side effects of adrenergic medications[9]	Reassess original indication, educate patient regarding nocturnal use of medication, consider use of hypnotic if nocturnal usage is unavoidable
Beta-blockers	Metoprolol, propranolol	Hypertension, tachyarrhythmias, migraine prophylaxis	Nightmares	Not known, likely related to central β-adrenergic blockade, lipophilic β-blockers may be more problematic[10,12]	Consider switch to less lipophilic agent (e.g., atenolol), or alternate drug class
Corticosteroids	prednisone, methylprednisolone	Rheumatologic disorders, COPD	Sleep-onset insomnia Sleep maintenance insomnia[13] Abnormal dreams[14]	Unknown	Consider nonsteroid alternatives if medically reasonable, consider low-dose hypnotic if corticosteroid medication is medically mandatory
Nonnucleoside reverse transcriptase inhibitors (antiretroviral)	efavirenz	HIV disease	Abnormal dreams[15]	Unknown	Consider alternate agent if severely troubling, consider low-dose hypnotic with low potential for drug–drug side effects (e.g., doxepin)[15]

(Continued)

TABLE 135.8 SELECTED COMMON MEDICATIONS THAT DISRUPT SLEEP (*Continued*)

Drug Class	Examples	Typical Indications	Patient Complaints	Mechanism	Potential Solution
Statins	atorvastatin, simvastatin, pravastatin, rosuvastatin	Hyperlipidemia	Sleep-onset insomnia or frequent awakenings due to muscle pain	Statin-induced myopathy, possible statin-induced arthralgia[16,17]	Reassess original indication, reassess treatment goals, consider decreased dose, consider alternate agent
Opiates	methadone, oxycodone, morphine	Chronic pain, restless legs syndrome	Frequent awakenings, nocturnal breathlessness, Nonrestorative sleep	Increased risk of obstructive and central sleep apnea[18]	Consider nonopiate alternatives, consider polysomnography with positive airway pressure if sleep-disordered breathing is severe
CNS stimulants	methylphenidate, dextroamphetamine	Narcolepsy, Idiopathic CNS hypersomnia, Attention deficit hyperactivity disorder	Sleep-onset insomnia, frequent awakenings	Central stimulation of dopaminergic alerting system	Consider earlier dosing, use of immediate-release formulations for later day dosing, replacement with modafinil
Social drugs	Caffeine Tobacco/nicotine	n/a	Sleep-onset insomnia Sleep maintenance insomnia Snoring	Caffeine may have hold-over stimulatory effects lasting into the nocturnal time frame; nicotine used at night can produce CNS stimulation; heavy smokers during daytime hours can experience nocturnal withdrawal during sleep-induced abstinence, leading to physical discomfort. Smoking increases upper airway inflammation, which can worsen sleep-disordered breathing	Decrease or discontinue use
Social drugs	Alcohol	n/a	Sleep maintenance insomnia Snoring Worsening sleep apnea	Alcohol tends to worsen propensity for sleep-disordered breathing, possibly by altering upper airway tone and by increasing arousal threshold; though it shortens sleep latency, prebedtime use often results in insomnia in the second half of the night.	Decrease or discontinue use

TABLE 135.9 SELECTED COMMON MEDICATIONS THAT DISRUPT WAKEFULNESS

Drug Class	Examples	Typical Indications	Patient Complaints	Mechanism	Potential Solutions
Selective serotonin reuptake inhibitors	sertraline, paroxetine	Major depression, anxiety, postmenopausal hot flashes	Daytime sleepiness	Sedating effects of medication[19]	Reassess original indication, consider taper or substitution of an agent with a more alerting side effect profile (e.g., venlafaxine or bupropion)
Tricyclic antidepressants	amitriptyline	Insomnia, major depression, anxiety, chronic neuropathic pain	Morning grogginess nonrestorative sleep, daytime sleepiness	Sedating effects of medication Prolonged half-life for some medications leads to next-day "hangover"	Reassess original indication, consider dose decrease, consider nocturnal dosing schedule, consider alternate agent
Benzodiazepines	diazepam, clonazepam, flurazepam	Insomnia, anxiety, muscle spasms, REM behavior disorder	Morning grogginess, nonrestorative sleep, daytime sleepiness	Sedating effects of medication; prolonged half-life for some medications leads to next-day "hangover"	Reassess original diagnosis, consider alternate agent, consider addition of daytime alerting agent if agent is considered medically necessary
Anticonvulsants	gabapentin, phenytoin, levetiracetam	Seizure disorder, neuropathic pain, migraine prophylaxis	Daytime sleepiness	Sedating effects of medication	Consider dose decrease, consider alternate agent, consider addition of daytime alerting agent if agent is considered medically necessary
Neuroleptics	quetiapine, risperidone, haloperidol	Psychotic disorders, major depression, attention deficit disorder	Daytime sleepiness	Sedating effects of medication	Reassess original diagnosis, consider alternate agent, consider addition of daytime alerting agent if agent is considered medically necessary
Beta-blockers	metoprolol, propranolol, bisoprolol	Hypertension, tachyarrhythmias, migraine prophylaxis	Daytime fatigue	Central adrenergic blockade→fatigue or drowsiness[20,21]	Consider less lipophilic agent (e.g., atenolol), consider alternate drug class
Statins	atorvastatin, simvastatin, pravastatin, rosuvastatin	Hyperlipidemia	Daytime fatigue, poor exercise tolerance due to muscle pain	Statin-induced myopathy, possible statin induced arthralgia[16,17,20]	Reassess original diagnosis, reassess treatment goals, consider lower dose, consider alternate agent
Antihistamines	Diphenhydramine, hydroxyzine	Allergic reactions, anxiety, pruritic conditions, insomnia	Daytime fatigue Daytime sleepiness Poor attention and concentration[22]	Blockade of central histaminergic receptors→drowsiness, anticholinergic effects on basal forebrain decreases concentration and information processing ability	Consider lower dose, consider nonsedating alternatives, consider addition of daytime alerting agent if agent is considered medically necessary
Social drugs	Alcohol	n/a	Daytime fatigue Headaches Depression Anxiety	Alcohol can lead to daytime impairment symptoms by virtue of its effects on sleep (see Table 135.8), by direct CNS sedative effects, toxicity ("hangover") effects, or due to withdrawal symptoms.	Taper and discontinue use

TABLE 135.10 CAFFEINE CONTENT OF SELECT COMMON FOOD, BEVERAGES, AND DRUGS

Product	Serving Size	Caffeine per Serving (mg)
Hershey's Milk Chocolate	1 bar (1.5 oz)	10
Hershey's Special Dark (45%) cacao content	1 bar (1.5 oz)	31
Coffee, decaffeinated	7 oz	5–15
Green Tea	6 oz	30
Black Tea	6 oz	50
Coca Cola Classic	12 oz	34
Mountain Dew	12 oz	54
Red Bull Energy	8 oz	80
Starbucks Vanilla Latte	16 oz	150
Monster energy drink	16 oz	160
Dunkin Donuts Brewed Coffee	16 oz	143–206
5-h energy	2 oz	207

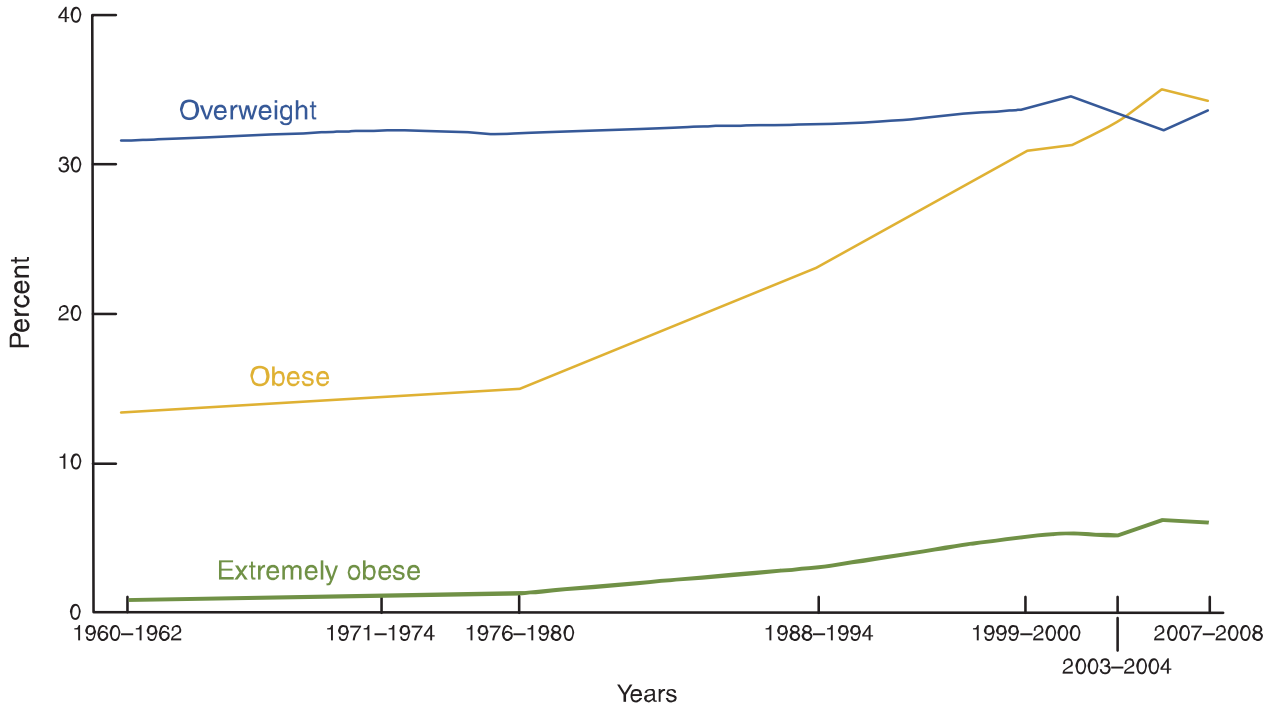
Similarly, individuals frequently underestimate their weight. It may be that they are embarrassed, have not weighed themselves in some time, or do not want their spouse to be aware of it. After the height and weight have been assessed, the BMI was developed in the 1800s by Belgian Adolphe Quetelet in the development of "social physics" (54).

TABLE 135.11 CATEGORIES OF WEIGHT CLASSIFICATION BASED ON BMI RANGES

Category	BMI (kg/m^2)
Severely underweight	<16
Underweight	16–18.5
Normal	18.5–25
Overweight	25–30
Obese Class I	30–35
Obese Class II	35–40
Obese Class III	>40

The BMI classification is commonly used to classify individuals as underweight, normal, overweight and obese. Obese is further grouped into class I, II, and III. The BMI should be calculated and communicated to the patient (Table 135.11). Results from the 2007 to 2008 National Health and Nutrition Examination Survey, using BMI, indicate that an estimated 34.2% of US adults aged 20 years and over are overweight, 33.8% are obese, and 5.7% are extremely obese (55) (Fig. 135.6).

BMI does not actually measure body fat. Because the BMI formula depends only upon weight and height, its assumptions about the distribution between lean mass and



NOTE: Age-adjusted by the direct method to the year 2000 U.S. Census Bureau estimates, using the age groups 20–39, 40–59, and 60–74 years. Pregnant females were excluded. Overweight is defined as a body mass index (BMI) of 25 or greater but less than 30; obesity is a BMI greater than or equal to 30; extreme obesity is a BMI greater than or equal to 40.
SOURCE: CDC/NCHS, National Health Examination Survey cycle I (1960–1962); National Health and Nutrition Examination Survey I (1971–1974), II (1976–1980), and III (1988–1994), 1999–2000, 2001–2002, 2003–2004, 2005–2006, and 2007–2008.

Figure 135.6 Trends in overweight, obesity, and extreme obesity among adults aged 20 to 74 years: United States, 1960 to 2008. http://www.cdc.gov/NCHS/data/hestat/obesity_adult_07_08/obesity_adult_07_08.pdf

adipose tissue are not always exact. BMI sometimes overestimates adiposity on those with more lean body mass (e.g., athletes) while greatly underestimating excess adiposity on those with less lean body mass (56). There are numerous Web sites and applications that are available for handheld devices that will perform this calculation.

A complete head and neck exam should be performed with attention paid to several areas especially important to the assessment of the patient with OSA.

The nasal examination should be performed to determine if there is a septal deformity, allergic/nonallergic rhinitis, or other nasal obstruction that may lead to difficulty breathing at night. If there is nasal obstruction that results in mouth breathing at night, the mandible opens causing posterior displacement of the tongue with a narrowed glossal pharyngeal airway and increased airway resistance. Adherence to treatment of OSA with CPAP and/or oral appliances can be improved with patent nasal airways.

Mallampati rating of the oral cavity was developed by an anesthesiologist to assess the difficult airway for intubation (57). Patients are asked to open their mouths wide and to protrude their tongues forward. A modified Mallampati or Friedman palate position is performed with the mouth open and without protrusion of the tongue (58). The oropharynx is assessed, and the classification of Mallampati I to IV is made based on the degree of visualization of the posterior pharyngeal wall, uvula, soft palate, and hard palate (Fig. 135.7).

Tonsils are evaluated and categorized on a scale of 0 to 4 (Fig. 135.8). Zero is used when the tonsil has been previously surgically excised, and four would be for tonsils that are "kissing" or touching in the midline. If a patient gags during the exam, the size of the tonsil may be incorrectly assessed. The tonsils will touch during the pharyngeal constriction and may be graded as touching when, in fact, this is physiologic. Removal of 3 to 4+ tonsil in some patients may result in elimination of the upper airway obstruction causing OSA.

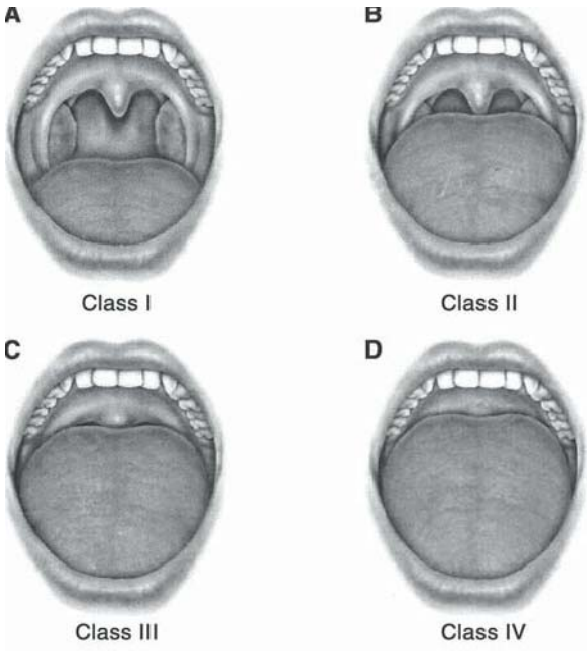


Figure 135.7 Friedman modification of Mallampati classification. **A:** Class I: Full visibility of tonsils, uvula, soft palate, and hard palate. **B:** Class II: Visibility of hard palate, soft palate, upper portion of tonsils, and uvula. **C:** Class III: Soft palate, hard palate, and base of uvula are visible. **D:** Class IV: Only hard palate is visible.

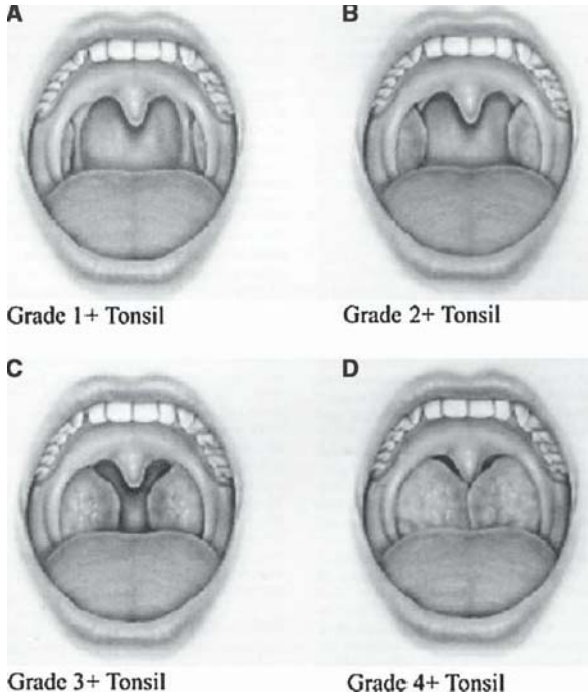

Figure 135.8 Tonsil size. **A:** Grade 1—Tonsil tissue is barely visible past anterior tonsillar pillar but not visible past posterior tonsillar pillar. **B:** Grade 2—Tonsil tissue is extending past anterior tonsillar pillar and obscuring posterior tonsillar pillar. **C:** Grade 3—Tonsil tissue is enlarged and almost obscuring pharyngeal airway. **D:** Grade 4—Tonsil tissue is meeting in the midline.

The Friedman clinical staging system for SDB takes into consideration the modified Friedman palate position, tonsil size, and BMI. It has been used as a predictor of the success of uvulopalatopharyngoplasty (UPPP) and to determine if additional surgical procedures would be useful (59).

Dental occlusion should be assessed and recorded as Class I, II, or III (Fig. 135.9). Class I is normal occlusion with the mesial buccal cusp of the first maxillary molar positioned into the intercuspal groove of the mandibular first molar. Class II occurs when patients are retrognathic, and the mesial buccal cusp of the first maxillary molar is positioned mesial to the intercuspal groove of the mandibular first molar. Class II occlusion will have posterior displacement of the tongue and suffer from glossopharyngeal airways that have decreased anterior posterior diameter. Class III occlusion occurs with mandibular protrusion, and the mesial buccal cusp of the first maxillary molar is positioned distal to the intercuspal groove of the mandibular first molar. Maxillomandibular advancement procedures for Class II and III occlusions can be extremely successful in patients with OSA and may improve cosmesis as well (60).

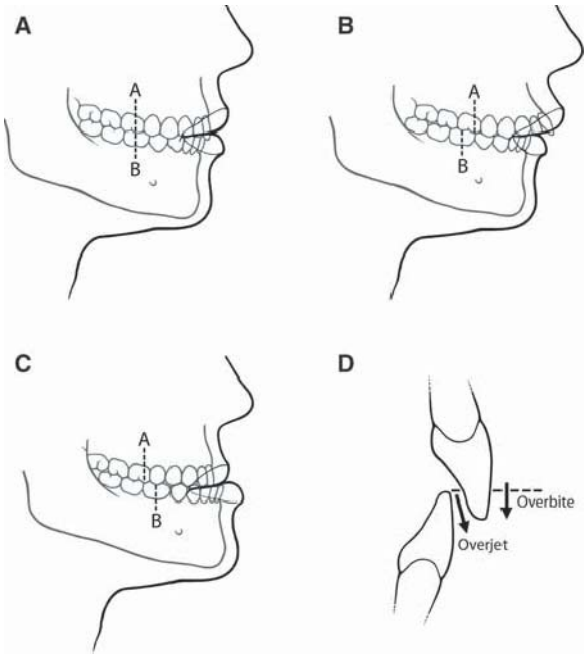

Figure 135.9 Dental occlusion is the classification between the maxillary and mandibular teeth when they come into contact during chewing or at rest. **A:** Class I molar occlusion: The mesial buccal cusp of the first maxillary molar is positioned into the intercuspal groove of the mandibular first molar and is considered normal occlusion. **B:** Class II molar occlusion is the mesial buccal cusp of the first maxillary molar positioned into the intercuspal groove of the mandibular first molar and is sometimes referred as an overbite or retrognathic. **C:** Class III molar occlusion is the mesial buccal cusp of the first maxillary molar positioned distal to the intercuspal groove of the mandibular first molar. **D:** There is normally 2 mm of overbite and overjet related to the central mandibular and central maxillary incisors.

Nasopharyngeal endoscopy with Mueller maneuver is often attempted to identify the sites of collapse in the upper airway during sleep. Introducing a flexible fiberoptic scope into the hypopharynx to obtain a view, the examiner asks the patient to inhale; patient attempts to inhale with the mouth closed and nostrils plugged, which may lead to a collapse of certain segments of the airway. This maneuver has been used to predict success of surgical treatment by guiding the surgeon to treat one or more sites of pharyngeal obstruction. However, a prospective study demonstrated that Mueller maneuvers are not predictive of surgical outcomes for UPPP (61).

Drug-induced sleep endoscopy is another diagnostic method that may help identify the specific site of obstruction during apneas more accurately than the Mueller maneuver and awake endoscopy. Described in 1991, the technique uses pharmacologic induction of sleep and the placement of a flexible fiberoptic endoscope transnasally for visualization of the upper airway (62). Sleep endoscopy is performed in an operating room or procedure room with the surgeon and with a provider administering anesthesia. During pharmacologic sleep, a fiberoptic exam includes a complete assessment of the upper airway including the palate, oropharynx, hypopharynx, and retroglossal regions (web video by Dr. Ofer Jacobowitz). There have been attempts to correlate sleep endoscopy with surgical outcomes, but it is unclear if this technique is superior in choosing candidates for a specific surgical procedure (63).

Neck circumference has been reported to be a better predictor of OSA than BMI. The neck circumference should be measured at the level of the superior border of the cricothyroid membrane with the patient in the upright position. A male with a neck circumference of 17 inches or a female with 14½ inches or greater and a BMI greater than 30 has a 70% incidence of OSA (64).

Abdominal obesity assessed by waist measurement or waist/hip ratio is related to increased risk of all-cause mortality regardless of BMI. The waist is measured simply at the smallest circumference of the natural waist, just above the belly button, and the hip circumference is measured at its widest part of the buttocks or hip. The relative risks seem to be relatively stronger in younger than in older adults and in those with relatively low BMI compared with those with high BMI. Waist–hip ratio is a risk factor especially in severe OSA syndrome (65).

The waist–hip ratio has been found to have better predictive value for ventilation abnormalities than BMI. A ratio of more than 0.9 for men and more than 0.85 for women is abnormal. Central obesity impairs ventilation to lower lung zones, resulting in abnormally lower ventilation–perfusion ratios (66).

RADIOLOGIC EVALUATION OF THE AIRWAY IN SLEEP-DISORDERED BREATHING

Patients with OSA often have a narrower pharyngeal airway than normal individuals because of fat infiltration, increased soft tissue volume, or reduced pharyngeal muscle tone (1). Imaging techniques have been used to evaluate the sites of upper airway obstruction through static or dynamic techniques. Static techniques are x-ray cephalometry, computed tomography (CT), and magnetic resonance imaging (MRI). Dynamic techniques would be fluoroscopy, somnofluoroscopy (performed during sleep), cine CT, ultrafast CT, and MR imaging and fluoroscopic MRI. Imaging is primarily used in the planning of surgical intervention, the fitting of oral appliances, and the evaluation of treatment failures.

X-Ray Cephalometry

Lateral x-ray cephalometry is one of the standard diagnostic tools for evaluation of craniofacial skeletal abnormalities (Fig. 135.10). While it has the advantage of low cost, ready availability, and excellent demonstration of bony detail, its drawbacks include the fact that it is a static two-dimensional assessment of the airway and it is less sensitive to soft tissue interfaces.

There are multiple studies comparing differences between the upper airway and craniofacial anatomy between OSA patients and controls. The results are difficult

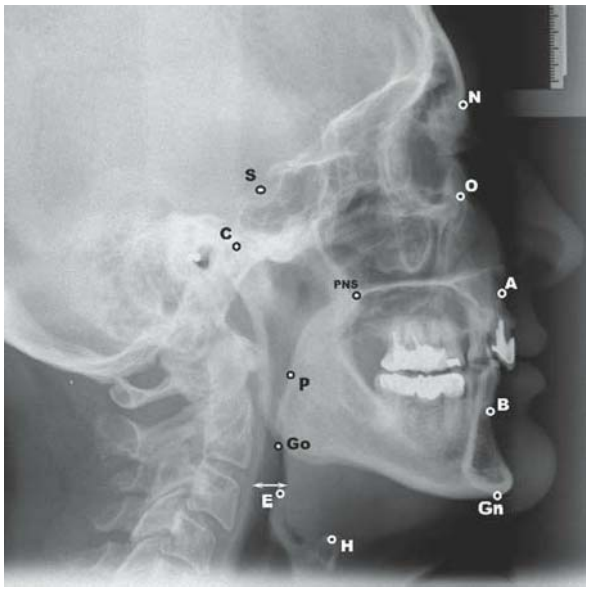

Figure 135.10 Lateral x-ray cephalogram. The cephalometric landmarks used in this study. *S* (sella), midpoint of sella; *N* (nasion), anterior point at the frontonasal suture; ANS (anterior nasal spine), most anterior point of the anterior nasal spine; *PNS* (posterior nasal spine), most posterior point of hard palate; *A* (subspinal point), deepest anterior point in concavity of the maxilla; *B* (supramental point), deepest anterior point in concavity of the mandible; *Gn* (gnathion), most inferior point of the mandibular symphysis; *H* (hyoid), most anterosuperior point of hyoid bone; *E* (epiglottis), base of epiglottis; *Go* (gonion), most posterior and inferior point of the angle of the mandible; *P* (soft palate), most inferior and posterior point of the soft palate; MP (mandibular plane), mandibular plane joining gonion with gnathion; SNA (deg), angle between nasion–sella line (NSL) and the line from *A* to *N* (measures projection, anterior or posterior of maxilla); SNB (deg), angle between NSL and the line from *B* and *N* (measures position of mandible); ANB (deg), angle between the line from *A* to *N* and the line from *B* to *N* (measures position of maxilla with mandible); *PNS*–ANS, linear distance between *PNS* and ANS; ANS-H, linear distance between ANS and *H*; ANS-E, linear distance between ANS and *E*; PNS-P, linear distance between *PNS* and *P* (measures length of velum of palate); MP-H, linear distance between the mandibular plane and *H*.

to compare because authors use different landmarks and calculated ratios to describe differences that were found. The reduction in mandible length and inferior displacement of the hyoid bone appears to be the most important skeletal abnormalities predisposing to OSA (67).

Fluoroscopy and Somnofluoroscopy

Fluoroscopic examination of the airway provides dynamic evaluation of the upper airway during wakefulness and sleep. Somnofluoroscopy demonstrates the dynamic events during apneas and has shown fluttering of the soft palate, which preceded airway collapse. This technique allows the examination of the sequence of events leading to airway collapse in OSA. It has also been used to determine the effect of oral appliances on airway size. Its clinical applicability is limited as this technique shows the upper airway in only two dimensions, and its use can result in high levels of radiation exposure.

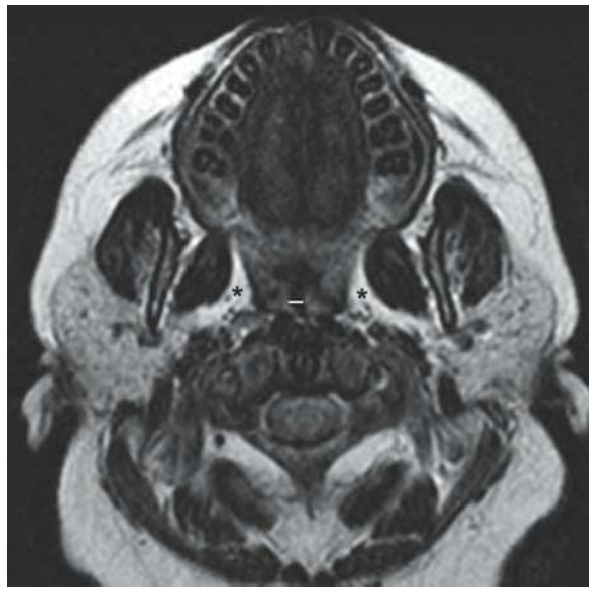

Figure 135.11 CT of patient with OSA–axial contrast-enhanced CT image at the level of the oropharynx demonstrating prominence of the lingual tonsils, which are seen to prolapse backward during sleep leading to obstruction. *Parapharyngeal fat pads.

Computed Tomography

CT scanning proves soft tissue contrast and allows precise measurements of cross-sectional areas at suspected levels of obstruction (Fig. 135.11). Newer technologies with fast scanning times allow a dynamic assessment of the upper airway during a respiratory cycle. There are scanning protocols under hypnotic sedation to replicate resting, sleep, sleep during apneas, and wakefulness (68). Concerns regarding the dose of ionized radiation remain problematic. CT images also lack soft tissue contrast particularly for adipose tissue when compared to MRI.

Magnetic Resonance Imaging

MRI offers several important advantages compared to cephalometry or CT scans. MRIs provide excellent soft tissue resolution and lack of ionizing radiation. Various studies have demonstrated the presence of parapharyngeal fat deposits in patients with OSA who are obese and anterolateral fat deposits in nonobese patients (69) (Fig. 135.12). Multiple studies have used MRI to determine structural risk factors for OSA with conflicting results. Do et al. (70) demonstrated a weak trend for larger tongues in patients with OSA; however, Schwab et al. (71), using three-dimensional MRI analysis techniques, have confirmed that the volume of the upper airway soft tissue structures, including the tongue, is enlarged in patients with sleep apnea and that this enlargement is a significant risk factor for sleep apnea. Ultrafast MRI can demonstrate dynamic three-dimensional changes in the upper airway during sleep and is used to identify site of obstruction, particularly in the pediatric population.

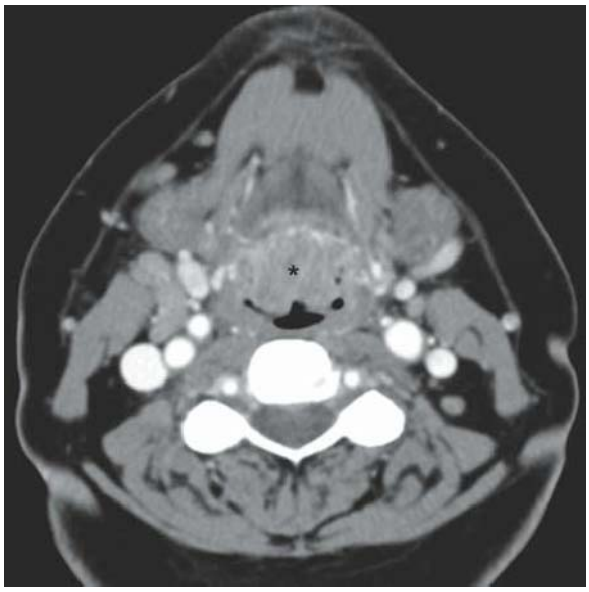

Figure 135.12 MRI demonstrating in OSA. Axial noncontrast MR image, demonstrating narrowing of the airway, which is more round than oval. In normal patients, airway is more oval with patent lateral recesses. Lateral parapharyngeal fat pads are indicated by the *asterisks* and appear larger in this apneic patient, although their role in genesis of OSA is uncertain.

DIAGNOSIS OF SLEEP DISORDERS

While the history and examination of the patient with symptoms of OSA can be highly suggestive of this diagnosis, confirmation with a sleep study is necessary. When Hoffstein and Szalai (72) studied 594 patients referred for possible OSA, they found that physician subjective impression only correctly identified 51% of the patients with OSA and 71% of the patients without OSA. The PSG is indicated in the diagnosis of SDB, positive airway titration studies, and some movement disorders of sleep (73). It consists of in-laboratory electrographic recordings of multiple physiologic parameters during drowsiness and sleep. Measurements may include EEG for sleep staging, electrooculogram (EOG) channels to measure eye movements, electromyography (EMG) measured superficially on the skin to assess for movement or atonia during REM sleep, airflow monitors including nasal pressure and thermistor, EKG leads, pulse oximetry, chest and abdominal excursion monitors to assess respiratory effort, auditory recordings of snoring, and video recording of movements in sleep (74) (Fig. 135.13). The data collected in a full night of sleep are scored in accordance with the American Academy of Sleep Medicine (AASM) guidelines (75). The variables scored in a PSG are listed in Table 135.12.

TABLE 135.12 VARIABLES SCORED AND PHYSIOLOGIC PARAMETERS USED IN POLYSOMNOGRAPHY

Variable Scored	Physiologic Parameters used in Scoring
Sleep stages	EEG, EOG, EMG (atonia)
Arousals	EEG
Respiratory events	Flow (nasal pressure and thermistor), respiratory effort, oximetry
Leg movements–periodic	EMG

Also recorded in a PSG are data defining sleep onset, sleep efficiency, awakenings, and body position during sleep. The number of scored events is reported as an index or events per hour of sleep. The AHI is the number of apneas + hypopneas per hour of sleep. The RDI is the number of apneas + hypopneas + respiratory-related arousals per hour of sleep (Table 135.13).

Polysomnography is the traditional test for diagnosis of OSA. While many otolaryngologists interpret these studies, often physicians are called upon to treat patients based upon a sleep study interpreted by another physician. The AHI and RDI are not the only relevant and useful values contained within this report. A systematic review of the data within the PSG report will help determine the appropriate treatment for the patient. Table 135.14 contains tips for the review of polysomnographic data.

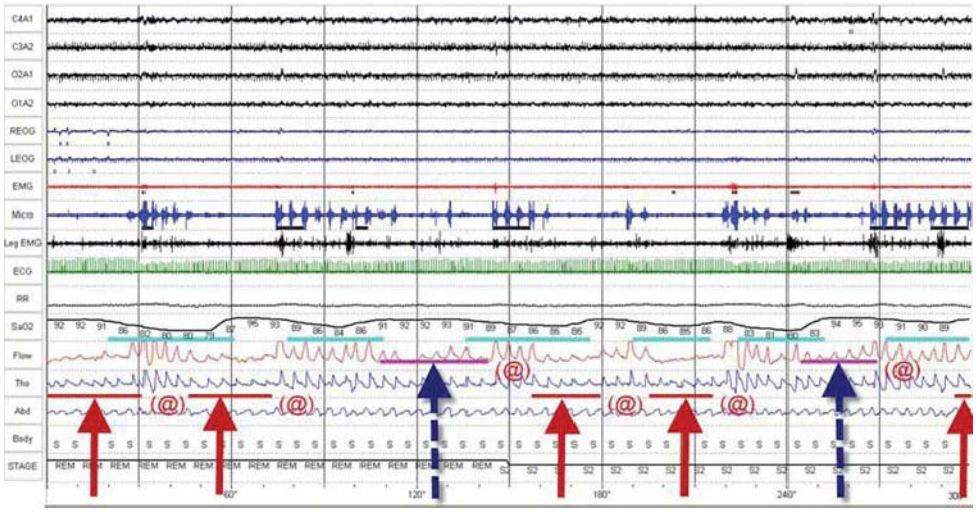

Figure 135.13 Three-hundred-second PSG recording in a 63-year-old male with snoring, hypertension, and EDS. Note snoring recorded on microphone channel apneas (*solid arrows*) and hypopneas (*dotted arrows*) on the flow channel with persistent respiratory effort and oxygen desaturations with respiratory events.

TABLE 135.13 GLOSSARY OF ADULT POLYSOMNOGRAPHY TERMS

Obstructive Apnea—Respiratory event with a drop in the respiratory signal (thermistor signal preferred) by ≥90% of baseline lasting at least 10 s associated with continued respiratory effort throughout the period of absent airflow.

Hypopnea—Respiratory event with a drop in the nasal pressure signal by ≥30% of pre-event baseline using nasal pressure or an alternative hypopnea sensor lasting at least 10 s associated with a ≥3% oxygen desaturation from pre-event baseline or an arousal.

Arousal—An abrupt change in EEG frequency >16 Hz that lasts 3 s with at least 10 s of stable sleep preceding the change. During REM sleep, a concurrent increase in submental EMG lasting at least 1 s is required.

Respiratory Effort-Related Arousal—A sequence of breaths lasting at least 10 s with a flattening of the nasal pressure waveform or increasing respiratory effort resulting in an arousal from sleep when this event does not meet criteria for an apnea or hypopnea.

AHI—Apneas + hypopneas per hour of sleep.

RDI—Apneas + hypopneas + respiratory effort-related arousals per hour of sleep.

Hypoventilation— There is an increase in the arterial PCO2 (or surrogate) to a value >55 mmHg for ≥10 min or there is a ≥10 mm Hg increase in arterial PCO2 (or surrogate) during sleep (in comparison to an awake supine value) to a value exceeding 50 mm Hg for ≥10 min.

Cheyne-Stokes Breathing— There are episodes of ≥3 consecutive central apneas and/or central hypopneas separated by a crescendo and decrescendo change in breathing amplitude with a cycle length of ≥40 s and there are ≥5 central apneas and/or central hypopneas per hour of sleep associated with the crescendo/decrescendo breathing pattern recorded over ≥2 h of monitoring.

Sleep Latency—Time in minutes from lights out until the first epoch in any sleep—usually Stage N1.

Sleep Efficiency—Total sleep time/total recording time (lights out to lights on) × 100.

REM Latency or Stage R Latency—Time in minutes from sleep onset to the first epoch of stage REM.

From Berry RB, Brooks R, Gamaldo CE, et al. *The AASM manual for the scoring of sleep and associated events: rules, terminology and technical specifications, version 2.0.* Darien, IL: American Academy of Sleep Medicine, 2012, www.aasmnet.org.

TABLE 135.14 HOW TO REVIEW A PSG REPORT

Study parameters—

Total sleep time and sleep efficiency—Review to be certain that the patient had a representative night of sleep. Normal adult sleep efficiency is 85%–90%, and sleep time in the laboratory is usually over 6 h. Very low sleep efficiency or a short sleep duration indicates a poor night of sleep that may not adequately represent the patient's usual sleep.

Sleep latency—Normal sleep latency is 10–30 min. A markedly decreased sleep latency of <10 min may signal excessive sleepiness. A sleep latency over 40 min can be secondary to a first night effect in the laboratory but may also indicate an underlying disorder such as DSPS.

REM latency—Normal REM latency is 80–110 min. A REM latency of <10 min may indicate the possibility of narcolepsy. A moderately reduced REM latency of 40–60 min can be seen in a number of conditions. It can be associated with depression, cessation of REM-suppressing drugs, alcohol withdrawal, and circadian rhythm disorders.

Sleep stages—SDB is often more prominent in REM sleep due to REM atonia. The lack of REM sleep during the study may mask or underestimate the presence or severity of SDB. Stage I (N1) sleep is a very light stage of sleep, which is normally present in 5%–10% of the night's sleep. A high percentage of N1 sleep suggests very disrupted sleep. Abnormal sleep stage distribution may also indicate medication effect, underlying sleep deprivation or other abnormalities of sleep. Since Stage N3 sleep declines with age, it is not abnormal for older adults to have little or no slow-wave sleep.

Respiratory summary—Within the respiratory summary is a detailed accounting of the number of apneas; the number and percent of each type of apnea: central, mixed, or obstructive; the number of hypopneas; and the number of RERAs. Presence of significant central apneas may indicate underlying heart failure, prior CVA, or medication effect. Also note the positional effect on the respiratory indices to determine if positional therapy may be helpful.

Arousal index—Arousals are abrupt changes of EEG frequency of 3 s or longer. These can be spontaneous, related to limb movements, or respiratory effort related. RERAs are included in the RDI, but not the AHI. A high number of spontaneous arousals may indicate an underlying medical problem such as fibromyalgia or pain. If the report does not include RERAs, the spontaneous arousals may include the respiratory arousals, and the RDI will not be reported. Studies that do not record and score arousals, including many home or portable studies, may not give a clear picture of the sleep disruption caused by SDB.

Graphic PSG data—This is a graphic representation of the data contained within the PSG report including the sleep hypnogram and graphs of the AHI, arousals, oximetry, heart rate, and body position. It is helpful in identifying associations within the study such as positional sleep apnea, REM-related events, and severely disrupted sleep.

An additional type of sleep test that determines the propensity to fall asleep during the day is an MSLT. It is recommended, with a PSG, for the diagnosis of narcolepsy or suspected idiopathic hypersomnia (76). It may also be useful in a patient with OSA who does not have resolution of EDS with adequate treatment of the OSA.

In 2007, the US Centers for Medicare and Medicaid Services (CMS) released a statement endorsing the use of certain types of portable monitoring for diagnosing OSA and initiating CPAP therapy (77). This has opened the door for the widespread use of home sleep testing or portable monitors in sleep diagnosis. This technology has the potential to provide cost savings in the diagnosis of OSA and to expedite diagnosis and treatment for patients. Portable monitoring devices generally measure airflow, oximetry, heart rate, and respiratory effort, but do not measure sleep. Some devices measure other parameters including peripheral arterial tone and pulse transit time as surrogate measures of arousals, respiratory effort, respiratory events, and sleep time. Since most portable devices do not measure sleep, the RDI reported in these devices is the number of apneas and hypopneas per hour of recording time.

A minimum of seven parameters are recorded in a PSG, and these studies require the onsite monitoring of the patient by a sleep technologist. These in-lab studies are classified as type I sleep studies. The level or type of a sleep study is determined by the number of physiologic parameters monitored (see Table 135.15).

Many patients can be successfully diagnosed with sleep apnea using portable monitoring devices. In some patients, this can be the preferred method of treatment due to issues of mobility, cognitive dysfunction away from the home environment, or safety (see Table 135.16).

There are certain medical conditions that limit the accuracy of these devices. In patients with comorbid medical conditions such as congestive heart failure, recent cerebrovascular accident (CVA), possible seizure disorder, and other sleep disorders, a PSG is recommended (78) (see Table 135.17).

TREATMENT OF SLEEP DISORDERS

Management of a patient with SDB requires a comprehensive long-term treatment plan and follow-up. Rarely does a patient have only one sleep disorder, so the entire sleep history should be considered when planning therapy. Even if the patient's SDB is successfully treated, if this patient is only sleeping 4 hours a night, the patient's chief complain of sleepiness will likely persist. Sleep hygiene issues, underlying insomnia or a circadian rhythm disorder, may require treatment to provide optimal therapy for the patient. Treatment of obesity, both with diet and lifestyle changes and with surgical intervention, has been shown to have a significant beneficial effect on OSA. A 10% loss in body weight can result in a 26% decrease in AHI (79).

OSA is a chronic disease that requires long-term follow-up. Even if symptoms are currently resolved, the patient should be made aware of the likelihood of progression of symptoms in the future and the factors that will hasten the return of these symptoms.

PAP therapy is the first line of treatment for most adult patients with SDB. Successful treatment with PAP is greatly enhanced by close support from the treating physician and staff and education for the patient about the therapy. PAP therapy is fully covered in Chapter 136. A large percentage of patients with SDB can be successfully treated with CPAP in the laboratory setting. Long-term compliance, however, is much more problematic. Adequate compliance is difficult to define and to achieve. Most studies show long-term usage by only about 50% to 65% of those patients who initially accept PAP therapy (80). Current CMS standards define successful use or adequate compliance as the use of PAP for longer than 4 hours for 70% of nights. Using this

TABLE 135.15 CLASSIFICATION OF SLEEP STUDIES

Type 1	≥7 physiologic parameters monitored and sleep technician in attendance
Type 2	≥7 physiologic parameters monitored, unattended
Type 3	4–7 physiologic parameters monitored, unattended
Type 4	≥3 physiologic parameters monitored, unattended

TABLE 135.16 INDICATIONS FOR THE USE OF PORTABLE MONITORING IN ADULTS—AASM GUIDELINES

Patients with a high pretest probability of moderate to severe OSA

Patients for whom in-laboratory PSG is not possible by virtue of immobility, safety, or critical illness

To monitor response to non-CPAP treatments for OSA including oral appliances, upper airway surgery, and weight loss

TABLE 135.17 CONTRAINDICATIONS FOR THE USE OF PORTABLE MONITORING

Patients with significant comorbid medical conditions (moderate to severe pulmonary disease, neuromuscular disease, congestive heart failure recent cerebrovascular accident, nocturnal hypoxemia requiring oxygen therapy)

Patients suspected to have other sleep disorders (CSA, periodic limb movement disorder, insomnia, parasomnias, circadian rhythm disorders, or narcolepsy)

General screening of asymptomatic populations

definition of compliance, a patient is adequately treated when wearing CPAP less than half of their sleep time.

Patients with a fixed, surgically correctable airway obstruction, such as marked tonsillar hypertrophy or large cervical osteophytes, may be candidates for primary treatment with surgery.

For patients intolerant of CPAP therapy, sleep surgery provides a viable secondary treatment option. Factors that influence surgical success include age, health, weight, tongue size, the presence of other areas of obstruction, and severity of OSA. Resolution of OSA is not the only appropriate goal of surgical therapy in a patient with OSA. Any intervention that improves CPAP compliance can have significant benefit to the patient. A procedure that relieves nasal obstruction or allows the patient to be adequately treated at a lower, more tolerable CPAP pressure may improve the patient's CPAP compliance. Similarly, resolution of nasal obstruction may allow an OSA patient to be adequately treated with an oral appliance.

Successful diagnosis and treatment of the patient with sleep disorders are best accomplished using a thorough systematic approach. Sleep disorders affect up to 30% of the population and are associated with significant sequelae including cardiovascular and endocrine disorders, exacerbation of depression and anxiety, heightened pain perception, impaired daytime functioning, and increased motor vehicle accidents. Often a multidisciplinary approach to these complex disorders will provide optimal patient outcomes.

HIGHLIGHTS

- Sleep disorders are prevalent in the population and are associated with significant physiologic consequences.
- Inadequate sleep or sleep deprivation can impair memory, learning, judgment, fine motor skills, and reaction time.
- SDB is associated with increased risk of cardiovascular events including MI and CVA, diabetes, obesity, neurocognitive deficits, motor vehicle accidents, and an increased risk of death from all causes.
- A complete history, including a focused review of systems, and physical examination are necessary to identify patients at risk for sleep disorders.
- Diagnosis of OSA is made with either an in-lab PSG or a home sleep test.
- First-line therapy for OSA is PAP therapy. Oral appliances can also provide adequate therapy for select patients with OSA.
- Surgery for OSA is reserved for patients with a specific correctable anatomic obstruction or those who have failed PAP therapy.

136 Medical Therapy for Obstructive Sleep Apnea

Ryan J. Soose *Patrick J. Strollo*

INTRODUCTION

Obstructive sleep apnea (OSA) is a chronic condition that will require management across the lifespan. Like most chronic diseases, *prevention* of OSA remains the primary goal and most attractive treatment from a public health perspective. At this juncture, *management* of the large population of patients diagnosed with sleep-related breathing disorders (as well as those who are still undiagnosed) remains the critical focus of most sleep physicians. As with hypertension (HTN), diabetes, and other chronic conditions, the individual treatment plan is not aimed at "cure" but rather (a) symptom and quality of life improvement and (b) reduction of cardiovascular and general health risk.

Both physician and patient understanding of OSA is the cornerstone for successful management. This approach allows for customization of each individual's treatment plan depending on their symptoms, airway anatomy, disease severity, and medical comorbidities. Across the lifespan, the same patient, with the same apnea hypopnea index (AHI), may benefit from different discrete treatment options, or a combination of treatment options, depending on the clinical context at that particular stage of life.

Positive airway pressure (PAP) therapy and oral appliances comprise the foundation of OSA medical management in the majority of patients. Nevertheless, there are many other management tools that can be employed to optimize clinical results, particularly when used in combination with PAP or oral appliance therapy. An individualized approach considering all available treatment options provides the most effective long-term management strategy for many patients.

POSITIVE AIRWAY PRESSURE

Introduction

The treatment of OSA with continuous positive airway pressure (CPAP) was first described by Sullivan et al. in 1981 (1). The introduction of CPAP marked an enormous advance in the management of OSA. The first commercially available PAP systems were marketed in the mid-1980s. CPAP rapidly became the mainstay of sleep apnea therapy and is still the most widely used treatment modality today.

In the Starling resistor model of the pathophysiology of OSA (Fig. 136.1), the collapsible segment of the tube (pharynx) is bound by an upstream and downstream segment with a corresponding upstream and downstream pressure (P_{us} and P_{ds}) (2).

Airway occlusion occurs when the surrounding tissue pressure, P_{out} (comprising tongue, pharyngeal muscles, parapharyngeal fat, mucosal edema, etc.), becomes greater than the intraluminal pressure (P_{in}).

The critical closing pressure (P_{crit}) is represented by the P_{in} when airway obstruction occurs. Inspiratory airflow depends directly on the difference between P_{us} and P_{crit}, and therefore, effective therapy for OSA requires widening the differential between P_{us} and P_{crit}. This goal can be accomplished in two ways: (a) increasing P_{us} or (b) reducing P_{crit}. PAP works by accomplishing the former with the application of increased pressure at the airway opening.

PAP systems for the treatment of sleep apnea consist of a generator that directs airflow downstream to the patient via tubing and an interface. Positive pressure is introduced into the upper airway providing a pneumatic splint through the entire length of the collapsible pharyngeal segment and thus maintaining airway patency and effective control of breathing. The splinting effect constitutes the primary mechanism of therapeutic action, although augmentation of lung volume may play a secondary beneficial role as well (3,4).

Modalities

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP), or fixed-pressure CPAP, was the first modality described and still the most widely used. This modality delivers the same

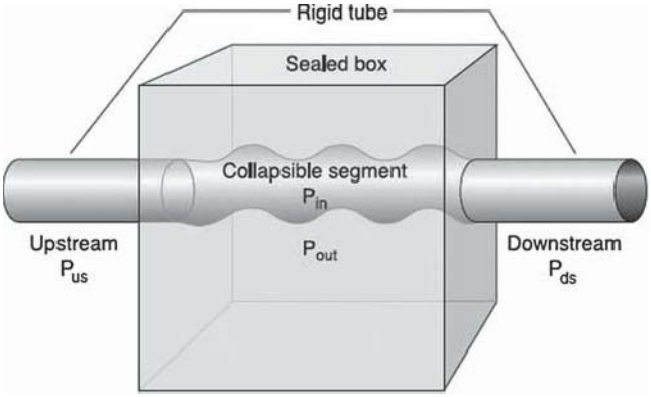

Figure 136.1 Pathophysiology of OSA: Starling resistor model of OSA depicting a collapsible tube (pharynx) with a corresponding intraluminal pressure (P_{in}) and surrounding tissue pressure (P_{out}). The upstream pressure (P_{us}) corresponds to the pressure at the nose or airway opening, and the downstream pressure corresponds (P_{ds}) to the tracheal or intrathoracic pressure. The critical closing pressure (P_{crit}) is represented by the P_{in} at which airway obstruction occurs and is directly dependent on the difference between P_{us} and P_{crit}. Successful management of OSA requires adequate increase in the P_{us} or reduction in the P_{crit}. (Reproduced from Dempsey JA, Veasey SC, Morgan BJ, et al. Pathophysiology of sleep apnea. *Physiol Rev* 2010;90:47–112, with permission.)

pressure to the patient during both inspiration and expiration and remains unchanged throughout the night.

Bilevel Positive Pressure

Bilevel positive pressure (BIPAP) provides the ability to independently adjust the inspiratory (IPAP) and expiratory (EPAP) pressure such that the pressure delivered during exhalation is lower than that delivered during inhalation (5). Several studies have confirmed the effectiveness of BIPAP in the treatment of OSA in adults (6–9).

Most BIPAP devices are used in one of two modes: spontaneous (S-mode) or spontaneous–timed (ST-mode). In S-mode, IPAP is delivered in response to a patient "trigger." In ST-mode, the patient may trigger the delivery of IPAP; in addition, the physician may set the device so that IPAP is delivered at prescribed intervals if a spontaneously triggered breath does not occur within that interval. This backup respiratory rate provided in the ST-mode is not commonly employed in the treatment of classic OSA but may be beneficial in selected patient groups with more complex sleep-disordered breathing, such as those with neuromuscular disorders, chest wall deformities, or congestive heart failure (CHF) with Cheyne-Stokes breathing.

Autotitrating Continuous Positive Airway Pressure

The pressure required to maintain airflow and control of breathing may vary throughout the night, as well as from night to night, and may be dependent on patient factors such as sleep staging, body position, and alcohol consumption. In autotitrating devices, the physician sets a prescribed pressure range, allowing the delivered pressure to vary throughout the night in order to meet the patient's changing pressure requirements in real time. Autotitrating devices employ computer algorithms to detect changes in airflow and adjust the delivered pressure accordingly. Autotitrating devices are available in both autotitrating continuous positive airway pressure (APAP) and autotitrating BIPAP (auto bilevel) forms.

One theoretical advantage of autotitrating technology is the reduction in the overall cumulative pressure exposure during the night and subsequent improvement in patient comfort and compliance. Compared to fixed CPAP, studies of APAP show similar effectiveness on both symptomatic and polysomnographic measures and a small (2 cm H_2O) average reduction in pressure. On an individual basis, some patients strongly prefer APAP over traditional fixed CPAP or BIPAP. The literature has not yet supported an improvement in adherence with autotitrating devices compared to fixed-pressure devices in CPAP naïve patients (10,11).

Methods of Titration

The traditional diagnostic and therapeutic evaluation of OSA involves two separate nights in the sleep laboratory. The first represents a full-montage attended overnight polysomnography for diagnostic purposes. If indicated, the patient then returns to the sleep lab a second night for a treatment study that again involves full-montage polysomnographic recording but in conjunction with manual PAP titration by the attendant sleep technician.

One method of improving cost-effectiveness and patient access is the consideration of a split-night study in certain clinical circumstances. A split-night study combines diagnostic polysomnography and a PAP titration in one night, rather than the traditional process of two separate nights (12,13). Proper clinical judgment in patient selection is essential, as inaccurate estimation of OSA severity and/or incomplete therapeutic titration may occur. Specific guidelines have been published by the American Academy of Sleep Medicine (AASM) for the use of split-night studies (14).

Alternatively, in-laboratory manual titration may be bypassed altogether with more recent developments in home portable monitoring and home auto-CPAP titration. Properly selected patients with a high pretest probability of OSA may undergo the initial diagnostic study at home with an unattended portable four-channel monitoring system. Additionally, the patient generally receives CPAP education and mask fitting in the clinical setting during the day. If the portable study is consistent with OSA and PAP therapy is indicated, the patient is then loaned an autotitrating device to use at home for a short period of time (e.g., 1 or 2 weeks).

The device is subsequently returned and the information downloaded with regard to effectiveness, usage, and mask leak. The patient can then receive a prescription for either fixed-pressure CPAP (usually set at the 90th percentile pressure) or an APAP as permanent therapy. At the

present time, home autotitration appears to be at least as effective as traditional methods with regard to both subjective and objective outcome measures as well as adherence rates (15). Additionally, it has the potential to be associated with improved cost-savings and increased resource availability across a population.

Interfaces

A variety of types of CPAP interfaces are widely available. The most common types fall under one of three categories: nasal masks, nasal pillows, and full-face masks (Fig. 136.2). Mask selection and sizing is generally accomplished by the sleep technician addressing the patient's comfort, concerns, and facial anatomy. Proper mask fitting, patient education, and close clinical monitoring and follow-up are essential to successful long-term management.

In one randomized crossover study comparing nasal pillows and a nasal mask, investigators reported that nasal pillows were associated with less frequent adverse effects, less air leak, and less insomnia symptoms, although adherence and functional outcome measures did not differ between the groups (16).

Effectiveness

With adequate pressure application and proper usage/adherence, PAP therapy often provides effective control of sleep-disordered breathing and subsequently accomplishes the main goals of symptom/quality of life improvement and reduction of cardiovascular and general health risks.

Symptom and Quality of Life Improvement

CPAP has been shown to improve both subjective and objective measures of OSA. On polysomnography, proper CPAP titration is associated with improved sleep continuity and architecture. During the first night of treatment, some patients may manifest an unusually large percentage of rapid eye movement (REM) sleep ("REM rebound") as a result of sudden reversal of the airway obstruction and associated chronic sleep deprivation. CPAP often has a beneficial impact on other nocturnal aspects of OSA, including treatment of snoring, decreased nocturnal awakenings, and a reduction in nocturia (17–22).

In studies of patients with OSA and hypersomnia, treatment of CPAP is associated with a reduction in daytime sleepiness and improvement in neurocognitive function and quality of life measures (23,24). The effect of CPAP on objective metrics of sleep propensity during the day (e.g., multiple sleep latency test [MSLT] or maintenance of wakefulness test) is less clear, with only some studies showing an effect and a less compelling impact in patients with mild OSA (17,23,25). Nevertheless, despite some controversy with regard to the sleep laboratory results, the data on motor vehicle collisions, one of the most important public health risks associated with OSA, are much more convincing. A number of studies employing driving simulators have demonstrated improved performance

Figure 136.2 PAP interfaces: Examples of the three most common categories of mask interfaces for positive pressure therapy are depicted: (**A**) nasal pillows, (**B**) nasal mask, and (**C**) full-face mask.

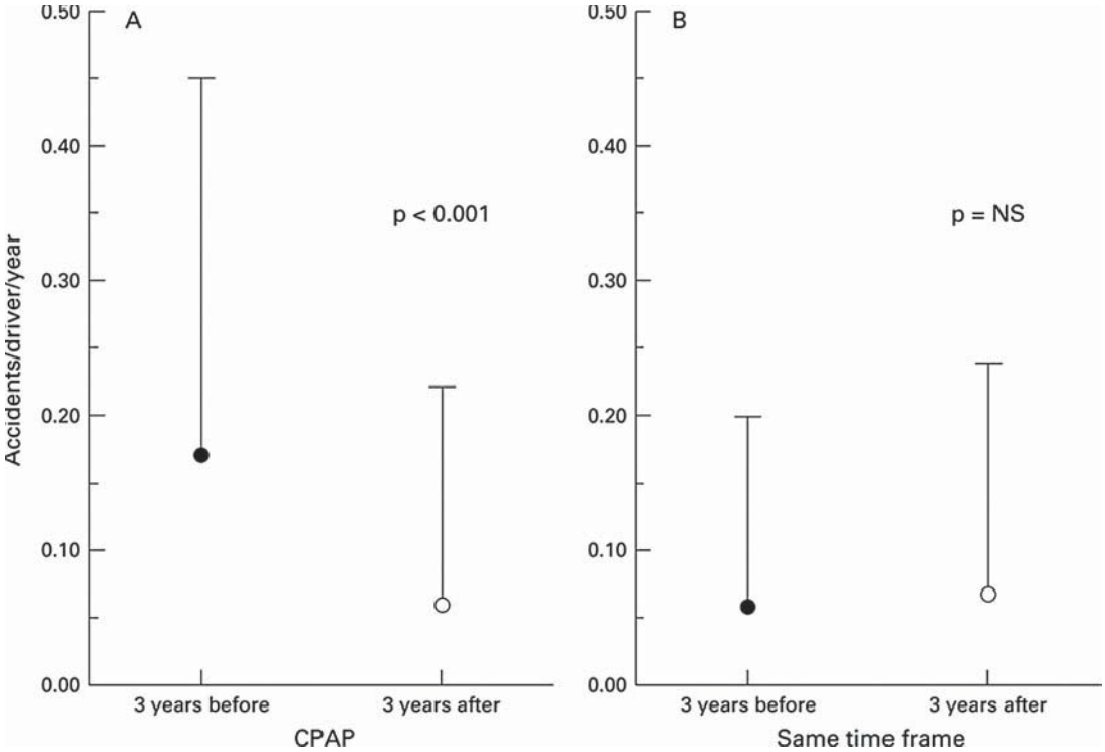

Figure 136.3 Reduction in motor vehicle collisions in patients OSA treated with CPAP: Mean motor vehicle collision rate in OSA patients during the 3-year period before CPAP treatment and the 3-year period with CPAP treatment (**A**). Mean motor vehicle collision rates in control subjects during the same time periods (**B**). (Reproduced from George CFP. Reduction in motor vehicle collisions following treatment of sleep apnea with nasal CPAP. *Thorax* 2001;56:508–512, with permission.)

following initiation of CPAP therapy (26–28). Similarly, a comparison of the number of accidents per driver per year over the 3 years before and following CPAP therapy in OSA patients demonstrated a notable reduction, reaching levels that were comparable to those in individuals without OSA (Fig. 136.3) (29).

Reduction of Cardiovascular and General Health Risks

Numerous studies have shown that OSA is associated with cardiovascular disease and that successful PAP therapy results in reduced cardiovascular mortality (30–32). In a prospective cohort from the Sleep Heart Health Study, investigators showed that sleep-disordered breathing is associated with increased overall mortality as well as mortality specifically due to coronary artery disease, particularly in those patients with severe OSA (AHI greater than 30) (Fig. 136.4) (31). A large observational study showed that men with severe OSA have an increased rate of both fatal and nonfatal cardiovascular events (32). Furthermore, treatment with PAP effectively lowered this cardiovascular risk (Fig. 136.5). Finally, Peker et al. (33) assessed incident cardiovascular events in middle-aged men with OSA over 7 years and noted that the incidence of cardiovascular events in patients who were adequately treated (by PAP, uvulopalatopharyngoplasty, or oral appliances) was about 7% in contrast to about 57% in patients who were inadequately treated.

Cardiac rhythm disturbances are common in OSA patients, and the favorable response of arrhythmias to CPAP therapy, especially in the absence of structural heart disease, reinforces the linkage between OSA and rhythm

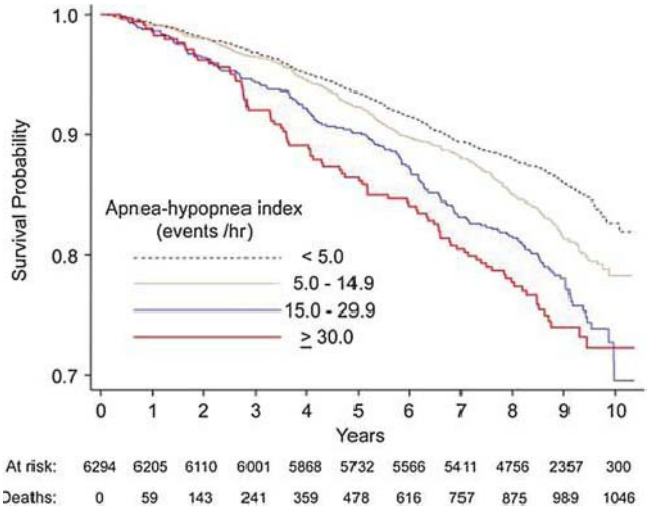

Figure 136.4 OSA severity and cardiovascular mortality: Prospective cohort analysis from the Sleep Heart Health Study showing that increased severity of OSA, based on AHI criteria, is associated with increased mortality from cardiovascular disease. (Reproduced from Punjabi NM, Caffo BS, Goodwin JL, et al. Sleep-disordered breathing and mortality: a prospective cohort study. *PLoS Med* 2009;6(8):e1000132, with permission.)

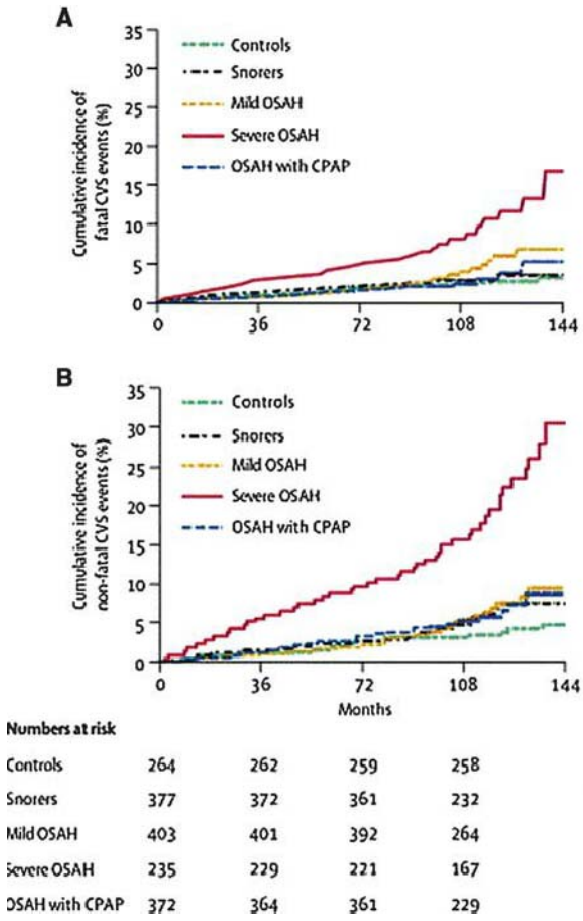

Figure 136.5 The effect of CPAP treatment on cardiovascular mortality in OSA patients: The risk of fatal (**A**) and nonfatal (**B**) cardiovascular event is increased in men with severe OSA, and that risk is significantly lowered with treatment of the OSA with positive pressure therapy. (Reproduced from Marin JM, Carrizo SJ, Vincente E, et al. Long-term cardiovascular outcomes in men with obstructive sleep apnea–hypopnea with or without treatment with continuous positive airway pressure: an observational study. *Lancet* 2005;365:1046–1053, with permission.)

disturbances (34–39). A recent randomized controlled trial reported that, after 1 month, CPAP therapy reduces the frequency of premature ventricular beats by nearly 60% in OSA patients with heart failure compared to patients who are not receiving CPAP, in whom there was no significant change (39).

Studies also support the improvement in left ventricular function after initiation of PAP therapy for patients with OSA and heart failure (40). The mechanisms by which PAP may improve cardiac function in OSA patients with heart failure include relief of sleep-related hypoxemia, elimination of cyclic increases in left ventricular afterload, reduction in sympathetic nervous system activation, and reduced inflammation.

Epidemiologic studies have provided compelling evidence that OSA is associated with increased risk for systemic HTN (41–46). Sleep apnea has been identified by the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure as a risk factor for HTN (47). Although it is plausible that PAP therapy would ameliorate diurnal HTN by eliminating intermittent hypoxic exposure and sympathetic nervous system activation and improving sleep continuity, the literature provides conflicting data in this regard (48–51).

Using a randomized, placebo-controlled design to compare ambulatory blood pressure on CPAP and sham CPAP in subjectively sleepy OSA patients, Pepperell et al. (52) observed a small but significantly greater reduction in mean blood pressure during sleep in the active CPAP-treated group. Although small, the reduction in blood pressure in the active CPAP group would have a notable public health impact on cardiovascular risk. Conversely, there are a number of well-designed studies of groups of OSA patients either with or without subjective sleepiness, and with HTN, that have failed to demonstrate a significant reduction in blood pressure with PAP therapy (53–55). In summary, it is evident that further research is required to define the effect of PAP on HTN in OSA patients.

The association between sleep-disordered breathing, including OSA, and increased risk for stroke is increasingly recognized. Data from the Wisconsin Sleep Cohort indicate that, even after adjusting for age, gender, smoking, HTN, alcohol use, and body mass index (BMI), sleep-disordered breathing is associated with increased risk for prevalent stroke (56). Further, there is increasing awareness of the association between OSA, abnormal glycemic control, type 2 diabetes mellitus, and other features of the metabolic syndrome (57). Further studies are required to determine if PAP therapy of OSA reduces risk for incident stroke and improves insulin sensitivity and glycemic control.

Adherence

Despite its documented effectiveness in improving symptoms and quality of life and reduction of cardiovascular risk, acceptance of and adherence to PAP therapy remains one of the greatest challenges in treatment. In studies using at least 4 hours of average usage per night to define adherence, a wide range of 29% to 83% of patients were considered nonadherent (58). The minimal and optimal durations of usage that confer benefit are unknown and likely vary depending on the individual patient as well as the outcome measure being evaluated. It does appear that increasing duration of use is associated with increasing levels of improvement (Fig. 136.6). At least 6 hours of use per night appears to be associated with greater cardiovascular mortality risk reduction compared with fewer hours of use per night (30).

Data card monitoring, with the use of smart cards or web-based technology, has revolutionized the assessment of PAP adherence. The data card provides information over a

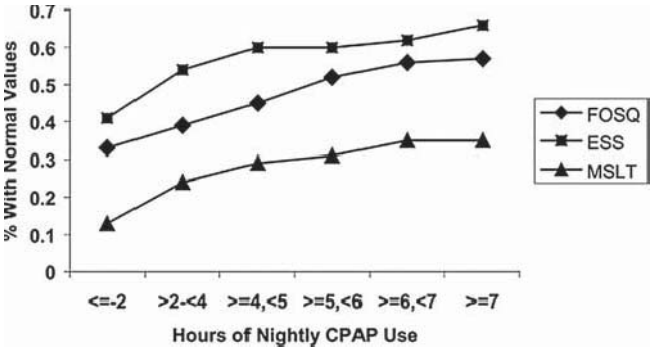

Figure 136.6 CPAP usage and dose–response of outcome measures: Cumulative proportion of participants obtaining normal threshold values on the Epworth Sleepiness Scale (ESS), MSLT, and Functional Outcomes of Sleep Questionnaire (FOSQ). (Reproduced from Weaver TE, Maislin G, Dinges DF, et al. Relationship between hours of CPAP use and achieving normal levels of sleepiness and daily functioning. *Sleep* 2007;30(6):711–719, with permission.)

selected period of time on multiple data points, including days used, hours of use per night, amount of mask leak, and a surrogate estimate of the residual AHI. Use of this technology to improve monitoring of adherence and effectiveness has the potential to dramatically improve long-term patient care. Any physician involved in the medical management of OSA should consider it part of the routine clinical practice.

Objective adherence monitoring has made it apparent that patterns of adherence, or nonadherence, are established early. CPAP use in the first week after initiating therapy often predicts long-term success or failure (59). Information regarding the degree to which a patient is adherent to PAP is essential for assessment of a suboptimal clinical response. If a patient's symptoms are inadequately resolved after the initiation of PAP treatment, possible reasons other than poor adherence include insufficient pressure delivery, mask leak, or a failure to recognize and treat a coexisting medical or sleep disorder that is also contributing to the patient's symptoms.

Since an individual's acceptance and adherence to PAP may be established shortly after initiating therapy, it stands to reason that close monitoring, education, and support during this period would be helpful. Studies have demonstrated improved adherence in conjunction with educational materials, available and knowledgeable staff, and patient support groups (60,61). Patient and family member understanding of the disease process itself, the associated functional and health implications, and the reasons and options for treatment likely contribute to more successful results.

There is increasing evidence that upper airway surgery may provide a useful adjunct to improve CPAP compliance and response to therapy. Unlike past concerns that associated traditional uvulopalatopharyngoplasty techniques result in mouth leak during CPAP use, newer, less morbid, and more effective reconstructive (rather than destructive) procedures may improve medical therapy results by lowering the critical closing pressure and reducing CPAP pressure requirements (62,63).

Side Effects and Complications

Initiation of positive pressure therapy is often associated with side effects that can impede successful management. The side effects are frequently minor and/or transient and may improve with continued use and adaptation. Others are more significant and troublesome and may negatively affect adherence and even result in discontinuation of therapy. Psychological factors, such as claustrophobia or the perceived lifestyle change associated with indefinite nightly use of a device, are common and often challenging to address (64,65). Table 136.1 provides a more comprehensive list of reported adverse events with CPAP use as well as some of the management strategies that can be employed to overcome these obstacles.

The most common adverse effects of CPAP therapy include mask leaks, rhinitis, and premature removal of the mask (66). Mask interface and proper fitting is one of the most important factors affecting adherence, and there are some data to support the potential for less side effects and improved adherence with use of a nasal pillows interface (16). Symptoms of chronic rhinitis and nasal obstruction commonly emerge or worsen with CPAP use. Empiric use of heated humidification and topical nasal steroids may be beneficial in some patients although the current literature shows variable results (67–72). A more thorough otolaryngologic approach, including endoscopic evaluation for both structural and inflammatory nasal pathology, should identify specific therapeutic targets. Surgical therapy for symptomatic structural nasal obstruction has the potential to dramatically improve PAP acceptance and adherence (73,74).

More significant morbidity and adverse health effects associated with positive pressure therapy use are *uncommon*; however, recent reports suggest some CPAP users are at risk for adverse craniofacial and ophthalmologic changes. Tsuda et al. (75) assessed craniofacial measurements in OSA patients after 2 years of CPAP therapy compared to baseline. After 2 years of CPAP, the subjects were found to have significant changes in craniofacial structure, including both maxillary and mandibular retrusion and maxillary incisor retroclination. Kiekens et al. (76) compared intraocular pressure (IOP) measurements in OSA patients before and 1 month after initiation of CPAP. The authors found a significant increase in IOP and a reduction in ocular perfusion pressure with CPAP therapy, particularly at night while CPAP was in use. As a result, they recommend routine vision screening and optic disk evaluation in patients on positive pressure.

ORAL APPLIANCES

Introduction

Oral appliances have been used for the management of snoring and OSA for last three decades, and they remain an underutilized tool in many patient populations, perhaps

TABLE 136.1 MEDICAL THERAPY FOR OBSTRUCTIVE SLEEP APNEA

Side Effects	Management Strategies
Pressure or airflow related	
Difficulty exhaling	Pressure ramp
Difficulty initiating/maintaining sleep	Mask refit
Aerophagia	Reduce expiratory pressure with bilevel therapy
Sinus or ear discomfort	
Chest wall discomfort	Reduce required pressure with adjunctive techniques (oral appliance, surgery, weight loss, positional therapy)
Device or interface related	
Nasal congestion	Mask refit
Rhinorrhea	Heated humidification
Dryness of the upper airway	Topical nasal treatments for chronic rhinitis
Epistaxis	Surgical nasal procedures to lower nasal resistance
Skin abrasion or rash of the nose/face	
Conjunctivitis from air leak	Protective skin covering
Machine noise	Longer tubing to move further from bedside
Psychological reasons	
Claustrophobia	Desensitization techniques
Cumbersomeness	Education for both patient and spouse
Travel inconvenience	Patient support group
Spousal intolerance	

due to simply a lack of familiarity of this treatment modality by the pulmonologists, neurologists, otolaryngologists, and even dentists who see patients with sleep-disordered breathing. The most commonly used appliances today fall under the general category of mandibular repositioning appliances (MRAs), also known as mandibular advancement devices (MADs). In 2006, an extensive review of the literature and practice parameters for the use of oral appliances in sleep-disordered breathing was published through the American Academy of Sleep Medicine (77,78).

Current AASM practice parameters recommend routine clinical use of oral appliances in patients with (a) primary snoring who do not respond to or are not appropriate candidates for treatment with weight loss or positional therapy or (b) mild–moderate OSA who prefer oral appliances to CPAP, are not appropriate candidates for CPAP, or do not respond to CPAP or other conservative measures. Additional data suggest that oral appliances can play a beneficial role in selected patients with severe OSA who fail or do not tolerate CPAP. A recent prospective study of patients with severe OSA and CPAP refusal showed significant improvement in objective sleep study measures as well as HTN with oral appliance as sole therapy (79). Further, in some patients with moderate–severe OSA, although data are limited, oral appliances can be combined with positive pressure or surgical therapy.

Types

Mandibular Repositioning Appliance

Also known as a MAD, it is by far the most commonly used type of oral appliance used today for sleep-disordered breathing. The MRA or MAD comes in two basic forms: a nontitratable type and a titratable type. The Thornton Adjustable Positioner (TAP) is a commonly used example of a titratable device. The TAP is composed of both a maxillary and a mandibular arch with a base and hook assembly and an internal adjustment mechanism (Fig. 136.7A).

Tongue Retaining Device

The tongue retaining device (TRD) holds the tongue forward in a suction bulb mechanism. Today, TRD's are used far less often than MRA's but may be a viable option in edentulous patients (Fig. 136.7B).

Thermoplastic Splints

Boil-and-bite appliances consist of one-piece prefabricated thermoplastic splints. They are significantly less expensive than custom-made devices and often can be ordered online and fitted directly by the patient. These cost-savings, however, must be cautiously weighed against the documented inferior efficacy, increased side effects, and lack of proper follow-up and dental monitoring compared to a custom-made MAD employed by a trained expert. A randomized, controlled, crossover trial concluded that a custom-made MAD results

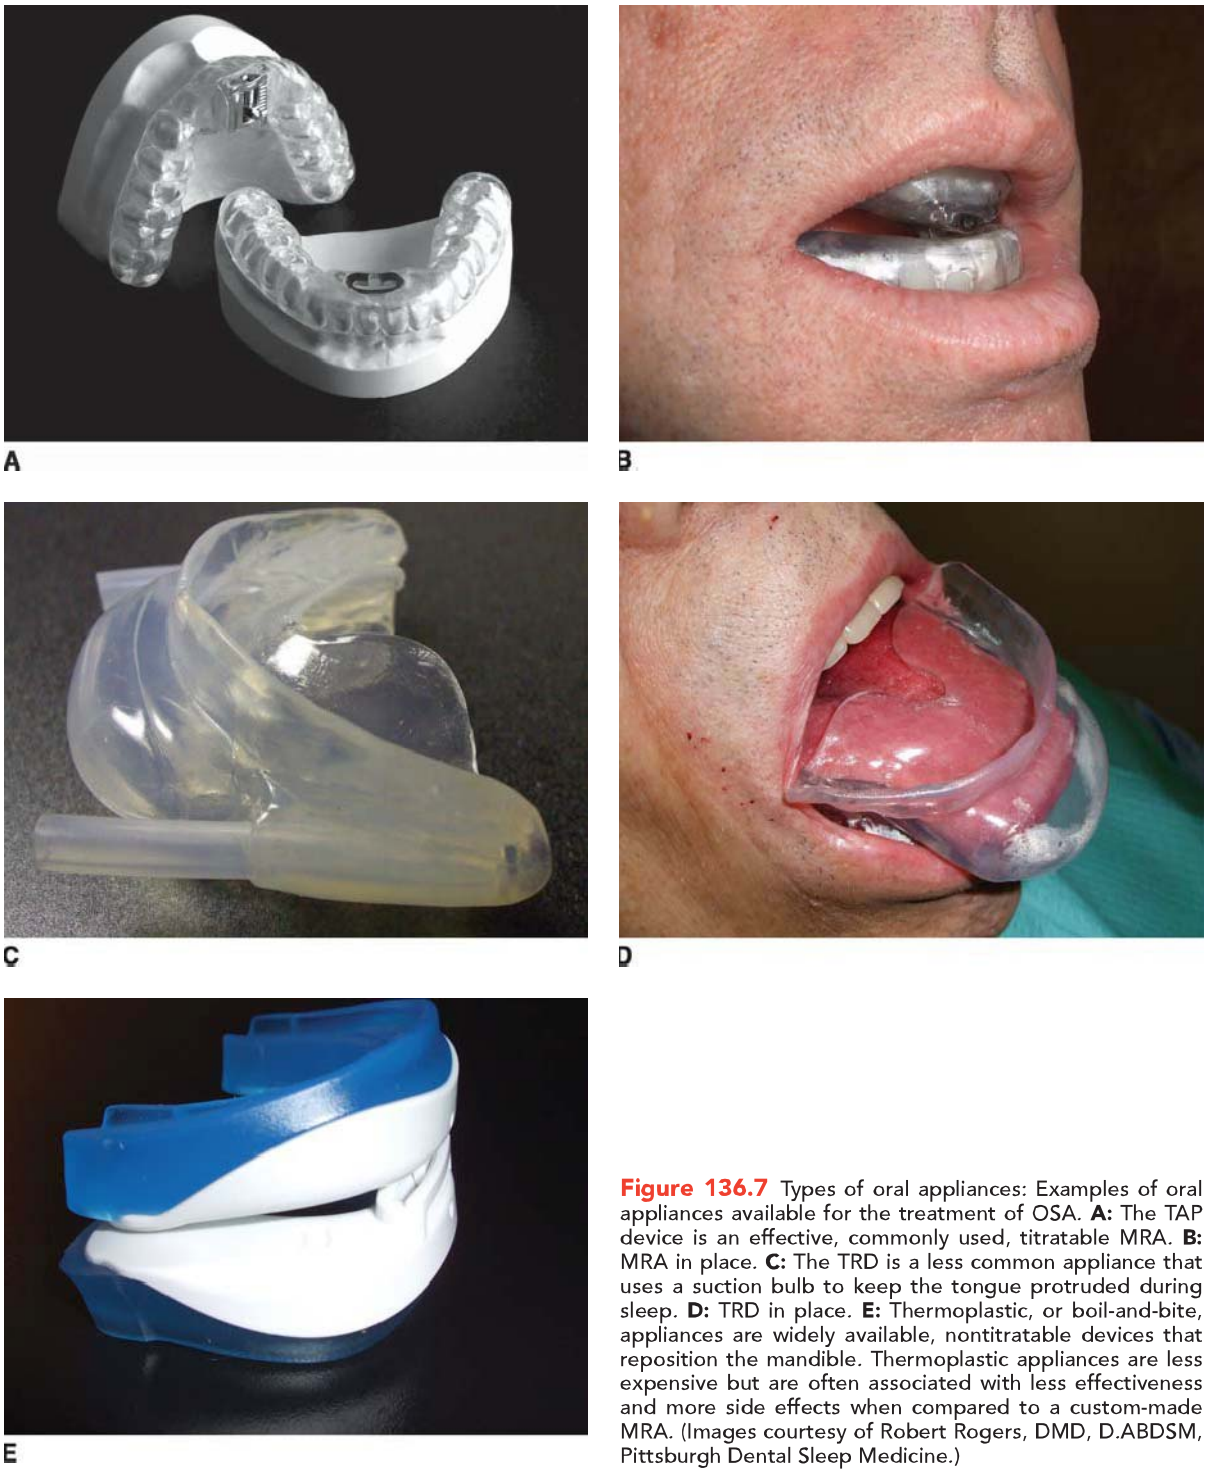

Figure 136.7 Types of oral appliances: Examples of oral appliances available for the treatment of OSA. **A:** The TAP device is an effective, commonly used, titratable MRA. **B:** MRA in place. **C:** The TRD is a less common appliance that uses a suction bulb to keep the tongue protruded during sleep. **D:** TRD in place. **E:** Thermoplastic, or boil-and-bite, appliances are widely available, nontitratable devices that reposition the mandible. Thermoplastic appliances are less expensive but are often associated with less effectiveness and more side effects when compared to a custom-made MRA. (Images courtesy of Robert Rogers, DMD, D.ABDSM, Pittsburgh Dental Sleep Medicine.)

in improved mandibular advancement, increased efficacy, and less side effects and noncompliance compared to boil-and-bite thermoplastic appliances (80) (Fig. 136.7C).

Effectiveness

In general, the mechanism of action of oral appliances, as with most successful treatments for OSA, involves enlarging the upper airway and/or reducing upper airway collapsibility (i.e., making the critical closing pressure more negative). Specifically, MRAs protrude and stabilize the mandible during sleep. MRAs have been shown to improve airway size at the level of both the palate and tongue base, including enlargement of the lateral dimension (Fig. 136.8) (81,82). Oral appliances may be used as sole therapy in some patients or in conjunction with other forms of OSA therapy including surgery, weight loss, and positive pressure.

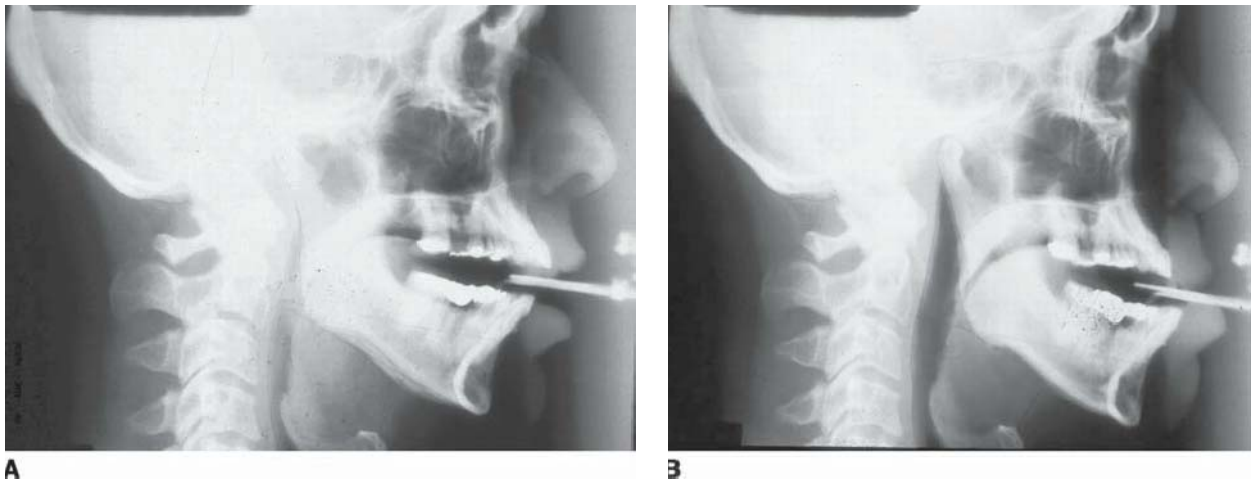

Figure 136.8 Effect of oral appliances on the airway: Lateral cephalometric radiograph in a patient with OSA, before (**A**) and after (**B**) application of a MAD. Note the enlargement of the pharyngeal airway with the oral appliance at both the retrolingual and retropalatal portions of the airway. (Images courtesy of Robert Rogers, DMD, D.ABDSM, Pittsburgh Dental Sleep Medicine.)

In the 2006 AASM-directed review of the literature on oral appliances, the overall effectiveness for controlling OSA based on polysomnographic criteria (defined as AHI less than 10) was 52%. This figure must be interpreted with caution, as the data reviewed as a whole represent a very heterogeneous group of patients, types of devices, titration protocols, treatment outcomes, and clinician expertise. When only the randomized, crossover, placebo-controlled studies were analyzed (five studies), the combined rate of "success" (treatment AHI less than 10) and "response" (AHI reduction of 50%) was 64% (83–88). Studies also report subjective improvement in snoring and daytime sleepiness, as well as nocturnal oxygenation, arousal index, and objective measures of sleepiness (i.e., MSLT). It must be kept in mind that these data are heterogeneous and conflicting and require further evaluation. Finally, there are three studies evaluating the effect of oral appliance therapy on HTN, and they each report a statistically significant reduction in blood pressure measurements (87,89,90).

Greater success rates may be achieved with proper patient selection and phenotyping of the individual patient anatomy and pathophysiology. At this juncture, the patient characteristics associated with more successful oral appliance therapy have not been readily established. For example, there is substantial evidence that a greater likelihood of success was achieved in patients with positional OSA (OSA primarily occurring in the supine position), although not all studies support this finding (91–93). Other studies suggest lower rates of effectiveness with increasing BMI and increasing severity of the AHI. Currently, custom-made oral appliances are reimbursed by Medicare as first-line therapy for mild OSA (AHI 5 to 14) with symptoms and moderate OSA (AHI 15 to 29) regardless of symptoms, as well as for severe OSA (AHI ≥ 30) if intolerant to PAP.

Drug-induced sleep endoscopy (DISE) represents one tool with promising potential to improve patient outcomes with oral appliance. Three recent reports used DISE to determine the likelihood of success with oral appliance therapy (94–96). The authors concluded that sleep endoscopy, with concomitant mandibular advancement to mimic treatment effect, could be a valuable prognostic indicator for successful management of both snoring and OSA. To ensure satisfactory benefit from oral appliance therapy, all patients with clinically significant sleep-disordered breathing should return for follow-up visits with a qualified sleep specialist to evaluate for symptom improvement. They should also undergo a follow-up sleep study evaluation with the oral appliance in place to assess adequate management of objective measures such as AHI and oxygen saturations (78).

Adherence

As with any device-related treatment for sleep-disordered breathing, successful management is critically dependent on usage. Assessment of adherence in the literature is complicated by heterogeneity of the types of devices and titration protocols used, patient characteristics and disease severity, and the level of clinical care and provider expertise. Further complicating matters is that the amount of usage required for improvement in subjective and objective outcome measures is unknown and likely varies between individuals. Finally, although oral appliance adherence data have relied primarily on patient self-reporting in the past, clinical trials are underway utilizing objective monitors to quantify use.

One-year subjective adherence rates range from 25% to 100%, with a median use of 77% of nights during the first year. Adherence rates tend to decrease with duration of use

past 1 year (97,98). Hoffstein combined adherence reports from 21 studies evaluating over 3,000 patients and found an overall average adherence of 56% to 68% at an average of 33 months follow-up (83). In crossover studies comparing CPAP and oral appliances, adherence rates were similar between the two devices (99,100).

Side Effects and Complications

A substantial portion of nonadherent patients may discontinue oral appliance use as a result of any number of side effects or adverse events. Many of side effects are minor and do not significantly affect long-term use or morbidity. Other complications such as bite changes, malocclusion, and temporomandibular joint (TMJ) dysfunction may be permanent. This supports the notion that oral appliances should be fitted, titrated, and managed by a clinician with training and expertise in both dental care and sleep-related breathing disorders.

Commonly reported minor side effects include TMJ pain, headache or facial pain, tooth pain, excessive salivation, dry mouth, gum irritation, and morning-after occlusal changes (83). There is a wide range of reported minor side effects from 6% to 86% although many of these side effects are reported to be transient and occur with initiation of treatment (77). Most authors report frequent improvement in these side effects with regular use and occasional adjustment of the device. More severe and persistent adverse sequelae include more significant TMJ dysfunction, tooth movement, and changes in occlusion and often lead to device discontinuation. The pathophysiology of and risk factors for these more severe complications are not yet fully understood but are likely multifactorial.

OTHER FORMS OF MEDICAL THERAPY

PAP therapy, oral appliances, and surgery are considered the mainstays of directed sleep apnea therapy for OSA, but a variety of other medical options may be appropriate in properly selected patients, either as a primary management strategy or as a useful adjunct to other primary modalities. Successful management of patients with OSA requires a comprehensive sleep history, general medical evaluation, and physical examination. A number of medical conditions, medications/drugs, and lifestyle practices can place persons at increased risk for OSA or worsen existing OSA. Conversely, modification of these factors can favorably affect risk and improve treatment outcomes.

TREATMENT OF NASAL OBSTRUCTION

A number of large population-based studies have analyzed the association of nasal obstruction and subjective sleep measures, snoring, and sleep apnea. In the Wisconsin cohort of almost 5,000 patients, patients with chronic rhinitis symptoms were more likely to report habitual snoring, nonrestorative sleep, and daytime sleepiness (101). Patients with nasal congestion due to allergy were 1.8 times more likely to have moderate–severe OSA compared to allergy patients without nasal congestion. Other epidemiologic studies have confirmed that, across large populations, nasal obstruction is an independent risk factor for both snoring and OSA (102–104).

Much of the research into medical therapy for allergic rhinitis and sleep-disordered breathing has focused on the role of nasal steroids. In a group of allergic rhinitis patients with subjective nasal congestion and sleep disturbance, Craig et al. (105) demonstrated that topical nasal steroid therapy improved subjective sleep quality and daytime function. Pediatric patients with symptomatic nasal obstruction and OSA have also been shown to respond favorably to nasal steroid therapy. Brouillette et al. (106) reported a reduction in the AHI from 10.7 to 5.8 with fluticasone nasal spray in a selected group of pediatric patients. Nevertheless, long-term adherence to nasal steroids may be suboptimal and difficult to monitor, particularly in pediatric patients with parental concerns about side effects.

Nakata et al. (107) recently demonstrated that nasal surgery, in the setting of nasal obstruction and sleep apnea, improves nasal resistance, sleep architecture, and daytime sleepiness. In these patients, the observed improvement in the mean Epworth Sleepiness Scale (ESS) from 10.6 to 4.5 with nasal surgery is comparable to the improvement obtained with other forms of OSA therapy, including positive pressure. Untreated nasal obstruction may explain, at least in part, the persistent hypersomnia seen in some OSA patients with adequate CPAP adherence and objective control of the AHI. In a prospective longitudinal cohort study of patients with nasal obstruction and OSA, surgical treatment of nasal obstruction also significantly improved both disease-specific and general health (SF-36) quality of life measures (108).

Finally, treatment of nasal obstruction in OSA patients can significantly improve adherence and effectiveness of both CPAP and oral appliance therapy. Mounting evidence suggests that increased nasal resistance negatively impacts success rates and tolerance of medical therapy devices for OSA, which critically depend on regular usage to be effective. In a recent study comparing oral appliance responders and nonresponders, increased nasal resistance, particularly in the supine position, was associated with poorer treatment outcomes (109). With logistic regression analysis, Suguira et al. (73) concluded that increased nasal resistance was one of only two factors associated with nonacceptance of CPAP. Further, in patients with poor CPAP adherence and nasal obstruction, lowering nasal resistance with surgical therapy has been shown to lower average CPAP pressures and improve subsequent adherence (74).

WEIGHT LOSS

The adverse effect of obesity on the pathophysiology of OSA may be mediated through a variety of mechanisms. Histopathologic analysis of the tongue has revealed that obesity is associated with increased lingual fat deposition and increased size and weight of the tongue (110). Imaging studies have confirmed the presence of increased parapharyngeal fat in OSA patients (111). Using three-dimensional volumetric analysis MRI techniques, Welch et al. (112) showed that weight loss was associated with a significant reduction in the size of the parapharyngeal fat pads and an increase in the volume of the upper airway. In a pig animal model, enlargement of the parapharyngeal fat pad has been demonstrated to increase upper airway resistance (113). Cervical obesity may also play a pathophysiologic role via mass loading of the anterior neck and subsequent transmission of pressure changes to the airway lumen. Increased neck circumference is a well-established clinical predictor of OSA and may correlate with this hypothesis. Furthermore, velopharyngeal collapsibility appears to increase directly with increasing neck circumference in OSA patients (114). Finally, to the extent that upper airway patency is increased by greater lung volume, greater truncal obesity may contribute to OSA through a thoracic mechanism of decreasing lung volume and hypoventilation.

Numerous studies over the past three decades support the positive effect of weight loss on the treatment of OSA; however, the specific relationship between the two and the response rate may vary considerably from one patient to another. Peppard et al. (115) demonstrated that a 10% weight loss predicted a 26% reduction in the AHI (Fig. 136.9). In a randomized trial of weight loss in patients with mild OSA, those patients with more successful weight reduction achieved a more significant reduction in the AHI, compared to control subjects (116). Based on these results, the authors concluded that, in patients with mild OSA, weight loss and lifestyle intervention may be considered first-line therapy, rather than positive pressure.

The Sleep AHEAD study is a recent multicenter randomized controlled trial evaluating the effect of weight loss on sleep apnea outcomes in a population of obese type 2 diabetes mellitus patients (117). Patients were randomized either to a behavioral weight loss program (intensive lifestyle intervention) or to a control diabetes support program. The patients in the behavioral weight loss program lost significantly more weight and in turn had significant reduction in AHI.

Some patients with successful weight loss may not achieve noticeable improvement in subjective or objective measures of OSA severity, particularly because there is not a linear relationship between weight loss and AHI reduction. These nonresponders may have other predisposing risk factors for persistent OSA including genetics, craniofacial or soft tissue anatomical abnormalities, neuromuscular weakness, or other cardiopulmonary loss of ventilatory control. Nevertheless, a multimodality approach to weight reduction may optimize clinical results, taking into consideration dietary and lifestyle modifications, cognitive–behavioral therapy, as well as pharmacologic and surgical options (118).

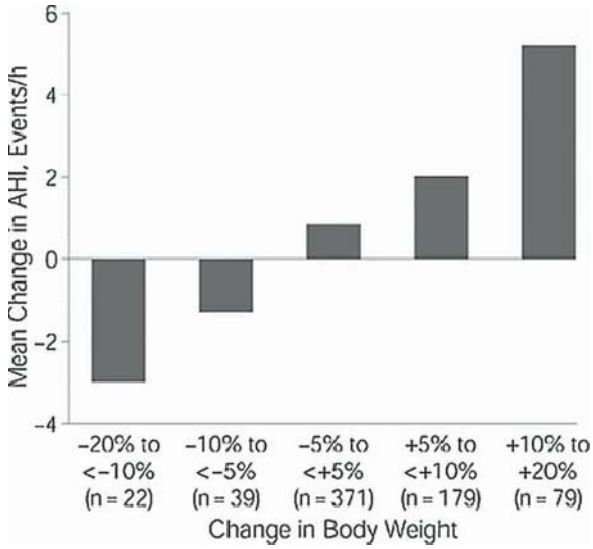

Figure 136.9 Relationship between weight change and AHI: In the Wisconsin Sleep Cohort Study, weight change across a large population was associated with change in AHI. A 10% weight gain correlated with a 32% increase in the mean AHI as well as a six-fold increased risk of developing moderate–severe OSA. A 10% weight loss was associated with a 26% decrease in the mean AHI. (Reproduced from Peppard PE, Young T, Palta M, et al. Longitudinal study of moderate weight change and sleep-disordered breathing. *JAMA* 2000;284:3015–3021, with permission.)

For patients with severe obesity, bariatric surgery may provide more substantial and more rapid control of obesity-related medical problems, including OSA (119). One study, with longer follow-up data on bariatric surgery patients with OSA, reported a 75% reduction in the respiratory disturbance index (120).

POSITIONAL THERAPY

For some patients, the frequency of obstructive respiratory events is substantially greater in the supine position compared to the lateral or prone position. Increased probability of upper airway narrowing in the supine position is hypothesized to occur via a gravity effect that results in retrodisplacement of the tongue, soft palate, and mandible. A comprehensive sleep history should include questioning of the patient and bed partner regarding the effect of body position on snoring and subjective measures. Likewise, polysomnography interpretation should comment on the presence or absence of any significant positional dependence to the patient's AHI, oxygen saturations, and overall control of sleep-disordered breathing.

For select patients with clinically significant OSA in the supine position and essentially no significant sleep-disordered breathing in the lateral recumbent position, a

number of conservative therapeutic options may obviate the need for positive pressure. The tennis ball or similar technique of placing objects in a sock that is subsequently pinned to the back of the patient's nightshirt has been recommend over the years. Newer, more user-friendly devices are now on the market to facilitate maintenance of the lateral sleeping position. One example, the Zzoma Positional Sleeper, consists of a Velcro elastic belt with a foam wedges across the lower back that prevent the patient from rolling over to the supine position. In a randomized crossover study of patients with strictly positional OSA, this device was shown to be as effective as CPAP at controlling the AHI and oxygen saturations (121). Finally, MADs may be an appropriate first-line treatment option in patients with positional OSA. Recent evidence suggests that oral appliances provide more effective control of the AHI in positional, compared to nonpositional, OSA patients (122).

Head of bed elevation, or postural therapy, is another positional method of reducing upper airway collapsibility in OSA patients. Critical closing pressure has been shown to be more negative, signifying greater upper airway stability, with 30 degrees of head of bed elevation compared to the supine position (123). Head elevation of 30 degrees may also lower the CPAP pressure requirements necessary to maintain control of breathing. Nevertheless, the ability of postural therapy alone to adequately manage OSA remains limited and highly variable from patient to patient (124).

OXYGEN THERAPY

In addition to sleep fragmentation and chronic sleep deprivation, many of the cardiopulmonary, metabolic, and neurocognitive sequelae of OSA are attributable to nocturnal intermittent hypoxemia. The current data suggest that supplemental oxygen during sleep is inadequate as a standalone treatment to effectively reduce apnea frequency and increase daytime alertness. There is a subgroup of patients, however, who have a relatively low AHI but experience unacceptable nocturnal oxygen desaturation. Studies suggest that desaturations of 4% were associated with fasting hyperglycemia and increased risk of cardiovascular disease (125,126). For these patients, particularly those with existing coronary artery disease or cerebrovascular disease, supplemental oxygen during sleep may be beneficial and even the primary therapeutic goal (127).

Oxygen therapy may also be combined with positive pressure therapy. Selected OSA patients with other confounding conditions such as obesity hypoventilation, CHF, or chronic obstructive pulmonary disease (COPD) may benefit from supplemental oxygen as an adjunct to other forms of directed therapy. OSA patients, who are hypoxemic during wakefulness and qualify for supplemental oxygen during the day, may meet the criteria for the addition of oxygen therapy at night, even if positive pressure therapy maintains upper airway patency. Finally, one recent small study demonstrated that high-flow (20 L/min) humidified air administered through a nasal cannula may effectively reduce the AHI (28 ± 5 to 10 ± 3) (128).

OROPHARYNGEAL EXERCISES

Recent developments in understanding the pathophysiology of OSA report that central and peripheral neuromuscular control mechanisms may have substantial impact on the disease process and evolution over time. It is well established that OSA patients have increased genioglossus muscle activity during wakefulness; however, this compensation is lost during sleep (129). More recent studies suggest that these findings are not simply a matter of compensation but rather signify neuromuscular denervation/renervation injury (130). White compared the genioglossus muscle activity in response to negative pharyngeal pressure in two patients: one with OSA and the other a normal healthy control. He found that the OSA patient did not respond with increased muscle activity as the healthy control did (131).

These findings may serve as the basis for improvement in OSA with oropharyngeal exercises. Initial anecdotal reports of reduced snoring and daytime sleepiness in students playing the didgeridoo instrument for several months lead to a randomized controlled trial. The authors concluded that regular didgeridoo playing resulted in significant improvement in subjective daytime sleepiness as well as the AHI (132). Guimaraes et al. (133) then derived a broad-based regimen of daily oropharyngeal exercises and employed them in a randomized sham-controlled trial of patients with moderate OSA. Compared to controls, patients undergoing oropharyngeal exercises had a significant improvement in AHI (22.4 to 13.7), snoring measures, daytime sleepiness, and subjective sleep quality measures. Although these findings are preliminary and the specific types and duration of exercises have not been established, oropharyngeal exercises hold promise as an effective, benign, inexpensive, and maybe more physiologically sound option for adjunctive or even sole therapy in some patients.

BEHAVIORAL MODIFICATIONS

Sleep deprivation is a well-established cause of daytime sleepiness, neurocognitive dysfunction, delayed reaction times, increased risk of motor vehicle accidents, as well as other cardiovascular, metabolic, immunologic, and general health-related negative sequelae. Additional evidence also suggests that sleep deprivation may predispose to or worsen existing OSA. The mechanism linking sleep deprivation and abnormal ventilatory control is unclear but may involve depression of the arousal threshold and blunting of chemoreceptor-mediated control of ventilation. A recent animal model suggests that sleep fragmentation attenuates the hypercapnic ventilatory response (134).

Maladaptive behaviors that may negatively impact sleep quality and quantity include untimely or excessive caffeine, alcohol or nicotine consumption, insufficient sleep duration, shift work, or a poor sleeping environment. A comprehensive sleep history, including information on evening habits, sleep times, and overall sleep hygiene, is warranted in the evaluation of all OSA patients. Likewise, counseling of patients on proper sleep hygiene and emphasis on the importance of adequate sleep duration will likely improve patient satisfaction and overall treatment outcomes.

Bed partners and family members are often the first to recognize the association between alcohol consumption and the impact on snoring and sleep disturbance. In patients with existing snoring or OSA, alcohol may increase both the frequency and duration of obstructive respiratory events. One study showed that a mean blood alcohol concentration of 0.07 g/dL in patients with mild OSA was associated with a modest increase in the AHI (135). Furthermore, compared to controls, OSA patients are more vulnerable to the detrimental effects of alcohol consumption on reaction times and simulated driving performance (136).

Smoking also has a known negative impact on sleep and potentially on sleep-disordered breathing as well. The stimulant mechanism of nicotine may explain in part why cigarette uses have more difficulty initiating and maintaining sleep (137). Smokers also have four to five times increased risk of having at least moderate sleep-disordered breathing (138). The association between OSA and smoking may be related to multiple factors including increased upper airway mucosal edema, increased laryngopharyngeal reflux, and a higher rate of cardiopulmonary disease in smokers. Although the exact effect of smoking cessation on the management of OSA is still unknown and controversial, cigarette smoking should always be discouraged for both general health as well as sleep-related reasons.

TREATMENT OF ASSOCIATED CONDITIONS

Many general medical and psychiatric conditions, as well as the medications used in their management, can directly impact sleep and also can complicate OSA management. Further, there are at least 70 other definable sleep medicine disorders that can coexist with OSA. Successful management of OSA patients and their sleep-related symptoms requires the ability to identify, and treat, these coexisting sleep and medical disorders.

Approximately one-third of patients with OSA may have another sleep disorder, such as restless legs syndrome or insomnia (139). Additional sleep pathology may be contributing to hypersomnia and other symptoms at least as much as the sleep-related breathing disorder. Therefore, persistent symptoms after apparent successful medical or surgical therapy for OSA may signify an unrecognized coexisting sleep disorder. Clinically significant insomnia is a common comorbid condition in OSA patients, and patients with both conditions may have more severe OSA as well as a higher rate of anxiety, stress, and depression (140). Furthermore, in a recent prospective crossover study of patients with both insomnia and mild OSA, Guilleminault et al. (141) found that treatment of the underlying OSA was more effective in improving insomnia than traditional cognitive–behavioral therapy for insomnia. The findings above underscore the need for a comprehensive sleep medicine history in every OSA patient.

Patients with CHF, for example, have a significantly higher risk of both obstructive and central apneas, including Cheyne-Stokes or periodic breathing. Increased venous congestion of the upper airway, high loop gain or increased central and peripheral chemoreceptor sensitivity, and decreased functional residual capacity may contribute to the increased sleep-disordered breathing seen in heart failure patients. Further, the symptoms from CHF itself, as well as commonly associated HTN, coronary artery disease, pleural effusion, pulmonary vascular congestion, and atrial fibrillation, can also negatively impact sleep and daytime function. As such, treatment of the patient with OSA and CHF often requires multimodality therapy including aggressive management of underlying heart failure, positive pressure therapy (CPAP, BIPAP, or adaptive pressure support servoventilation), cardiac pacing, supplemental oxygen, and behavioral/lifestyle modifications including diet and weight control.

COPD, asthma, interstitial lung disease, kyphoscoliosis, neuromuscular disease, and other impairments of pulmonary function are often associated with OSA and sleep disturbance. The coexistence of COPD and OSA has been termed "overlap syndrome." Hypoxemia and quality of life may be worse in patients with overlap syndrome. Careful attention to both OSA and the underlying pulmonary disease is essential to successful improvement of symptoms and quality of life as well as reduction of long-term morbidity.

HIGHLIGHTS

- PAP therapy and oral appliances provide the foundation for the medical management of OSA; however, other treatment options can play an important role as well and include weight loss, smoking cessation, behavioral modifications, positional therapy, treatment of nasal obstruction, and management of coexisting sleep disorders and/or medical conditions.
- Successful management of patients with OSA requires a comprehensive sleep history and examination, proper diagnostic evaluation, and an individualized approach that takes into account each patient's unique presentation and considers all available and applicable treatment options.

- With proper titration and acceptable adherence, positive pressure therapy has been shown to improve both subjective and objective sleep measures, improve daytime function and quality of life measures, reduce risk of motor vehicle accidents, and reduce the cardiovascular risks associated with OSA.
- Acceptance and adherence remain the greatest challenges to effective management with medical device therapy, and data card monitoring technology currently provides the best objective assessment of usage. The optimal usage that is required to achieve both sleep and health benefits is unknown and variable depending on the patient and the outcome being measured.
- A variety of side effects related to the mask/equipment, airflow/pressure, or psychological reasons may negatively impact sleep and preclude successful use of positive pressure. Proper patient education, problem identification, and early intervention can overcome many of these hurdles.
- Oral appliances can provide an effective form of medical therapy, particularly for those patients who are nonaccepting or intolerant of positive pressure. The most commonly used and most effective appliance is a custom-made titratable MAD.
- Across a population, oral appliance therapy may not provide as effective AHI reduction compared to positive pressure; however, long-term adherence may be higher resulting in comparable efficacy. Most side effects of oral appliance use are minor and transient; however, more severe and persistent adverse effects can occur and often preclude long-term use.
- Nasal obstruction is an independent risk factor for snoring, disrupted sleep, daytime sleepiness, and OSA, and it can negatively impact successful management of OSA with positive pressure and oral appliance therapy. Medical and/or surgical therapy to lower nasal resistance in patients with OSA and nasal obstruction can improve subjective and objective sleep measures as well as compliance and results with positive pressure and oral appliances.

Nasal and Palatal Surgery for OSA

137

Peter D. O'Connor *Tucker Woodson*

An inherent problem in obstructive sleep apnea (OSA) for any given individual is that the airway is structurally vulnerable to collapse. Multiple physiologic and anatomic factors contribute to maintain airway patency. The complex interaction between respiratory control, arousal thresholds, neuromuscular tone, and transmural pressure in the pharynx determine the patency of the airway through the respiratory cycle. Simply put, the upper airway including the pharynx and to a lesser degree the nasal cavity can be thought of as a collapsible tube. The flow of air through the upper airway is influenced by the difference in upstream, downstream, and intraluminal forces. Stabilization of airflow in an airway compromised by OSA often requires multimodality treatment.

Surgical treatments for sleep-disordered breathing (SDB) will vary depending on the structures involved and the morbidity of the intervention, severity of disease, obesity, and cost of care for many patients. The role of surgical intervention has classically been viewed as an attempt to influence the structures involved with airway collapse. An alternative and perhaps more accurate way of looking at the role of surgery is that of a reconstructive approach. The goal of airway reconstruction is to improve the patency of the tube and the flow of air. Ultimately, we want to reduce the severity of disease and sequelae. Surgical intervention is one modality that should be considered in patients presenting with SDB.

Surgical treatment often requires a combination of procedures. It is not a single unique surgery. In adults, a single anatomic structure is not usually the sole cause of obstruction, and multiple sites or levels of the airway often require treatment for optimal results. Although tracheotomy as a single procedure should be considered in certain clinical presentations of OSA, it is not practical in most cases. A vast array of surgical treatments are described and variable reported responses to them exist. This is in part due to the distinct character of each airway based on the craniofacial anatomy, neuromuscular tone, influence from other soft tissues, and physiologic elements. Understanding the pathophysiology of OSA along with the airway phenotype will aid in the selection and surgical application of procedures. Impacting only one of these factors surgically may be inadequate to achieve the desired end state. Ideally, the surgical approach is tailored to a patient rather than the application of a one method suits all approach.

The pathogenesis of SDB and luminal compromise is rarely confined to a single anatomic location. Obstruction and narrowing of both the upper pharyngeal (retropalatal) and lower pharyngeal (retroglossal) airways occurs in 70% to 80% of patients (1). Ethnic and gender variation may exist and not all sites contribute equally (2–4). Obstruction occurs in the pharynx for most events but obstruction of laryngeal tissues as a primary site is uncommon (4,5). The cause of obstruction is complex, and abnormalities of palatal and pharyngeal muscles, mucosa, lymphoid tissues, vascular structures, and other influential elements such as airway mechanoreceptors have been reported. Abnormal nasal resistance is an important but indirect cause of apnea in adults. Ultimately, the common finding is an upper airway that is structurally vulnerable to collapse. Multiple surgeries and variations of them have been described with a desired effect of improving the flow of air during sleep.

Snoring has traditionally been regarded as a social nuisance rather than a source of morbidity. It is one of the most important presenting signs in patients suspected of having OSA. When patients present with a complaint of snoring, OSA needs to be ruled out rather than assuming a diagnosis of primary snoring. Data from the Wisconsin Sleep Cohort Study showed that 31% of middle-aged females and 53% of middle-aged males had habitual snoring and an even more had nonhabitual snoring (6). Treatment of snoring to this point has emphasized the importance on bed partner quality of sleep. However, new evidence is emerging that suggests there is an association

between snoring and increased mortality (7). Whether snoring is a discrete condition or there is a synergistic effect on SDB needs to be explored further.

Since surgery for sleep apnea is not a single intervention for many patients, algorithms describing planned interventions have been described. The most commonly quoted is the Stanford protocol that defines surgical procedures as being phase 1 or phase 2 procedures. Phase 1 procedures included segmental pharyngeal interventions such as uvulopalatopharyngoplasty (UPPP), genioglossal advancement, and hyoid suspension. Phase 2 procedures were maxillomandibular advancement or similar interventions (8). Others have described phased procedures using radiofrequency, lingual tonsillectomy, and glossectomy procedures as part of the phased protocol. To date, few studies have compared outcomes using different protocols. In addition to assessing how surgery may modify different structural elements of the airway, it is also important to define what the ultimate goal of surgical treatment for sleep apnea is going to be. Three general classifications for intervening may include complementing medical management (continuous positive airway pressure [CPAP] use, weight loss), salvage therapy in patients where medical management has failed, or when surgical cure is likely for select individuals. The treatment algorithm for patients may include a reassessment of prior failed therapies. It must also be recognized that OSA is a chronic disease and remittance is common. For a significant number of patients, CPAP tolerance following surgeries may be improved. Both retrospective and prospective studies suggest that nasal surgery may improve CPAP adherence and may lower CPAP pressures. Case series suggests that in some patients pharyngeal surgery may also improve CPAP use in selected patients. In the authors' anecdotal experience, a subset of patients with marked lymphoid hyperplasia or other isolated soft tissue abnormalities may benefit from surgery that has the goal of improving CPAP use. Concerns exist, however, that aggressive UPPP may worsen CPAP use in some patients by creating or worsening "mouth leak." Mouth leak occurs from over shortening of the palate, which then cannot seal against the tongue when positive pressures applied. The clinical significance of this is uncertain for most patients.

A successful outcome following surgery depends on at least three additional key elements. First, the preoperative clinical evaluation accurately defines the structures influencing the flow of air. A complementary or alternative way is describing the airway phenotype. Second, it is important to select the appropriate one or combination of procedures followed by skillful application of the procedure. The third element involves an understanding of what the potential effect of a procedure will be, the desired goal, and how the effect may change over time for a chronically, often progressive disease. An example of the latter class of patients is the nonobese pediatric patient with adenotonsillar hypertrophy and no other craniofacial or neurologic abnormalities.

In adults, positive airway pressure therapy is considered the gold standard although it does have its limitations. Certain patients are unable to tolerate positive airway pressure therapy. This is despite more sophisticated delivery methods available today. A variety of interfaces and other noninvasive pressure modalities may be beneficial for some patients. These include nasal masks including nasal pillows, masks which cover the nose and mouth, and full face masks. Varying positive pressure modalities also exist and include bilevel pressures (BiPAP), autotitrating units, devices with relaxation modes during exhalation, and newer devices with adaptive ventilation based on a continuous monitoring of flow through the device and interface.

Defining the criteria for successful outcome is also important. In the literature, this has traditionally focused on an improvement in respiratory parameters (apnea–hypopnea index [AHI], and lowest oxygen saturation [LSAT]). A threshold of treatment that defines a successful response does not exist based on current data. In addition to objective data, the subjective response should not be overlooked (9,10). Subjective improvement in sleep with reduction in nasal airway obstruction (NAO), reduction in snoring, and improved quality of life should also be elements of the treatment discussion with the patient. The remainder of the chapter focuses on nasal and palate surgery. The treatment goals and physical evaluation of a patient with sleep apnea and snoring is critical and should set the foundation for the preoperative decision making, what procedures to consider, and the postoperative management.

NASAL SURGERY

NAO is a recognized contributor to SDB. Patients with NAO report a worse quality of life, increased fatigue, and decreased quantity and quality of sleep. Some studies have shown a link between NAO and OSA (11). Population-based studies have identified chronic nocturnal nasal obstruction as being significantly more likely in individuals with SDB (12) and habitual snorers without OSA (13).

Treatments will vary depending on the pathologic findings and symptoms. Historically, the primary symptom warranting treatment was subjective nasal obstruction. The finding of such strong associations with SDB, or quality sleep, and OSA support that these are also symptoms related to nasal obstruction. Improvement in sleep quality is a major component of validated nasal treatment outcome questionnaires (nose scale). In large cohorts and randomized controlled trials, surgical therapy has been shown to significantly improve sleep architecture, subjective sleep quality, and daytime sleepiness. Studies also support that in most patients as an isolated treatment, nasal surgery does not affect the AHI. A patent nasal airway, however, has been significantly associated with patient's favorable response to treatment. A higher nasal resistance and nasal obstruction appears to decrease the use of both nasal CPAP and oral appliances, and negatively affect surgical

outcomes. Use of objective data on nasal airflow is not yet common in the clinical setting. Treatments may include correction of a septal deviation, reduction in turbinate size, correcting nasal valve collapse, or removal of nasal polyps.

There are differences in the literature regarding daytime symptoms of NAO, measures of nasal resistance, and objective polysomnogram data. This is in part because nasal airflow is a complex phenomenon, and how patients perceive airflow can be quite variable at different times and from one another. The physiologic nasal cycle, controlled by the hypothalamus, alters nasal mucosa every few hours. Air entering the nasal passageway is affected by shape of turbinates, mucosal properties, and nasal cilia. The nasal mucosa, especially overlying the turbinates, has an extensive vascular bed. Expansion of the network of vessels can lead to obstruction from acute or chronic inflammation and significantly impact the level of nasal resistance.

An important distinction to consider is how nasal resistance during wakefulness compares to the resistance of the nose while lying supine during sleep. There is evidence that nasal resistance changes throughout the course of the night. Increases in nasal resistance are greater in OSA compared to non-OSA populations. Whether this is due to differences in physiology (such as vascular compliance) or anatomy of the upper airway are unknown.

Predicting how nasal obstruction will impact CPAP use is also difficult. A common complaint of patients is that they cannot tolerate their mask and may remove it during the night. Why this occurs despite a proper level of therapy is unclear. Many patients report NAO and some authors have reported an increase in nasal symptoms in certain patients after starting CPAP therapy (14).

Despite the lack of a clear understanding about the role NAO plays in SDB, it can be an important component of the overall treatment algorithm for patients. However, nasal surgery alone is not accepted as a primary treatment alone for OSA in part because a linear relationship between daytime symptoms and severity of SDB does not exist. Clinical examination for the presence of nasal obstruction remains important to rule out compromised airflow through the nasal cavity and nasopharynx.

Evaluation

Physicians currently utilize subjective surveys, visual examination with endoscopy, and computed tomography scans to help in diagnosing patients with NAO. Objective testing of the nasal airway has most commonly been done using acoustic rhinometry and rhinomanometry. Acoustic rhinometry, although still primarily used as a research tool, provides a volumetric measure of the nasal cavity (15,16). The anatomic measurement is taken during a breathhold and does not provide direct data on the flow of air through the nose. Rhinomanometry measures nasal obstruction and changes in resistance by assessing pressure and nasal airflow together during normal breathing (15).

Other methods have been utilized but to a lesser degree. These include nasal spirometry, laser Doppler velocimetry, and forced oscillation rhinomanometry to better describe nasal airflow, resistance, and potential sources of obstruction (17–23). These tests have varied acceptance and are not always practical in the clinical setting, and studies reveal differing conclusions (21,24). More recently, some investigators have begun using computational fluid dynamics to model nasal airflow (25–28).

Nasal Breathing and Impact on Sleep

NAO likely contributes to upper airway resistance through both indirect and direct mechanisms. Humans should breathe through their nose when sleeping. Nasal airflow is an important factor for maintaining neural tone and the patency of the airway. Nasal obstruction is ultimately a subjective sensation processed in the brain from numerous neurophysiologic receptors.

Use of a topical anesthetic to decrease afferent stimuli from the nasal airway has been shown to increase pharyngeal resistance resulting in an increased number of respiratory events over the course of a night (29). Decreased nasal airway flow should similarly result in a reduction of nasal afferent reflexes and subsequent decrease in muscular tone. Optimizing nasal airflow to maximize this feedback is important.

Nasal obstruction may also lead to mouth opening. Oral cavity opening leads to posterior rotation of the tongue base and displacement of the hyoid bone (30). Vertical opening with inferior displacement of the hyoid and a decrease in the hyomandibular distance results. These movements place the musculature of the tongue and pharyngeal tissues into a mechanically disadvantaged position and lead to increased upper airway collapsibility and increased hypopharyngeal obstruction. Despite mouth opening, the soft palate and tongue may remain in close apposition even if nasal breathing continues.

Additional evidence of the importance of having and maintaining nasal airflow during sleep comes via the concept of a Starling resistor. The upper airway is a collapsible tube. The larynx in humans, unlike other mammals, has a more caudal position creating a greater distance with the soft tissues of the pharynx in between. The soft tissues of the pharynx are not directly surrounded by osseous structure and are capable of collapse. The flow of air through the pharynx is influenced by upstream, downstream, and luminal forces. Tissues at multiple levels can contribute to collapse with the nasal cavity and nasopharynx providing upstream resistance. The flow of air and maximum velocity, through the collapsible segment, is inversely proportional to the upstream resistance. Areas downstream are susceptible to collapse including the retropalatal and hypopharyngeal segments. Optimization of airflow through the pharynx is impacted by reducing resistance upstream in the nasal cavity and can be extended to the nasopharynx.

TABLE 137.1 SNORING PATIENTS DIAGNOSED WITH OSA BY POLYSOMNOGRAM

Study	N	Prevalence (%)
Viner et al. (69)	410	46
Hoffstein and Szalai (70)	594	46
Deegan and McNicholas (71)	250	54
Vaidya et al. (72)	309	73
Tami et al. (73)	94	72
Rowley et al. (74)	370	67

Weighted average = 0.597 (95% CI = 0.497–0.696).

For patients who do present with a complaint of snoring, symptoms of OSA, or disease proven by polysomnogram, it is important to explore the presence of NAO. Patients may present with a variety of findings (Table 137.1) (septal deviation, polyposis, nasal valve collapse, concha bullosa, adenoid hypertrophy, turbinate hypertrophy, choanal atresia, neoplasm, case reports of skull base, and neoplastic lesions). Chronic rhinosinusitis, allergic rhinitis, turbinate hypertrophy, polyps, and nasal septal deviation may to some degree all cause NAO (17,18,25,31). Surgical correction of an obstructing lesion is justified if there are corresponding daytime or functional symptoms or other concerns. The effect on breathing at night or the use of CPAP is less clear.

The nasal passage functions as a resistor to airflow with both dynamic and static components. The static tissues include the septum and the structural foundation of the nasal cavity and nasopharynx is the maxilla. The dynamic elements of the nasal airway include the internal and external nasal valves as well as the nasal mucosa. The internal nasal valve is the narrowest cross-sectional area of the upper airway. It can therefore have a significant impact on airflow and accounts for nearly two-thirds of the total upper airway resistance. The anatomic components which define the internal valve include the nasal septum medially, the upper lateral cartilage positioned superolateral, the anterior tip of the inferior turbinate, and the pyriform aperture inferiorly. Numerous procedures are available for improving the nasal valve function and include both grafting and suspension techniques. Recognizing the influence of the bony structures is also important because they provide the foundation for the nasal airway. To a lesser degree, the bony foundation may be modified in some patients with improvements in nasal airflow having been shown after maxillary expansion (32,33).

Investigators have attempted to produce nasal obstruction to determine its impact on respiratory parameters during sleep. Sleep disturbance has been shown in the setting of acute nasal obstruction. Following artificial simulation of NAO with catheters and balloons, an increased number of respiratory events including apneas can be seen (34,35). Some of the events include a significant increase in the number of oxygen desaturations. More recently, Friedman et al. (36) have shown that in patients with mild OSA (RDI < 15), nasal packing increased their RDI, duration of snoring, and oxygen desaturation index in the immediate postoperative period.

Nasal obstruction is also associated with poor quality sleep independent of respiratory parameters. Anecdotally, patients with symptomatic seasonal allergies or increased nasal congestion from an upper respiratory infection may present with increased complaints of snoring and CPAP intolerance during the exacerbations. Correction of chronic NAO has been shown to have a significant impact on improving quality of life and daytime somnolence measures (37,38). These findings were independent of any changes in AHI during overnight polysomnograms. This supports the notion that using a measure like AHI alone to assess the impact of nasal surgery is potentially incorrect.

Nasal Surgery

When considering nasal surgery on patients with OSA or snoring, the general categories include septoplasty, valvuloplasty, and turbinoplasty. Preoperatively, it is beneficial to contrast and compare a patient's perception of their breathing and how it correlates to physical exam findings. Knowledge about what CPAP interfaces have been tried and successful may also be beneficial. A patient with weak lower lateral cartilage and significant internal or external nasal valve collapse may do well with a nasal pillow mask if the interface stabilizes this area. Poorly fitting nasal masks can also be problematic if they cause impingement of the nasal vestibule or alar side wall. Surgical correction of increased nasal resistance can be beneficial for patients.

Most studies regarding the impact of nasal surgery on OSA have focused on septoplasty. Some authors have assessed this in combination with other procedures including turbinate reduction (37,39), UPPP (40), and sinus surgeries. Extensive study and literature addressing the nasal valves can be found elsewhere in this text. Further research into the impact of nasal valve surgery on sleep and CPAP is needed.

The ability to relieve SDB via surgery has been more difficult to demonstrate because of the complex nature of SDB and multiple structures involved. Prospective studies have shown significant changes in subjective symptoms following nasal surgery despite no significant difference on sleep parameters, AHI, or oxygen desaturation (37,41,42). One study did show a significant difference in the degree of AHI and snoring after septoplasty with or without turbinoplasty (39). Another interesting finding has been that for some patients there may be an improved tolerance of CPAP or a decrease in overall pressure required to treat their OSA following nasal surgery (37,43). This potentially could improve CPAP tolerance in patients where higher CPAP pressures are the suspected etiology for poor compliance.

The role of the nasal turbinates and the impact turbinoplasty has on OSA and snoring is another area that requires

further evaluation. The ability of the nasal passage to function as a resistor depends on the ability of the turbinates to react to stimuli and change vascular tone.

In a large systematic review of the literature, Batra et al. (44) evaluated the efficacy of surgery for symptomatic adult inferior turbinate hypertrophy resulting in NAO. The majority of the studies were level 4 or 5 evidence. Of the 96 studies which met inclusion criteria for their review, 93 studies (96.9%) reported data showing a positive benefit from surgery with subjective symptom improvement in 50% or greater patients. Three studies showed no change or negative benefit. The findings reported were regardless of surgical technique utilized. In 2001, Clement and White (45) published a report on trends in research on turbinate surgery over the past four decades. They indicated a greater emphasis on technology trends rather than patient benefits in the literature. Surgical techniques utilized included turbinectomy, laser surgery, thermal techniques with predominantly radio frequency ablation and coblation, and turbinoplasty including microdebridement. Today the thermal techniques, including radiofrequency ablation and coblation, and the submucosal resection techniques with microdebridement seem to be the preferred procedures. General consensus of which is better requires more research and depends to some degree on what the surgical goal is. Some authors have shown a greater long-term benefit with powered microdebridement versus coblation or radiofrequency turbinate reduction (46–48). How these surgeries impact sleep parameters is unclear.

Objective data were reported in several studies following surgery of the inferior turbinates (44). Nasal resistance measured by rhinomanometry was improved in 83% of the studies (10 of 12) where it was performed and nasal airflow measured by acoustic rhinometry was improved in 100% (14 of 14). Unfortunately, we do not yet have a predictive mechanism to measure NAO with great specificity to determine who will tolerate and respond to CPAP or may benefit from inferior turbinate reduction.

Over a dozen techniques have been described for reduction of the inferior turbinates (49). There are some reports showing good correlation between preoperative topical decongestant and post-radiofrequency ablation of the turbinates with a visual analog score for nasal obstruction. These results have not been tested with other techniques or the impact on sleep parameters or CPAP use. Although most surgical techniques demonstrate some benefit in nasal airflow postoperatively, the most reliable technique with both sustained subjective and objective benefits is unclear. Nasal surgery can also have a large placebo effect that influences subjective scores making more research critical for this area (50).

NAO and the presence of SDB often coexist. The data supporting an improvement in subjective symptoms, decreased CPAP pressure required after nasal surgery, and improved tolerance of CPAP do not consistently correlate to the severity of disease. A beneficial outcome from surgery could be defined as improvement in both objective and subjective measures of nasal airflow. This would include improvements in sleep and a response to CPAP for patients with SDB. However, objective measurements do not always correlate with the patient's symptoms of nasal obstruction. This suggests something other than AHI and nasal airflow conductance as a link between SDB and subjective symptoms.

PALATE SURGERY

Upper airway obstruction and OSA may occur at multiple sites. The upper pharynx in the retropalatal airway is frequently a primary site of obstruction during sleep (1). Obstruction occurs due to loss of muscle tone and compensatory reflexes during sleep. The airway associated with the soft palate is particularly vulnerable since this is the smallest and most compliant portion of the pharynx. Multiple surgical procedures have been developed and advocated to treat both sleep apnea and snoring. The use of these procedures is still evolving. As a primary first-line treatment, palatal surgery is controversial. Success rates vary and causes of surgical failure are poorly understood. Failure is often attributed to obstruction at nonpalatal airway sites. Although this may contribute to failure in some patients, considerable data support that airway obstruction persists at the upper pharynx in the majority of patients (51,52). Increasingly, it is recognized that palatal surgery for sleep apnea and snoring is not a single procedure but a reconstructive approach that can be used as part of an integrated treatment plan for selected patients with OSA. The surgeon can be an important contributor to successful treatment. This requires an understanding of upper airway structure, physiology, and tools of airway reconstruction but also of upper respiratory and sleep pathophysiology and disease. In the authors' experience, understanding the airway phenotype and anatomical structures involved at the palate is important and can aid in determining which palatal procedure may be most beneficial. It is also important to recognize that many patients who fail following traditional UPPP (up to 84% in some studies) have residual retropalatal obstruction. This palatal obstruction may be in addition to hypopharyngeal collapse, further complicating decision making.

Anatomy of the Upper Pharynx

From a structural standpoint the upper pharynx and retropalatal airway is a valve. It is the smallest and most compliant segment of the pharyngeal airway in most individuals regardless of the presence or absence of OSA or snoring. This structural vulnerability combined with a loss of muscle tone to the muscles that maintain patency results in collapse and a significant risk of obstruction. The retropalatal airway is an isthmus with multiple structures determining its final configuration. There is considerable

variability between individuals and anatomic structure of the upper pharyngeal airway or pharyngeal isthmus. To date there is no consensus as to how to describe this variability. Multiple anatomic elements combine to define the pharynx. Structures such as tonsil and adenoid size are well accepted as impacting the size of the pharynx. Less well recognized are how other structures such as the pharyngeal lateral walls, velum, levator palatine muscle, palatal aponeurosis, hard palate, and posterior pharyngeal wall anatomy impact the upper airway anatomy.

A number of studies have tried to use anatomic structures to predict outcomes of palatal surgery for OSA (53–56). Several approaches have been used. Methods varied based on what factors were considered to be contributing to palatal surgical failure. Traditionally, failure has been attributed to lower pharyngeal airway obstruction, and anatomy was assessed to identify obstruction at nonpalatal sites. Other studies have used pharyngeal characteristics such as tonsil size and a modified Mallampati classification (Friedman system) to predict outcomes (53,54). A third approach postulates that failure of palatal surgery is due to persistent obstruction at the palatal airway and attempts to better describe and define this portion of the airway.

Diagnosis and Evaluation

Effectiveness of UPPP varies. Its use is controversial. Because of such variability in techniques and outcomes, the effect of UPPP is still only partially understood. Failure likely occurs due to inadequate airway diagnostics, failure of technique, and failure of application. Although much of the literature in UPPP has focused on failure resulting from poor patient selection and obstruction at nonpalatal sites, more recent analysis and data suggest that much of UPPP failure is technical and failure often occurs at palatal sites following surgery. For this reason, newer more physiologic and reconstructive techniques have been advocated and developed. To date, however, these are not in widespread use.

Diagnostic prediction of UPPP has been improved by the Freidman staging system (Fig. 137.1) (53,54). This staging system has proven valuable in predicting which patients will have a greater likelihood of failure with UPPP alone. The Friedman staging system for the oral cavity and oropharyngeal portions of the upper airway defines four stages based on the following: (a) tonsil size (1 to 4+), (b) a modification of the Mallampati classification (1 to 4+), (c) presence or absence of severe obesity (> or <BMI of 40 kg/m^2), and (d) major craniofacial abnormalities. The Friedman staging system identifies patients at risk for apnea who present with symptoms of snoring. It also demonstrates both positive and negative UPPP predictive values.

Friedman staging stratifies groups into favorable and unfavorable characteristics. Large tonsil size is a "favorable" (tonsil grades 3 and 4, large tonsils) surgical characteristic. Small tonsils are "unfavorable" (tonsil grades 1 and 2, small tonsils). The Mallampati classification is

	Friedman Palate Position	Tonsil Size	BMI
Stage I	1	3, 4	<40
	2	3, 4	<40
Stage II	1, 2	1, 2	<40
	3, 4	3, 4	<40
Stage III	3	0, 1, 2	<40
	4	0, 1, 2	<40
Stage IV	1, 2, 3, 4	0, 1, 2, 3, 4	>40
All patients with significant craniofacial or other anatomic deformities.			

BMI = Body Mass Index.

Figure 137.1 Modified Friedman staging system. (Reprinted from Friedman M, Ibrahim H, Joseph NJ. Staging of obstructive sleep apnea/hypopnea syndrome: a guide to appropriate treatment. *Laryngoscope* 2004;114(3):454–459, with permission.)

"favorable" (grades 1 and 2, visualizing the free margin of the soft palate) when the tongue size is small for the mouth and "unfavorable" (grades 3 and 4, free margin of palate not visible) when the tongue is large and fills the oral cavity. Severe obesity (BMI > 40 kg/m^2) is unfavorable. Using the Friedman staging system, outcomes can be better stratified (Friedman stage 1 = 70% success, stage 2 = 40% success, and stage 3 = 10% success).

Analysis of patients who failed traditional UPPP alone has been done. Localization of airway obstruction following traditional UPPP has generated interesting results. In one cohort of patients who failed following traditional UPPP, airway manometry was utilized showing 73% of the patients were found to have obstruction at the palate compared to 27% in the hypopharynx (51). The cross-sectional airway in the palatal area has also been noted to be significantly improved in responders to traditional UPPP versus patients who fail (52). The patients who failed were noted to have a persistent palatal bulge into the pharyngeal lumen. Ideally, in the preoperative setting, we could identify structures involved with airway compromise and tailor the reconstruction rather than applying a one method suits all ablative approach.

Palatal Surgery

Historically, palatopharyngoplasty was defined by UPPP as described by Fujita. Initial techniques described excision of tonsils, posterior soft palate, and uvula. Suture subsequent closure of the tonsillar pillars was then performed. Subsequently, multiple modifications have been described. Although frequently successful for the treatment of snoring, outcomes of UPPP for sleep apnea based on polysomnographic measures are variable. A 1995 review by Sher (57) identified that success rates differed by identified level of pharyngeal obstruction. In patients with obstruction isolated to the upper pharynx (Fujita type I), success rates of

reducing AHI by more than 50% and to an AHI of less than 20 events/h or an apnea index (AI) of less than 10 events/h was 52.3%. In contrast, those with lower airway obstruction response using the same criteria were only 5.2%. Sher also observed that the retrospective studies reviewed had a baseline severity of disease (AHI and AI) significantly lower in the group with isolated upper pharyngeal obstruction. Using this data some authors have concluded that surgical outcomes are better for mild sleep apnea. Adequate data were not available to assess the effects of different surgical techniques or different methods of airway evaluation.

A more recent review of UPPP assessed the AHI outcomes of 15 papers, which included individual data from each subject (papers with pooled data were excluded) and demonstrated an overall reduction of AHI of 33% (58). From these studies it was not possible to assess outcomes in women, elderly, or other patient subgroups. The review also excluded what were described as "novel variations" in pharyngeal surgery such as the extended uvulopalatal flap, lateral pharyngoplasty, expansion sphincteroplasty, Z-plasty pharyngoplasty, and palatal advancement. The review also highlighted that few surgical studies have adequately evaluated non-AHI outcomes such as sleepiness, cardiovascular outcomes, or mortality.

Multiple techniques have been described for UPPP. The following procedures have been described to treat OSA by modifying the palate and retropalatal airway. The list is not comprehensive, and data supporting individual procedures vary in quality and magnitude. Few studies have attempted to objectively compare procedures on clinical outcomes, complications, or technical outcomes. Most have been reported as isolated surgical techniques or a small case series. Use of any given procedure has often been based on surgeon's preference. Techniques that have been most extensively evaluated include the extended uvulopalatal flap, lateral pharyngoplasty, expansion sphincter pharyngoplasty (ESP), Z-plasty pharyngoplasty, and palatal advancement (59–64).

A wide variety of complications have been described associated with palatopharyngoplasty for sleep apnea. The most serious risks are those associated with the surgery itself. Perioperative risk of OSA patients is increased due to commonly associated perioperative risk factors such as obesity, hypertension, difficult intubation, and hypersomnolence (65,66). Risk of mortality is uncommon with a recent Veterans Administration population review demonstrating a risk of less than 0.5% of mortality or serious cardiovascular events (67). Other side effects are common but may also be dependent on technique. Side effects include minor changes and swallowing, sensation of throat dryness, increased phlegm, increased gag, and coughing with eating.

Outcomes other than AHI are very important to consider when evaluating surgery for OSA and comparing with and against other treatments. Quality of life outcomes, measures of daytime somnolence, and mortality are a few of the parameters recently reported with a beneficial outcome following surgery (9,10,65).

Uvulopalatopharyngoplasty

UPPP is a procedure that modifies the upper pharynx and palate to reduce or eliminate obstruction during sleep and treat OSA. It is the most common of multiple palatoplasty and palatopharyngoplasty techniques used to treat OSA. Initially described by Fujita in 1981, it was the first specific procedure to treat OSA as an alternative to tracheotomy. UPPP was revolutionary not only as a less morbid surgical intervention but directed attention to the upper airway where there was not yet any consensus of upper airway pathology contributing to disease. Since its inception, UPPP similar to other procedures has evolved and technical variations have been described. In contrast to procedures that only remove or ablate tissue, UPPP involves tissue modification and primary reconstruction. Although the initial description included excision of distal soft palate, tonsils, uvula, and redundant mucosa, other reconstructive approaches are now described. These not only promise lower morbidity in many cases but preserve anatomy and are more effective in randomized clinical trials.

A small number of studies of UPPP and related procedures have been performed demonstrating it as effective in treating physiologic measures of sleep and respiration and quality of life (9). Additionally, population-based studies show that UPPP reduces risks of motor vehicle accidents and likely reduce cardiovascular risk, while large population studies support that it reduces mortality and adult OSA. Although severe complications with UPPP are infrequent (67), side effects of surgery are common. Side effects include minor difficulties and swallowing, dry throat, sensation of foreign body, and increased sensation of phlegm.

A common application of UPPP is the treatment of snoring. Various procedures including laser uvulopalatoplasty (LAUP), injection snoreplasty, placement of Pillar implants, and other stiffening procedures of the palate have been described. Outcomes of these procedures differ in short-term but not likely long-term studies. Procedures likely differ significantly in side effects. More invasive procedures may have higher short-term effectiveness but do so at the price of increasing side effects. Fortunately, the trend of recent procedures is lower side effect rates.

Adult Tonsillectomy

Tonsillectomy and adenoidectomy are common procedures in children and adults who demonstrate enlarged tonsils with OSA. In pediatric patients, the effect of this treatment can be dramatic on AHI, quality of life, and cognitive abilities. The procedure, however, should not be considered "curative." Most of the data to date is case series data in highly selected patients. Few studies have control groups. Data suggest outcomes vary by population treated, airway and facial structure, obesity, and presence of other pathologies. In adults the outcome of simple tonsillectomy is likely limited. In a subset of patients, removing isolated palatine tonsils may be

definitive; however, identifying this population is difficult. Exposing an adult to the risk of two general anesthesia procedures, in order to perform isolated tonsillectomy, must be weighed against the additional morbidity of palatopharyngoplasty. Often the decision as to proceed is made intraoperatively after tonsillectomy is performed.

Evolution in Surgical Technique

Recognizing some of the technical failures of traditional UPPP to address the palatal obstruction has led to various modifications in technique. Conceptually, more aggressive treatment of the distal soft palate may be appropriate for a few patients, but alternatively other patients need the surrounding structures modified. The transpalatal advancement and ESP are examples of two techniques which aim to address structures not directly addressed by the traditional UPPP.

The transpalatal advancement pharyngoplasty (TPA) technique (68) was developed to address the retropalatal obstruction by effecting the position of the soft palate (Fig. 137.2). It can be particularly useful to increase the retropalatal space in a patient who has a very posterior based hard, soft palate junction. Phenotypically, this airway can be described as having a *vertically* oriented soft palate.

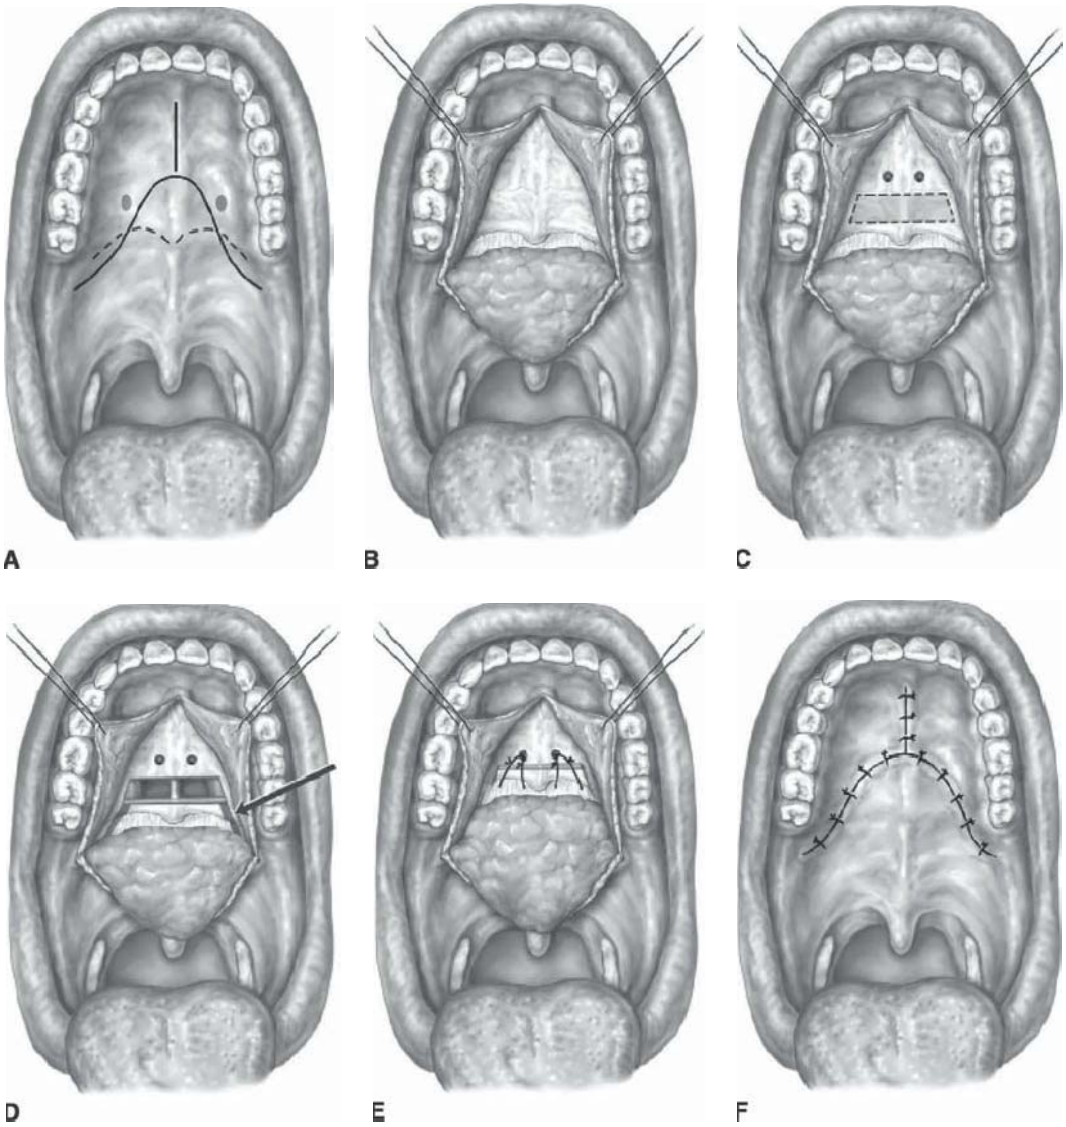

Figure 137.2 Transpalatal advancement pharyngoplasty. **A:** Palatal incision is made medial to the greater palatine foramen and extended posterior and lateral to the hamulus. **B:** Soft tissue flaps are raised exposing the hard palate. **C:** The planned osteotomy window is outlined by *dashes.* **D:** Osteotomy has been completed with 1 to 2 mm of bone preserved posteriorly. The *arrow* highlights the area for the tendolysis. **E:** Sutures are passed through the palatal drill holes and around the remaining distal hard palate and aponeurosis. **F:** The palatal incisions are closed. (Reprinted from Woodson BT. Transpalatal advancement pharyngoplasty. *Oper Tech Otolaryngol Head Neck Surg* 2007;18(1):11–16, with permission.)

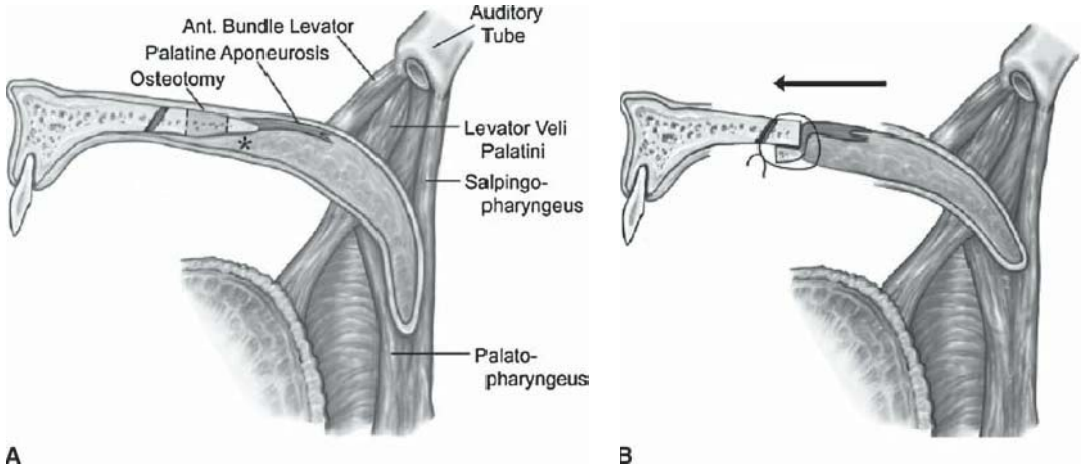

Figure 137.3 Sagittal view of a transpalatal advancement pharyngoplasty utilized to address a more *vertically* palate. **A:** The osteotomy site of the hard palate allows the soft palate to be advanced. **B:** Increased patency in the proximal nasopharynx after the soft palate is advanced creating an *obliquely* oriented palate. The uvula and distal soft palate may need to be addressed in some patients. (Reprinted from Woodson BT. Transpalatal advancement pharyngoplasty. *Oper Tech Otolaryngol Head Neck Surg* 2007;18(1):11–16, with permission.)

Specifically, the nasopharyngeal opening is narrowed in the anterior–posterior dimension at the proximal soft palate as well as distally. An *obliquely* oriented soft palate is one that has a wide proximal nasopharyngeal dimension and tapers or narrows at the distal soft palate (Fig. 137.3). During a TPA, movement of the soft palate anteriorly following osteotomy and release of the tendon aponeurosis can be beneficial to address the proximal palate where one would otherwise have to aggressively resect soft tissue with traditional UPPP methods hoping to achieve a similar result. Improvement in outcomes with TPA versus traditional UPPP has been shown in some patients (Table 137.2) (61).

The ESP (60) technique is an example of a useful technique to address the lateral wall, specifically the position of the palatopharyngeus muscles (Fig. 137.4). UPPP alone is more of a mucosal operation and does not directly affect the position of the pharyngeal muscles. Lateral pharyngeal wall collapse can play a significant role in the pathogenesis of OSA and should be recognized. The goal of ESP in airway reconstruction is to increase tension of the lateral wall and reduce lateral collapse. The technique is a modification of an earlier procedure described by Cahali (62,63) which showed promised but resulted in significant dysphagia. The ESP technique repositions the palatopharyngeus muscles with reduced morbidity and has been shown versus UPPP to provide increased success rates (Table 137.3) (60). Additional modifications of technique to reposition the palatopharyngeus muscles and reduce lateral wall collapse are available but have not been widely utilized or studied.

Conceptually, one of the major causes of failure of palate surgery is obstruction at other nonpalatal sites. Hypopharyngeal airway narrowing has been implicated as a cause of surgical failure. Combining treatments of the hypopharyngeal airway may improve UPPP outcomes. These involve manipulation of skeletal structure as well as soft tissue. Procedures include partial glossectomy, ablational glossectomy, mandibular advancement, limited mandibular advancement, tongue and hyoid suspension procedures, lingual tonsillectomy, and limited laryngeal procedures. Only a small amount of evidence-based medicine is available on any of these procedures. Few have been compared and selection of procedure is often based on surgeon's preference. Some procedures are selected on specific anatomical abnormalities such as lingual tonsillectomy for lingual tonsil hypertrophy.

TABLE 137.2 APNEA HYPOPNEA INDEX FOR PALATAL ADVANCEMENT COMPARED WITH UPPP

Procedure	Pre-AHI	Post-AHI	Change in AHI	*P* Value, Pre vs. Post	*P* Value Between Groups
UPPP (n = 44)	47.9 (30.0)	30.9 (24.2)	17.1 (30.1)	<0.000	
Palatal advancement (n = 30)	48.3 (24.6)	19.8 (16.8)	28.5 (25.6)	<0.000	<0.02

MINIMALLY INVASIVE TECHNIQUES AND PROCEDURES FOR SNORING

Surgical therapy for snoring continues to evolve. UPPP was the first palatal procedure performed for the treatment of snoring. It continues to be an option but not frequently used because of the need for a general anesthetic and significant morbidity associated with the recovery. There has been significant interest in developing minimally invasive procedures for patients to treat SDB. In this context, we most commonly think of primary snoring as the focus of the interventions. There are a variety of reasons for this. Foremost is the fact that more invasive, multilevel, and combined therapies are required for treating OSA. Treating OSA surgically in almost all cases requires a general anesthetic in the operating room. Primary snoring on the other hand is addressed in the clinical setting were minimally invasive techniques would be ideal. Furthermore, insurance companies will often not reimburse for treatment of snoring in the operating room. Development of simple in office procedures is highly desirable. Until the 1980s, UPPP was the mainstay to treat palatal flutter snoring. In 1987, laser-assisted uvulopalatoplasty (LAUP) was performed by in Europe and later brought to the United States in 1993. The advantages over UPPP included the fact that it could be done in the office under local anesthetic with a lower incidence and severity of complications. However, significant postoperative pain was still a significant problem when treating snoring, and many patients required subsequent sessions to obtain success, if they even came

TABLE 137.3 PREOPERATIVE AND POSTOPERATIVE AHI RESULTS OF ESP AND UPPP WITH SUCCESS RATE AT AHI 50% REDUCTION AND <20

	ESP	UPPP
Preoperative AHI	44.2 ± 10.2	38.1 ± 6.6
Postoperative AHI	12.0 ± 6.6	19.6 ± 7.9
P value	<0.005	<0.05
Success rate AHI reduction 50% and <20	82.60%	68.10%

From Pang KP, Woodson BT. Expansion sphincter pharyngoplasty: a new technique for the treatment of obstructive sleep apnea. *Otolaryngol Head Neck Surg* 2007;137(1):110–114.

back. Since then, less invasive and more tolerable procedures have been evolving with a goal of simple, durable, and with lasting effects. Overall, the things to consider when choosing a procedure would be presenting anatomy, short-term and long-term effectiveness based on scientific evidence, the number of sessions required for treatment, morbidity or postprocedural pain, and cost. The goal is reduce the severity and duration of snoring that is bothersome and potentially harmful without subjecting the patient to too much risk.

The most important aspect of evaluating someone with a presenting complaint of snoring would be to rule out OSA. Snoring has a prevalence of greater than 50% in the general population. Establishing the symptom as a diagnosis of primary snoring requires the AHI to be less than 5 in most cases. A review of studies evaluating snoring patients for OSA with overnight polysomnogram showed that the ability to clinically predict OSA in snoring patients is around 60% (Table 137.1) (69–74). Therefore, because of the morbidity associated with OSA and low sensitivity in predicting OSA in snoring patients on clinical exam alone, formal evaluation for OSA should be done prior to intervention for a complaint of snoring.

Snoring has traditional thought of as solely a socially bothersome problem. When evaluated against sleepiness, the importance of subjective snoring and impact on the bed partner was greater in terms of quality of life (75). This highlights the impact snoring can have socially for many patients. The impact of snoring on quality of life for the individual may be comparable to having a chronic disease (76) and may be different between certain populations (2).

More recently, snoring is being considered to have greater health impact than previously thought. There is evidence that heavy snoring is related to increased carotid artery atherosclerosis (77). An overall increase in mortality has also been identified in patients who snore despite accounting for age, sex, BMI, and AHI (7).

The sound generated during snoring is generally accepted to be from the palate in roughly 80% to 85% of patients. The remainder of patients has a pharyngeal source or a combination of areas where the snoring arises from. This is important because essentially all snoring procedures work on the principle of stabilizing or stiffening the palate. It is no coincidence therefore that palatal procedures have a reported efficacy of around 80%. Brietzke and Mair (78) explored at using acoustical analysis to predict the probability of success and showed that subjective results were positively impacted when the level of snoring could be identified.

There are a variety of factors to consider when considering procedures even if minimally invasive. They may include wound healing issues such as diabetes, the presence of a strong gag reflex, and previous snoring or OSA surgery. The use of immunosuppressant medications is also important because many of the procedures rely on the generation of scar. This could potentially be reduced with concurrent use of steroids. Lastly, occupation and hobbies of the patient should also be considered. There are limited data on voice impact, but many vocalists and instrumentalist will be reluctant to proceed if there is any chance on negatively impacting their performance. Foodies are also another category of patients to be wary of. Taste information could theoretically be impacted by modifying receptors in the soft palate. In addition, balancing an improvement in nasal cavity airflow without deflecting too much airflow away from the olfactory tissues may be difficult when treating SDB or other NAO.

Procedures

There are a variety of procedures available in the office to treat primary snoring. Some of the same principle techniques are also being adapted for use on the nasal turbinates to improve NAO in a minimally invasive setting. In order to offer a less invasive and more tolerable following the development of UPPP and then LAUP, in 1997 Powell introduced radiofrequency tissue ablation (RFTA) of the palate for the treatment of snoring (79). Since that time additional devices and procedures have been introduced.

Radiofrequency Tissue Ablation and Coblation Techniques

RFTA, or temperature-controlled radiofrequency palatoplasty, is also done in the office under local anesthesia with the patient off any anticoagulant medications. The RF energy is delivered to the palate with a 22-gauge RF needle electrode. The generator automatically modulates the power and maintains the target temperature at 80°C to 90°C (Somnus Medical Technologies Ltd). Most patients are treated with three energy doses, one midline and two paramedian, at each treatment session. The needle is inserted in to the muscle of the soft palate with the entry point being near the junction of the hard palate. The active portion of the electrode should not extend into the base of the uvula or to the free margin of the soft palate. Most patients will require multiple treatment sessions. In a prospective, nonrandomized, multicenter study of 113 patients being treated for snoring, the multiple lesion protocol was deemed most successful. However, an extended follow-up study noted that a relapse rate at 14 months was 29% (80). Terris et al. published a prospective randomized trial of LAUP versus RFTA. Twenty patients diagnosed with mild SDB were treated with LAUP achieving 86% satisfactory resolution of their snoring, and 60% of RFTA patients achieved the same results (81). Single versus multiple lesion techniques have been evaluated with multiple lesion treatments having a greater likelihood of success (82). In 2004, Stuck et al. (83) reviewed 22 studies most of which were primarily prospective, noncontrolled trials. In 345 patients, the visual analog score for snoring was significantly reduced from 8.1 ± 1.8 preoperatively to 3.5 ± 2.2 postoperatively. The primary complication noted included ulceration of mucosa (up to 43% of patients in one study). Additional findings reported were palatal fistula, uvular sloughing, and bleeding in one patient. Overall, the literature supports the possibility of

a satisfactory result, but relapse has been noted long-term (84) and controlled trials are required.

Postoperative pain management is typically achieved with nonsteroidal anti-inflammatory medications such as ibuprofen and topical anesthetic lozenges. Occasionally, for any of the procedures where there is mucosal breakdown, increased analgesia may be required. If significant discomfort or palatal edema, or erythema is noted by the patient, they should be evaluated for infection and oral antibiotics considered.

Coblation, or "cold ablation," is a form of submucosal bipolar RF energy delivery. It operates at a lower energy level than RFTA (frequency range of 100 kHz and voltage of 100 to 300 V). It does require an isotonic field from saline to generate the voltage differential and subsequent reduction in tissue size by molecular disintegration. A long, thin, submucosal lesion is produced surrounding the coblation zone along the probe (*Arthrocare ENT, Sunnyvale, CA*). Palatoplasty technique can be with a single or multiple directional passes on sites in the soft palate. Comparison to other snoring procedures has been reported with comparable results and complication rates (85). Coblation techniques have also been applied to the inferior nasal turbinates with a desire for volumetric reduction and decreased NAO. Office-based use of this technique is also possible.

Injection Snoreplasty

In 2001, Drs. Brietzke and Mair (86) introduced a simple, cost-effective procedure known as snoreplasty. They found it to be highly effective in the majority of patients with easy application in the office setting. Their original procedure was developed using sodium tetradecyl sulfate (STS), but this is not always commercially available. Subsequently, other substances have been utilized including ethanol, polidocanol, and ethanolamine oleate. After the application of a topical anesthetic using spray or gel, the STS or a 50 to 50 combination of 2% lidocaine and 98% dehydrated ethanol is injected. It is typically applied as a single, midline palatal injection in the submucosal plane with a 27-gauge 1.5-inch needle. The total volume is typically 1.5 to 2.0 mL. The base of the uvula should not be injected as this may cause significant swelling. The injection should also not be in the deep muscular plane. This could theoretically lead to a greater chance of palatal fistula and increased discomfort. The submucosal plane is targeted with expected mucosal sloughing and subsequent development of scarring over the next 4 to 6 weeks. If repeat injections are needed, roughly 10% of the time, the lateral areas of the soft palate are treated approximately 6 weeks later. For patients with a strong gag reflex, they can be asked to hum, elevating their soft palate with simultaneous injection of the agent.

Postoperative management is straightforward with moderate discomfort at the most for 1 to 3 days typically. Throat lozenges, acetaminophen, or ibuprofen as needed along with regular diet as tolerated and no steroids or antibiotics are the typical instructions given. Snoring may worsen temporarily and mucosal breakdown is expected. Follow-up is typically scheduled for 4 to 6 weeks.

An initial short-term success rate of around 80% was reported in unselected patients (86). Subsequent preoperative evaluation with acoustical analysis of snoring yielded better results with patient selection (78). Additional studies with other agents and application patterns along with comparisons to other procedures have demonstrated similar results for this simple in office procedure (87,88).

Pillar Soft Palate Implants

An additional procedure that lends itself well to the office setting with local anesthesia is the placement of Pillar implants into the soft palate. The braided polymer implants can be inserted in the office under local anesthesia. The 18 mm long by 1.5 mm round implant is designed to be placed near the junction of the hard and soft palate. The implants are deployed into the muscular layer of the soft palate using the single use delivery tool. Two additional implants are placed in parasagittal locations of the soft palate approximately 2 mm on each side. Preparation for the procedure includes the administration of a preoperative antibiotic dose and use of local anesthetic. The potential advantages with this procedure are there is potentially less pain than other palatal procedures and it could in theory have a long-term effect if extrusion does not occur. Patient selection is important. Patients with a long soft palate and uvula, narrow transverse distance between the posterior pillars, significant nasal obstruction, and snoring from the pharyngeal tissues or large tongue base would not be good candidates.

There are over a dozen articles in the literature that evaluate the response in snoring patients both with short-term and long-term follow-up. Additional studies can be found regarding the response for mild OSA and in combination with other procedures including UPPP, hypopharyngeal procedures, and CPAP use. Short-term efficacy for the reduction of snoring at 90 days was statistically significant in several studies. Long-term results defined as 12 months have also shown (89–93). An extrusion rate of 20% was noted in some of the studies; however, when this was analyzed separately, it was felt that no increase in snoring resulted if two of three implants remained in position (91,94). Despite short-term benefit which was statistically significant in several studies, a trend toward relapse has been noted long term (94,95). Studies for the treatment of mild to moderate OSA have shown limited effectiveness overall to this point (96) and of no benefit in reducing pressure needed or the improvement of compliance when combined with CPAP (97).

Anterior Palatoplasty

In 2000, the cautery-assisted palatal stiffening operation (CAPSO) was reported with a short-term efficacy of around 92% and long-term (12 months) of 77% (98). The simple

office procedure for the treatment of palatal flutter snoring could be done under local anesthesia. Complications were less than 1% and included bleeding, transient velopharyngeal insufficiency (VPI), and dry mouth. Pain can be significant in some patients; however, as the demucosalized area of the soft palate heals by secondary intention.

A modification of this technique was published in 2007 for use in patients with snoring as well as mild to moderate sleep apnea (99). The procedure now known as anterior palatoplasty has been reported to have long-term benefit approximately 3 years out (100). The advantages of the procedure versus the original CAPSO are that the postoperative morbidity in one authors experience is significantly reduced. In addition, for patients with an obliquely oriented or long, redundant soft palate with extensive posterior pillar webbing and demonstrating retropalatal collapse or palatal flutter snoring, a favorable response can be achieved with low morbidity. (*For a demonstration of the procedure in the clinical setting, please refer to the online video.*)

CONCLUSION AND HIGHLIGHTS SECTION

Surgical treatments for patients with OSA continue to evolve. Select patients may benefit from a single procedure, but in the majority of adult patients, multiple sites contribute to the decreased luminal patency during sleep in patients with OSA. The nasal airway can be a critical component of airway collapse because of upstream resistance. Improved quality of sleep, compliance with other medical therapies including nasal CPAP, and improved OSA parameters have been shown in patients following nasal surgeries. A variety of palatal procedures exist for OSA and snoring. Multiple publications describe variations of the original Fujita UPPP technique and attempt to address observed anatomy among select patients. Newer techniques do provide some promising results based on improved selection of patients and airway phenotypes. Staging systems introduced by Friedman and others highlight the need for palatal surgeries to be combined with other surgeries of the airway in many cases. Snoring procedures are primarily based on reducing the social disruption from palatal flutter and vary primarily based on invasiveness, morbidity, and cost. More recent data suggest that the presence of snoring may associated with increased mortality and other health risk.

Studies evaluating a single or combination of procedures including those of the nasal and palate are difficult to compare because of wide variability in techniques. Standardization of outcomes and study parameters has been proposed to improve the understanding and role of surgery in populations of patients with OSA (101). Although the AHI and other sleep parameters are common outcome measures previously reported, newer studies have highlighted the positive impact surgery can have on quality of life (9). Additional research beyond select case series is needed to compare the effectiveness of surgery on morbidity and mortality, outcomes from various techniques, and ability to improve outcomes based on patient selection. Outcomes beyond the traditional measures of AHI should be included. It must also be recognized that OSA is a chronic disease and remittance is common. Continued follow-up for patients is not uncommon. Improved airway phenotyping and selection systems along with identification of a genetic basis for OSA may lead to improved results in the future.

HIGHLIGHTS

- Palatal surgery for OSA continues to evolve from the original UPPP that was published by Fujita. No single procedure has proven to be successful for all patients. Limited controlled trials exist which compares the various techniques.
- The interaction between respiratory control, arousal thresholds, neuromuscular tone, and transmural pressure in the pharynx combines to effect to the patency of the airway during sleep.
- A key component of the evaluation of patients with snoring is to rule out the presence of OSA. More than half of patients who present with snoring as a complaint will have OSA.
- Surgery of the upper airway may be beneficial as a single therapy in select patients but often requires manipulation of multiple sites or levels of the airway.
- Nasal and palatal surgery may serve as an adjunctive treatment to other medical therapies including the continued use of CPAP.

138 Hypopharyngeal and Skeletal Surgery for OSA

Eric James Kezirian *Edward M. Weaver*

Obstructive sleep apnea (OSA) results from a combination of numerous factors related to anatomy, airway dilator muscle activation, ventilatory control, lung volumes, and arousal threshold, with wide variation in the specific factors involved for affected individuals (1). Surgical OSA treatment is designed to alter upper airway anatomy and/or collapsibility, and a key goal of surgical evaluation is the determination of the anatomical factors that contribute substantially to obstruction in an individual patient. One approach divides the upper airway into three regions: the nasal, retropalatal, and so-called hypopharyngeal (also called retrolingual or retroglossal) (2). Another approach divides anatomy into skeletal (the box) and soft tissue (the contents) components that impact the airway. In OSA, obstruction often occurs in more than one of these regions and may be related to both bony and soft tissue components.

While all regions and components of the airway are evaluated together and integrated, this chapter presents aspects of patient evaluation relevant to hypopharyngeal procedures and skeletal surgery and then presents these procedures with their reported outcomes and risks.

OSA SURGICAL EVALUATION

A thorough history and physical examination are the foundation of any surgical examination, but there are specific components and possible additional studies that have particular relevance to hypopharyngeal and skeletal surgery. As is true for nasal and palatal surgery, the examination must evaluate the anatomical factors that can contribute substantially to upper airway obstruction. Hypopharyngeal procedures are ultimately directed at one or more of the structures that can produce hypopharyngeal obstruction: the oropharyngeal lateral walls, tongue, and epiglottis. In contrast, skeletal surgery enlarges airway dimensions along the entire length of the pharynx without a specific focus on individual structures.

The role of the history in detection of hypopharyngeal obstruction is limited, as no studies have indicated that any of the common OSA signs and symptoms are unique to hypopharyngeal obstruction. The same is true for sleep study results, as the apnea–hypopnea index (AHI) has not shown a consistent or strong association with patterns of obstruction or specific involved structures. However, these evaluations help determine the severity of OSA and its burden and, therefore, the aggressiveness of treatment.

In contrast, physical examination can identify factors that can be highly suggestive of hypopharyngeal obstruction. Table 138.1 lists some evaluation techniques that have been used for pharyngeal examination, with the goal of characterizing the pattern of airway obstruction. Because obesity and weight gain are well-established risk factors for OSA (1), measurement of the height and weight (with calculation of body mass index (BMI), a commonly used but crude measure of obesity) is an essential component of physical examination, as is questioning about changes in body weight and an association with signs or symptoms in the patient history. There are multiple mechanisms that may explain the association between increased body weight and OSA, including an increase in soft tissue mass surrounding the pharyngeal airway and decreased lung volumes that develop with increases in body weight. Magnetic resonance imaging (MRI) studies have demonstrated that weight loss results in a decrease in lateral pharyngeal wall volume (3). Increases in body weight may also result in fat deposition within the tongue base, based on a higher fat content of that tissue, relative to other portions of the tongue, shown with computed tomography (CT) (4) and a correlation between BMI and fat content of the tongue base that was notably stronger than for other parts of the tongue (5). BMI and changes in body weight are major

TABLE 138.1 AIRWAY EVALUATION TECHNIQUES

Necessary
- Awake physical examination
- Awake fiberoptic endoscopy

Adjuvant
- Plain film radiography, including lateral cephalometry
- Computed tomography
- Magnetic resonance imaging
- Airway pressure monitoring
- Acoustic techniques, including acoustic pharyngometry and flextube reflectometry
- Drug-induced sleep endoscopy

factors in treatment outcomes, and these are discussed later in this chapter.

In addition to measurement of body weight and BMI, visual examination of the oral cavity, including the tongue, tonsils, mandible, and lateral pharyngeal walls, can prove invaluable. The modified Mallampati position reflects absolute tongue size, soft palate length, and the dimensions and position of the mandible (which define the space for the tongue) (6,7). The combination of modified Mallampati position, tonsil size (according to the Brodsky classification), and BMI enables classification according to Friedman stage, which has demonstrated a stronger association with outcomes after uvulopalatopharyngoplasty (UPPP) with tonsillectomy than the AHI has (6,8). The improvement in outcomes for a combination of hypopharyngeal surgery (submucosal tongue radiofrequency) and UPPP with tonsillectomy, compared to UPPP with tonsillectomy alone, in Friedman stage II and III patients (9) suggests that these groups have at least some component of hypopharyngeal obstruction and that the Friedman stage can play an important role in considering hypopharyngeal procedures.

The position and dimensions of the mandible and dentition can contribute to OSA and affect treatment outcomes. The mandible is an important component of the bony framework housing the soft tissues surrounding the upper airway, and both retrognathia and mandibular deficiency/insufficiency compromise the airway, particularly the hypopharyngeal airway. Examination of the mandible can occur with direct inspection, indirect evaluation based on the dental occlusion, or imaging studies. Direct inspection is the simplest technique. Dental occlusion is commonly defined by the Angle classification comparing the position of the mesiobuccal cusp of the maxillary first molar to the buccal groove of the mandibular first molar. This can reflect the mandible position and size relative to the maxilla, but two limitations are that the Angle classification can be affected substantially by dental and orthodontic treatment, including dental extractions, and that relative position and size of the mandible may not be as important as absolute measures (also true for the maxilla). Multiple imaging modalities can assist in evaluation of the mandible, and of these, lateral cephalometry has been studied most extensively in OSA. Although somewhat limited as a two-dimensional assessment of the airway, lateral cephalometry can image multiple aspects of bony and soft tissue anatomy. Individuals with OSA and normal BMI have demonstrated retrognathia (decreased sella–nasion–mandible B point angle, or SNB angle), a narrowed space between the tongue base and posterior pharyngeal wall (posterior airway space), and an increased distance between the mandible and hyoid bone (mandibular plane–hyoid distance) (10). Findings of lateral cephalometry have also demonstrated an association with outcomes after certain hypopharyngeal procedures, and these findings are discussed later in this chapter.

There is no standardized or objective assessment of the lateral pharyngeal walls during physical examination. Subjectively, certain factors may suggest a greater contribution of the lateral walls to airway obstruction: their thickness (determined indirectly by visual inspection of the pharyngeal aspect), folds or redundancy in the mucosa covering the underlying musculature (suggesting increased thickness and/or tissue laxity), and any narrowing of the transverse dimensions of the pharyngeal airway that can occur with thickened walls. MRI offers the most detailed assessment of the lateral pharyngeal walls, but currently it is used solely for research purposes. Improved methods for examination of the lateral pharyngeal walls will likely contribute substantially to understanding OSA and treatment outcomes.

Awake fiberoptic endoscopy is an invaluable tool for evaluating not only the nasal and retropalatal regions but also the hypopharyngeal region. Indirect laryngoscopy can inspect the larynx and tongue base, but its use in OSA is limited for three reasons. First, many individuals with OSA have a large tongue that impairs visualization of the hypopharynx due to physical blockage of the line of sight and/or increased likelihood of triggering a gag reflex. Second, indirect laryngoscopy requires mouth opening and tongue retraction, both of which disturb the natural anatomy of the hypopharyngeal airway. Third, it does not allow visualization of the hypopharyngeal airway under varying clinical states. Fiberoptic laryngopharyngoscopy enables a more-detailed evaluation of the hypopharyngeal airway and the individual structures surrounding it under various conditions, making it a mainstay of hypopharyngeal evaluation. The airway caliber, site of narrowing, and surrounding structures (tongue base, lateral walls, and epiglottis) can be seen under conditions such as mouth open versus closed, during snoring versus restful breathing, inspiration versus end-expiration, upright versus supine, mandible advanced forward versus neutral position, and with increased negative intrathoracic pressure (Muller maneuver). The Muller maneuver can be performed during awake endoscopy, but there are no reported studies related

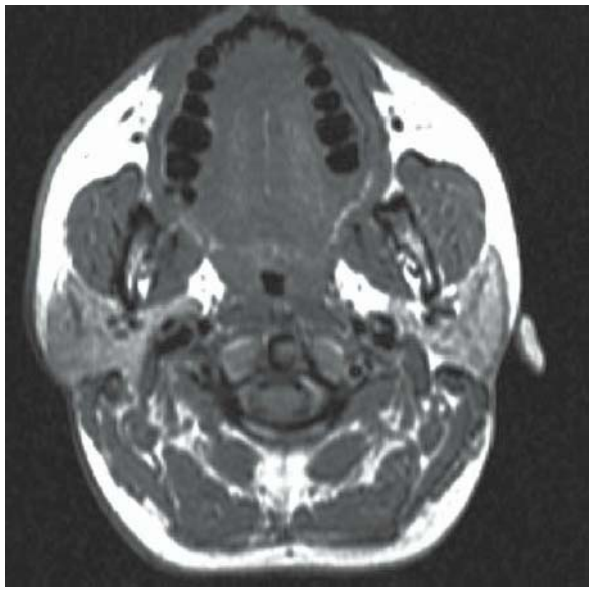

Figure 138.1 Axial T2-weighted MRI showing narrow hypopharyngeal airway posterior to the tongue base.

to hypopharyngeal procedure selection or outcomes. Subjective evaluation of airway dimensions and structures using endoscopy can provide important and useful information (11), but there are currently no commonly used, standardized, and objective measurements.

Studies based on MRI (Fig. 138.1) (12) and CT (4), in addition to a number of other modalities such as acoustic methods, airway pressure sensing, optical coherence tomography (13), and computational fluid dynamics (14), have provided a greater understanding of anatomical abnormalities among individuals with OSA and, to some extent, outcomes after palate procedures. Thus far, they have largely been limited to research purposes or surgical planning. However, these studies have important limitations for this discussion, for three reasons: most of these studies have been performed during wakefulness, they have generally characterized all hypopharyngeal region obstruction as similar without differentiation among possible subtypes, and, other than the lateral cephalogram, they have not been examined for a possible association between imaging findings and outcomes after hypopharyngeal procedures or skeletal surgery. The first two limitations are discussed here.

Airway examination during wakefulness—whether physical examination, endoscopy, or imaging—has important limitations related to the physiologic changes that occur during sleep, such as the marked decrease in genioglossus muscle tone that occurs at sleep onset (15) and the further decrease in rapid eye movement (REM) sleep (16). Of course, individuals with OSA demonstrate airway obstruction only during sleep, often with increased frequency during REM sleep. The implications for evaluation of hypopharyngeal airway obstruction (especially that related to the tongue) may be substantial. Although awake evaluation, especially office examination, generally has relatively low cost, there are likely important differences between examinations performed during wakefulness and sleep, and further investigation will elucidate how important those differences are.

Multiple investigators have studied the airway under conditions of anesthesia, including drug-induced sleep endoscopy (DISE) (17), originally described as sleep nasendoscopy in 1991 (18). The continuum of sedation ranges from wakefulness to conscious sedation to unconscious sedation to general anesthesia, and DISE involves endoscopic examination of the pharyngeal airway during unconscious sedation. While unconscious sedation under propofol may not be a perfect simulation of natural sleep, with identical effects on upper airway collapsibility, pharyngeal dilator muscle activity during DISE appears to lie somewhere between natural non-REM and REM sleep (15,16,19,20). DISE findings have suggested that there may be multiple subtypes of hypopharyngeal region obstruction; during unconscious sedation, individuals with OSA generally have one or more of the following structures contributing to hypopharyngeal obstruction: the oropharyngeal lateral walls, tongue, and/or epiglottis (Figs. 138.2 to 138.4, respectively) (17,21). Although hypopharyngeal procedures are ultimately directed at specific structures (including these three), it remains unclear whether this diversity of patterns within the broader category of hypopharyngeal obstruction has implications for outcomes of surgical and nonsurgical treatment (i.e., whether tongue-directed procedures work better in individuals with tongue-related hypopharyngeal obstruction than in those with obstruction more related to the oropharyngeal lateral walls or epiglottis). It is possible that alleviation of one source of airway narrowing/obstruction

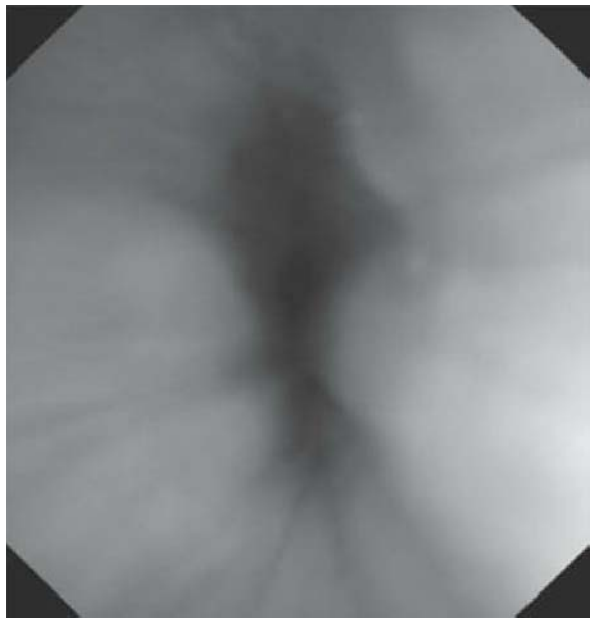

Figure 138.2 Oropharyngeal lateral wall collapse during DISE.

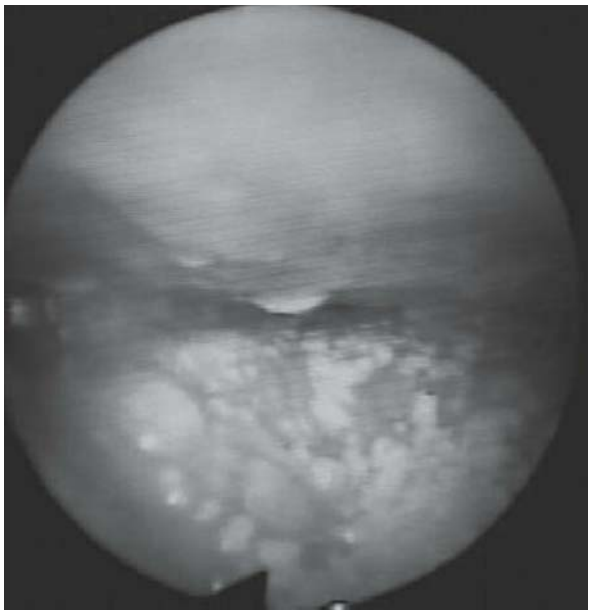

Figure 138.3 Tongue base prolapse during DISE.

may alleviate that from others, for example, by reducing resistive Bernoulli forces. Thus, the interaction of anatomy, physiology (e.g., depth of sleep, collapsibility, and ventilatory control), airflow dynamics, and conditions (e.g., body position) is complex. At a minimum, the grouping of all hypopharyngeal region obstruction together, as has occurred with most evaluation techniques, does not capture this diversity. Although DISE findings have demonstrated an association with outcomes for palate surgery (22,23), similar evaluations have not occurred for hypopharyngeal procedures.

Figure 138.4 Epiglottic prolapse (anteroposterior) during DISE.

The importance of preoperative evaluation—and the association between findings of the preoperative evaluation and surgical outcomes—cannot be overemphasized. The next section discusses outcome assessment, followed by the available hypopharyngeal procedures and skeletal surgery and their reported outcomes, highlighting the factors that may be apparent during preoperative evaluation that have shown an association with outcomes, as well as their risks.

OUTCOME ASSESSMENT IN OSA SURGERY

It remains unclear how best to measure treatment outcomes for sleep apnea (24). Treatment should address primarily clinical outcomes, such as mortality, cardiovascular disease, motor vehicle crashes, daytime function, symptoms, and quality of life deficits. Surrogate measures of treatment outcome, like sleep study parameters (such as the AHI) and inflammatory markers, are important if they translate into clinically important effects. Unfortunately for patients diagnosed with sleep apnea, improvements in sleep study parameters do not necessarily translate directly into all the desired outcomes (25). Whenever possible, clinical outcomes should be measured primarily in preference to surrogate outcomes (26). Table 138.2 highlights clinically important outcomes, while Table 138.3 lists common surrogate outcome measures.

Sleep Testing Outcomes

Surgical treatment often does not physiologically cure sleep apnea (i.e., permanently normalize the AHI). This fact has left some people to suggest that surgical treatment too often fails (27–29). This view neglects the risk to patients who are otherwise inadequately treated. When considering surgical outcomes, one must view them in the context of outcomes from alternative therapies for each patient (24).

Although continuous positive airway pressure (CPAP) at the optimal pressure determined in the sleep laboratory dramatically improves physiologic measures, this is not the case for all patients (30) and often does not completely normalize the AHI (31). Moreover, the physiologic

TABLE 138.2 CLINICAL OUTCOMES

- Mortality risk
- Cardiovascular disease and events
- Motor vehicle crashes
- Symptoms
- Daytime function
- Quality of life (patient and partner)

TABLE 138.3 EXAMPLES OF SURROGATE OUTCOME MEASURES

- Sleep study parameters
  - Apnea-hypopnea index
  - Oxygenation parameters
  - Arousal indexes
- Physiologic measures, such as airway collapsibility (critical airway closing pressure)
- Inflammatory markers

improvement with CPAP depends on the duration of use during sleep time. The minimum usage needed to consider CPAP physiologically successful is unknown (30). The current standard of 4 hours per night on over five nights per week (32) is probably inadequate (33). This minimum threshold amounts to 20 hours of use per week (4 hours per night × 5 nights per week), covering just 37% of the recommended 56 hours of sleep time per week (8 hours per night × 7 nights per week). Indeed, emerging data indicate a monotonically increasing dose–response relationship between the amount of average nightly CPAP use and its effect on improving clinically important outcomes like subjective sleepiness, objective sleepiness, and functional outcomes (34). Likewise, 5-year survival increases with the amount of CPAP use, with the best outcome achieved with more than 6 hours of average nightly use (35).

Because the AHI defines OSA, it is the most common primary OSA treatment end point for clinicians and in research studies. However, other sleep study parameters may be more reliable and physiologically more important (e.g., apnea index, desaturation index, percentage of sleep time with oxygen saturation below 90%). The use of AHI for outcome assessment is complicated by the variation in definitions of respiratory events (especially for hypopneas) over time and the multiplicity of definitions proposed in guidelines (36,37); the result is that notable differences exist across sleep laboratories and for different studies.

The large majority of studies for hypopharyngeal surgery and skeletal surgery are case series, and there have been attempts to compare results across procedures or, for hypopharyngeal procedures, the combination of soft palate surgery and a hypopharyngeal procedure (38–40). Because most studies of OSA surgery report AHI outcomes, these comparisons have focused largely on AHI and have examined the proportion of treated individuals who have achieved an arbitrary threshold "response" to treatment or "success," typically a reduction of at least 50% in the AHI to a level below 20 or 15 events per hour. However, this is a major oversimplification, as OSA treatment is not solely a number. Beware that the use of a single parameter in reporting trial outcomes oversimplifies the complexity of OSA disease burden and treatment outcome.

Clinical Outcomes

More important than the physiologic outcomes are the clinically important outcomes. Surgical treatment improves symptoms such as daytime sleepiness, quality of life, and daytime performance and function. One study of staged, multilevel surgical therapy compared to CPAP users showed similar symptoms and quality of life following treatment (41). Objective outcomes are possible for some clinical end points but can be cumbersome, expensive, or unavailable. Valid, reliable measures can evaluate subjective outcomes, with specific statistical and analytical approaches to evaluate potential placebo effects. Most of the research evaluating clinical outcomes in OSA surgery has focused on soft palate surgery, but there are a number of studies of hypopharyngeal surgery that have used validated measures of symptoms, daytime functioning, and sleep-related quality of life.

HYPOPHARYNGEAL PROCEDURES AND OUTCOMES

Hypopharyngeal procedures can be differentiated based on whether they are designed either to increase tissue tension to reduce collapsibility or to decrease tongue tissue volume and whether they are directed at the tongue, epiglottis, and/or, in some cases, the lateral pharyngeal walls. Overall, these procedures can be grouped into three categories, presented in Table 138.4.

Summary of reported outcomes for these procedures, generally when performed in combination with palate surgery, are presented in Table 138.5. One striking finding is that all hypopharyngeal procedures or procedure categories have a wide range of reported outcomes both for an overall case series and for individual subjects within each series. This likely reflects the importance of subject-specific characteristics that are not immediately apparent in these case series reports. This chapter discusses factors that have been associated with outcomes, but future investigations

TABLE 138.4 HYPOPHARYNGEAL PROCEDURES

- Tongue Advancement/Stabilization
  - Genioglossus advancement and mortised genioplasty
  - Hyoid suspension
  - Tongue stabilization suture
- Tongue Reduction
  - Submucosal radiofrequency reduction
  - Midline glossectomy
  - Lingualplasty
  - Hyoepiglottoplasty
  - Lingual tonsillectomy
- Epiglottis Correction
  - Hyoid suspension
  - Epiglottoplasty

TABLE 138.5 SUMMARY OF OUTCOMES OF HYPOPHARYNGEAL PROCEDURES[a]

	Response (AHI)		Range of Response Rate in Individual Series	Daytime Sleepiness	Quality of Life	Association with Outcomes
Genioglossus advancement (43–47)	57%	70/122	39%–78%			BMI
Mortised genioplasty (48)	48%	16/33				BMI, AHI
Hyoid suspension (49–55)	58%	174/300	18%–78%	Improved[a]		BMI? LSAT?
Genioglossus advancement + hyoid suspension (46,47,54,56–68)	55%	342/620	24%–78%	Improved		BMI, AHI
Tongue stabilization suture (69–79)	54%	116/216	20%–82%	Improved	Improved	BMI, technique
Submucosal tongue radiofrequency (9,70,71,80–99)	49%	408/868	20%–81%	Improved[a]	Improved[a]	Technique, FS; ±AHI
Tongue reduction procedures (other than submucosal radiofrequency) (100–112)	50%	60/121	25%–83%			BMI
Epiglottoplasty (113)	78%	21/27				

FS, Friedman stage; LSAT, lowest oxygen saturation on sleep study.
Note: Most subjects in these studies underwent previous or concurrent soft palate surgery.
[a]A single study or small minority of studies do not show improvement.
[?]Possible association with outcomes, based on some studies showing an association, with other studies showing none.

can enhance procedure selection with greater focus on examination of these factors and more standardization in the reporting of outcomes of surgical trials (42).

The tongue advancement and/or stabilization procedures include genioglossus advancement, mortised genioplasty, hyoid suspension, and the tongue stabilization suture. These can be performed in isolation or concurrently with palate or other hypopharyngeal procedures.

Genioglossus advancement (Fig. 138.5) involves creating an anterior mandibular osteotomy to capture the insertion of the genioglossus muscle at the genial tubercle, advancing the bone fragment 10 to 20 mm (often the thickness of the mandible) and thereby increasing tension on the genioglossus muscle (114). With the decrease in genioglossus muscle tone that occurs during sleep, this increased muscle tension can reduce tongue prolapse that can narrow the hypopharyngeal airway. Mortised genioplasty is a variation that includes a portion of the inferior border of the anterior mandible, advancing the bone fragment to increase tension on not only the genioglossus muscle but also the digastric and mylohyoid muscles;48 there is less advancement of the bone and muscle attachments in this procedure, as instead of advancing the osteotomized bone fragment the entire thickness of the mandible (as in genioglossus advancement), typically some bony overlap along the osteotomies is maintained to facilitate healing. Outcomes for these procedures appear to be improved in individuals with BMI below 30 kg/m^2 and those with lower AHI (45,46,48). Risks of genioglossus advancement and mortised genioplasty include hematoma, incisional dehiscence and infection, dental injury, dental numbness or paresthesias, mental nerve injury, and mandible fracture (115).

The human hyoid bone is uniquely mobile, and its attachments to adjacent muscles (hyoglossus, mylohyoid, digastric, sternohyoid, thyrohyoid, and middle pharyngeal constrictor) and ligaments (hyoepiglottic and stylohyoid) led to the development of the hyoid suspension procedure. Specifically, the attachments of the hyoid bone to the inferior tongue base (hyoglossus), epiglottis (hyoepiglottic ligament), and lateral pharyngeal walls (middle pharyngeal constrictor) suggest that the hyoid suspension procedure may help stabilize the hypopharyngeal airway. The hyoid suspension procedure (Fig. 138.6) advances and stabilizes the hyoid bone to the thyroid cartilage (116) or, through some tethering material, to the inferior border of the mandible (62); it remains unclear which technique is preferable, as these have never been compared side by side. Outcomes for hyoid suspension as a sole surgical treatment for hypopharyngeal obstruction appear to be improved for subjects with BMI below 30 kg/m^2 (although this comes from a comparison of different studies only) and those with lower AHI (49–55). Hyoid suspension has resulted in improved control of symptoms such as daytime sleepiness, measured by the Epworth Sleepiness Scale (ESS) (49,50,52,54,55,117). Risks of hyoid suspension include seroma or hematoma, infection, dysphagia (via local edema and/or injury of the superior laryngeal or hypoglossal nerves), hyoid fracture, suspension material breakage, or pharyngocutaneous fistula (115).

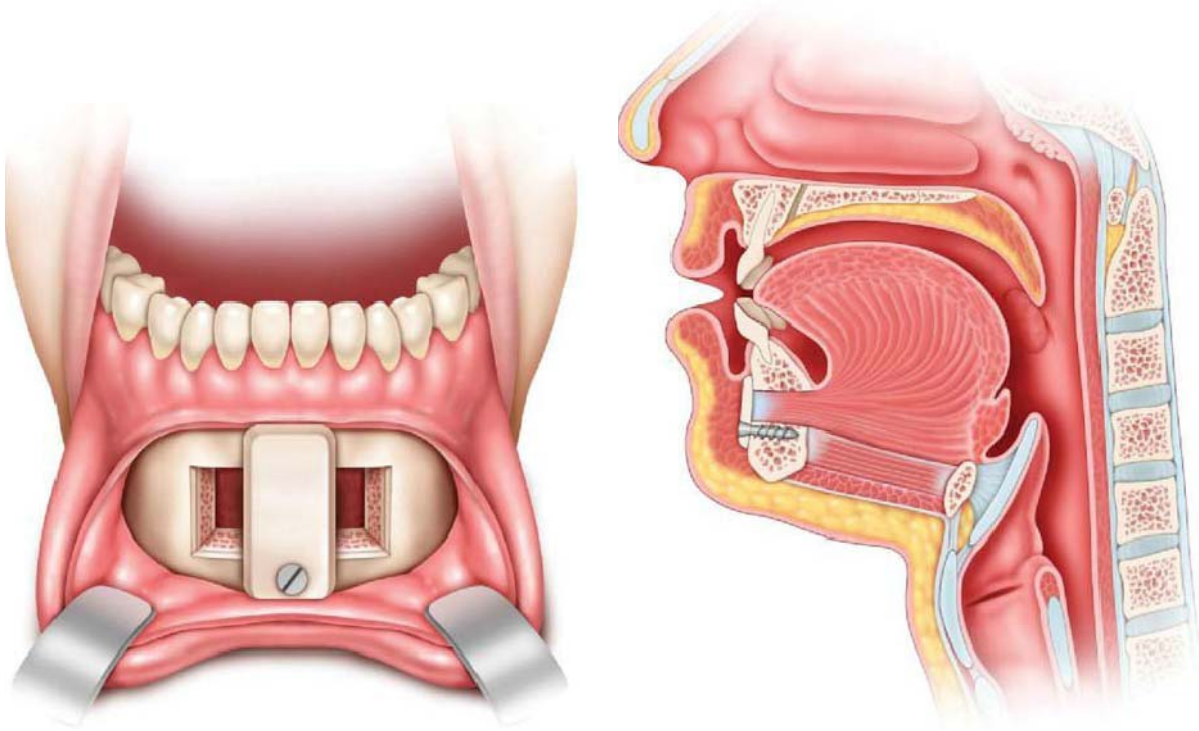

Figure 138.5 Genioglossus advancement procedure. On the **left**, an anterior view shows the mandibular osteotomy with fragment advanced, rotated, and secured inferiorly. On the **right**, a sagittal view demonstrates the advanced position of the genioglossus muscle insertion. (Reprinted with permission of www.sleep-doctor.com)

Outcomes for the combination of genioglossus advancement and hyoid suspension as treatment of hypopharyngeal obstruction have been reported. Some studies demonstrated an association between improved outcomes in subjects with lower BMI (generally below 30 or 32 kg/m^2) (47,57,59,62,66,68), lower AHI (46,47,57,59,61), and greater SNB angle on lateral cephalometry (47,60), although the associations were not seen in all studies (56,60,65,68). Concerning clinical outcomes, studies have also shown a decrease in daytime sleepiness (ESS) (56–59,61,63,65–67,97,116) and improvements in sleep-related quality of life (68).

Tongue stabilization involves securing a suture to the anterior mandible and then passing that suture though the tongue base to tether it and reduce its ability to obstruct the airway when muscle tone decreases during sleep. Outcomes appear to be improved with lower BMI (generally below 29 or 30 kg/m^2) (70,76,79) and the degree of suture tightening (74). Risks include those related to placement of the fixation screw in the anterior mandible (dental injury or numbness), passage of the suture towards and through the tongue base (sialadenitis and injury to the lingual or hypoglossal nerves), or the degree of suture tightening and the related tethering of the tongue (suture breakage or migration, dysphagia, and dysarthria) (115). Tongue stabilization studies have shown a decrease in daytime sleepiness (ESS) (70,71,75,77,79,98) and improved sleep-related quality of life (98).

Tongue reduction procedures improve the retrolingual airway by decreasing tongue tissue volume. This can be accomplished either with direct tissue removal or with submucosal radiofrequency treatment that creates tissue injury and reduces tongue volume indirectly through fibrosis. Submucosal tongue radiofrequency (Fig. 138.7) involves creation of a submucosal scar with the bulk of the tongue itself that stiffens the tissue and reduces tongue volume by a mean of 17% after five treatment sessions (91); the changes in tissue characteristics that occur with fibrosis may also increase tongue tension and reduce tongue prolapse during sleep. Submucosal radiofrequency is less invasive than direct tissue resection, which translates into simpler recovery but, in general, lower effectiveness than the surgical excision techniques. Outcomes are presented in Table 138.5, and a number of studies have demonstrated that submucosal tongue radiofrequency improves daytime sleepiness (ESS) (70,71,82–85,87,89–95,98,99) and sleep-related quality of life (91,93,95,98,99).

Most published submucosal tongue radiofrequency case series studies have subjects with a mean BMI below 30 kg/m^2, a group that may be easier to treat due to less tongue volume at baseline (5). That being said, as opposed to other hypopharyngeal procedures for which the literature consists almost exclusively of case series or randomized pilot studies, higher-level evidence demonstrates the benefits of submucosal tongue radiofrequency. In a double-blinded, sham/placebo-controlled randomized trial of subjects with mild to moderate OSA, active submucosal tongue (combined with palate) radiofrequency produced improvements in the apnea index, daytime sleepiness, reaction time, and quality of life, with improvements similar to CPAP and even greater 2 years after treatment than at 6 months (99,118). In another study comparing isolated soft palate surgery to the combination of soft palate surgery and submucosal tongue radiofrequency, results were improved with the addition of submucosal tongue radiofrequency for both Friedman stages II and III (85). For the published case series studies, outcomes are enhanced in those with lower Friedman stage (II vs. III) (85) and BMI below 29 kg/m^2 (90). Risks include mucosal ulceration; hematoma; infection, including abscess; injury of the lingual or hypoglossal nerves; and sialadenitis (115). One literature review suggested that the incidence of complications of moderate or major severity was 2.7% in total, with none occurring in a series from an experienced group (119).

Multiple procedure approaches enable direct tissue excision: midline glossectomy (midline trench in the tongue base) (103), lingualplasty (extends the tongue base dissection laterally) (108), submucosal minimally invasive lingual excision (midline excision from the tongue base and posterior oral tongue) (102,120), submucosal lingualplasty (midline and lateral removal of tissue from the tongue base and posterior oral tongue) (106), and hyoepiglottoplasty (transcervical resection of tongue base tissue, with hyoid suspension to the mandible's inferior border) (101). These procedures can reduce tongue volume considerably, and the resulting scar in the tongue base also likely reduces its collapsibility. Lingual tonsillectomy (Fig. 138.8) improves the airway by removing obstructing lingual tonsil tissue without resecting tongue base musculature. In the past, these procedures were performed with lasers or electrocautery. With the newer irrigating, suctioning, bipolar instruments, bleeding and collateral tissue damage are minimized, and morbidity is decreased considerably (121). Recently, lingual tonsillectomy (alone or in combination with epiglottic procedures, such as those outlined below) has been performed as transoral robotic surgery (111). Although the reported outcomes from tongue tissue excision procedures appear to be similar to other procedures (Table 138.5), it must be noted that these case series studies generally include subjects with BMI above 30 kg/m^2 and with moderate to severe OSA, a group that has largely shown poorer outcomes for the alternative procedures in the table. Risks of tongue excision procedures are similar to (but more likely than) those after tongue radiofrequency (115).

Posterior displacement or retroflexion of the epiglottis impairs the airway, and there are procedures to debulk or stabilize the epiglottis. Hyoid suspension, as noted above, tethers the epiglottis indirectly through its attachment to the hyoid bone via the hyoepiglottic ligament. Epiglottoplasty resects part of the epiglottis directly and can be accomplished via a transoral approach (122) or a

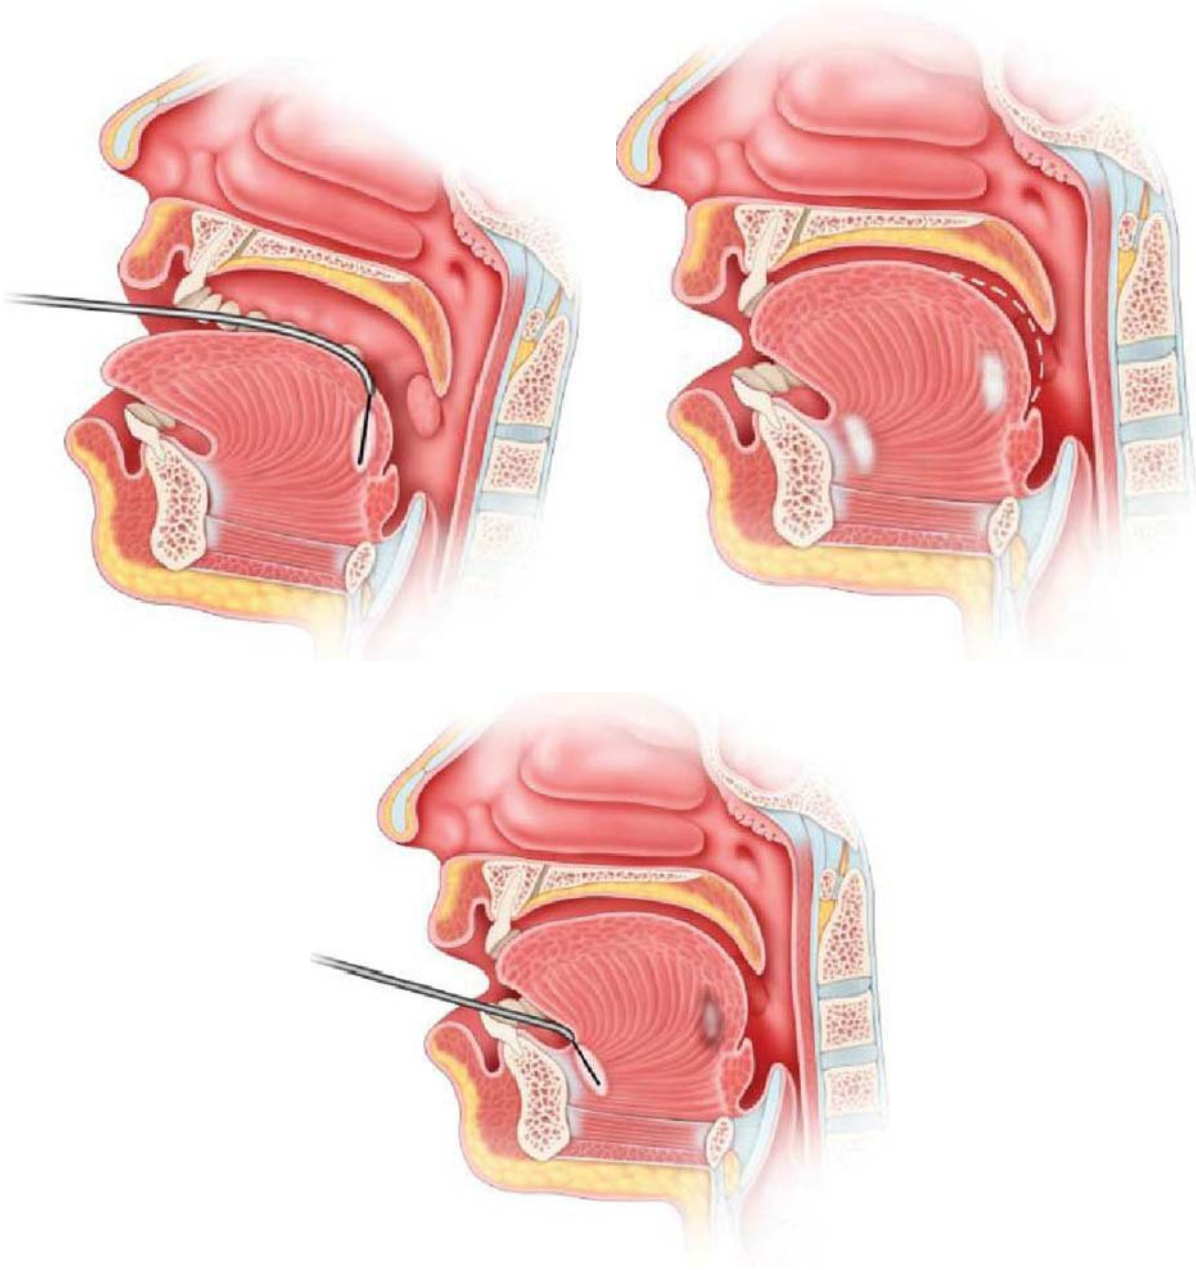

Figure 138.7 Submucosal tongue radiofrequency. Figures show the creation of tissue injury in the tongue base (**left**) and ventral tongue (**middle**), both of which heal with the development of fibrosis at these sites (**right**). (Reprinted with permission of www.sleep-doctor.com)

neck incision (typically as part of another procedure that may include tongue tissue resection, as hyoepiglottoplasty does). It is important to note that outcomes for epiglottoplasty reported in Table 138.5, while impressive, are from a single study with a highly selected group of subjects with low BMI (mean 23.4 kg/m^2) and a specific finding on fiberoptic endoscopy: posterior displacement of the epiglottis away from the tongue base (113). In addition to a low risk of bleeding, the most important risk of transoral epiglottoplasty is dysphagia due to potential compromise of the epiglottis function as a protector of the airway during swallowing.

SKELETAL SURGERY AND OUTCOMES

Maxillomandibular advancement (MMA, Fig. 138.9) projects forward the entire lower facial skeleton and attached soft tissues. The dental arches are either moved in unison to maintain baseline occlusion or moved differentially to correct a malocclusion (generally requiring pre- and postoperative orthodontics). This multilevel procedure stabilizes and improves the entire pharyngeal airway and thereby treats both the retropalatal and hypopharyngeal regions of the upper airway (and all structures that can contribute to obstruction). Awake endoscopy suggests that

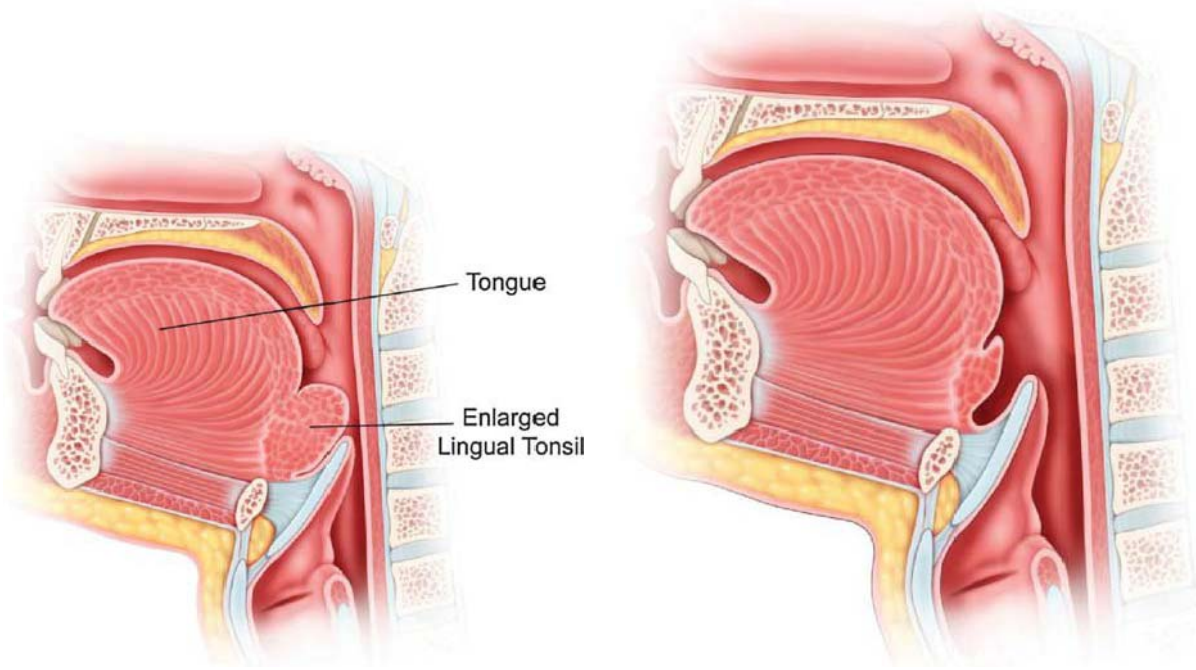

Figure 138.8 Lingual tonsillectomy. Sagittal views showing an enlarged lingual tonsil prior to excision (**left**) and following healing (**right**). (Reprinted with permission of www.sleep-doctor.com)

this treats the lateral pharyngeal walls by placing soft tissues under tension (123).

MMA can be performed as primary surgery, although because this is a major operation, it is typically performed as a secondary procedure for patients with persistent significant OSA following other site-directed surgical treatments (124). A recent metaanalysis found that reported studies showed that MMA was associated with an 87% reduction in the AHI, whether performed as primary or secondary surgery—although MMA was performed in combination with other airway procedures in some of the included studies (125). There are no higher-level studies of MMA, but the published case series studies (44,48,56,67,124,126–136) do demonstrate a more consistent improvement in AHI (although not a cure of OSA) (137) than for hypopharyngeal procedures. As with all procedures, MMA is technique dependent, with greater degrees of advancement associated with greater improvements in airway dimensions and improved outcomes (135). Published studies suggest that the improvements in AHI do persist over a relatively long period of time, except in individuals who gain significant body weight. In a long-term follow-up of 40 patients, Riley et al. (135) showed 90% success more than 4 years from surgery. Limited data suggest that MMA also improves certain clinical outcomes, whether quality of life (138) or daytime function, with improvements similar to a group undergoing treatment with positive airway pressure therapy (127). The risks of MMA include bleeding, infection, dental injury, dental and facial numbness, malocclusion, bony malunion or nonunion, change in facial appearance, and temporomandibular disturbance.

FUTURE RESEARCH

A major challenge for the field is to conduct definitive studies to test the effectiveness of current and future surgical interventions and to develop best strategies for surgical decision making. These studies should test adjunctive surgical treatments aimed at facilitating CPAP or oral appliance therapy, and they should test comprehensive surgical approaches for definitive therapy in the absence of CPAP or oral appliance therapy, ideally measuring long-term, clinical outcomes primarily. Both observational studies and definitive trials of high quality are desirable, as they are complementary (24).

There are unique challenges to designing and conducting ethical, randomized, double-blinded, sham/placebo-controlled trials for definitive, staged, anatomically tailored, invasive surgical interventions. Examples of challenges include difficulties providing an adequate placebo, blinding the surgeon and investigators, and obtaining long-term outcomes. Recruitment, generalizability, and cost will be difficult because it is the unusual patient who is willing to be randomized to or away from invasive therapy. The feasibility of randomized trials of surgical versus nonsurgical treatment is uncertain, as studies like this have often either failed in enrollment (139) or required federal mandates preventing surgery outside the trial (140). There are competing interests of providing surgical flexibility to reflect real-world surgical decision making (e.g., which variation of UPPP, what additional procedures to include, when and how to stage) on the one hand while standardizing the treatment protocols for methodologic purity on the other hand. Staging surgery, as is done in best practice, complicates trial design analysis by requiring repeated measures analysis and accommodating midstream crossovers. Comparing surgery to CPAP is not appropriate currently, because each treatment is offered to a different patient population in practice: CPAP is offered as first-line therapy, and surgery is offered to CPAP failures. Furthermore, testing differences between two treatments with similar effects requires particularly large sample sizes, which is especially challenging when enrollment is expected to be difficult as noted above.

These challenges are difficult, but surmountable. They will require a sophisticated group of researchers to design and conduct the studies, with major financial support and with study participation from community practitioners. Steps are underway to meet these challenges.

HIGHLIGHTS

- Individuals with OSA may experience airway obstruction in the hypopharyngeal region of the pharynx. Similarly, skeletal abnormalities may contribute substantially to OSA.
- Evaluation of the hypopharyngeal airway must include physical examination and fiberoptic laryngopharyngoscopy.
- Sleep testing outcomes are often used to measure the benefits of OSA treatment, but clinical outcomes are likely more important.
- A number of procedures are available to treat hypopharyngeal obstruction in OSA. Selection among them is based on an understanding of their mechanism of action and individual patient characteristics, among other factors.
- MMA surgery can be used as primary surgery or, more often, as a secondary procedure for those with residual OSA following previous site-directed procedures.
- High-quality observational studies or controlled clinical trials will help define the outcomes of surgical treatment for OSA. However, there are unique challenges to attempts at conducting these studies for hypopharyngeal procedures and skeletal surgery.

139 Pediatric Sleep-Disordered Breathing

Stacey L. Ishman *David F. Smith* *Sally R. Shott*

INTRODUCTION

Sleep-disordered breathing (SDB) represents a continuum of obstructive disease that encompasses a range of specific diagnoses including snoring, upper airway resistance syndrome, obstructive hypoventilation, and obstructive sleep apnea (OSA). OSA, itself, is characterized by increasing limitation of flow through the upper airway, sometimes resulting in complete obstruction of the airway. OSA presents differently in children than it does in adolescents and adults, and identification can be hampered by the fact that children are far less likely to complain about problems with sleep than adults. In many cases, parents or guardians will be the first to express concerns about a child's sleep, and they often highlight complaints of increased fatigue or sleepiness (hypersomnia), difficulty initiating or maintaining sleep (insomnia), sleeping in strange positions and restless sleep, or other abnormal behaviors that are recognized during the sleep cycle. For this reason, a thorough history provided by the caregivers, in addition to a complete physical exam, is essential for the assessment of pediatric sleep disorders.

Epidemiology

Many epidemiologic studies have sought to accurately identify the number of children in the United States (US) with SDB and OSA, as well as to identify the risk factors associated with both; however, these figures are highly variable. In a recent study, 3.2% to 34.5% of parents reported that their children snored often to always (1), while another notes that approximately 25% of children aged 3 to 12 years old snore (2). Most population studies indicate that 1% to 4% of children in the US have OSA (1). However, OSA seems to be more prevalent in the male gender (1), and SDB is strongly associated with low socioeconomic status. This relationship may simply reflect a higher body mass index (BMI) within this subgroup (3).

Ethnicity and genetic factors are also associated with a higher risk of SDB. Black children in the US are at an increased risk of developing OSA when compared to white children (4–7). Other studies utilizing validated questionnaires, polysomnography (PSG), or cephalometric measurements have verified a higher rate of OSA in black and Asian children (8–10). Airway obstruction and OSA may be missed in children with craniofacial anomalies unless specifically addressed as parents may assume that this is "normal" for their child. One study showed more than a doubling of OSA diagnoses when using a specifically applied sleep questionnaire in a group of children with Apert, Crouzon, and Pfeiffer syndrome (11). A full list of children at higher risk for OSA is presented in Table 139.1. SDB has also been associated with specific clinical risk factors including nightly snoring, caregiver witnessed apneas, male gender, exposure to cigarette smoke, and anatomic factors including adenotonsillar hypertrophy and obesity (12,13).

Consequences of OSA

Over the last decade, studies have sought to identify the long-term complications associated with SDB and OSA. Behavioral problems that can occur as a result of untreated OSA include hyperactivity, attention-deficit disorders, aggression, and poor socialization (2). Neurocognitive disorders linked to OSA include poor school performance and variable learning disorders, such as deficits in memory, learning, and problem-solving skills (2). Much of what has been learned over the last decade suggests that children with OSA are at a much higher risk to suffer from behavioral, neurocognitive, and emotional difficulties, as well as a decrease in quality of life (QOL). In fact, both neuropsychological behavior and QOL tend to normalize after the airway obstruction has resolved (14–16). Besides the host of behavioral and neurocognitive disorders, children with OSA for prolonged periods can suffer from cardiovascular

TABLE 139.1 CONDITIONS CAUSING AN INCREASED RISK OF SDB AND OSA IN CHILDREN

Syndromic	Nonsyndromic
Apert syndrome	Achondroplasia
Beckwith–Wiedemann syndrome	Cerebral palsy
Crouzon syndrome	Choanal atresia
Down syndrome	Cleft palate
Klippel–Feil syndrome	Lymphangioma
Pierre Robin sequence	Mucopolysaccharidosis
Pfeiffer syndrome	Obesity
Prader Willi syndrome	Pharyngeal flap patient
Treacher Collins syndrome	Recurrent respiratory papillomatosis

TABLE 139.2 FREQUENTLY WITNESSED SIGNS AND SYMPTOMS OF OSA IN CHILDREN

Daytime Symptoms	Nighttime Symptoms
Open-mouth breathing	Frequent loud snoring
Frequent nasal obstruction	Gasping or choking
Hyperactive behavior	Frequent nighttime sweating
Aggressive behavior	Witnessed apneas
Attention deficit disorder	Paradoxical breathing
Poor school performance	Frequent position changes/restless sleep
Daytime somnolence	Hyperextension of the neck
	Nocturnal enuresis

and pulmonary complications. Elevated systemic blood pressure has been found in children with OSA (17–21). More importantly, children with elevated blood pressures are more likely to suffer from hypertension and metabolic syndrome as adults (22). Although previous studies evaluating the association between primary snoring and increases in blood pressure in children have been somewhat conflicting (23–26), more recent data suggest that children with primary snoring have higher nighttime blood pressures when compared to those control patients without snoring (27). Further, a dose–response relationship exists between SDB and the severity of blood pressures in children (27). Although not fully understood, clear risks exist for those children with prolonged SDB.

DIAGNOSIS

History

The American Academy of Pediatrics (AAP) first recommended universal screening for snoring in 2002 (28). Although a PSG remains the most commonly recommended method for diagnosing SDB, a comprehensive "sleep history" is a vital clinical tool for evaluating the presence of SDB in children. This history, more often provided by caregivers, should include information about nightly hours of sleep, sleep hygiene, sleep latency, abnormal sleep behaviors, the presence and character of snoring, daytime behavior (including hypersomnia), behavioral disorders, and school performance. It is also important to understand napping behavior of children with suspected SDB.

Parents and caregivers routinely report witnessing nightly snoring, apneas, choking or gasping, increased work of breathing, hyperextension of the neck, restless sleep and night sweats, nocturnal enuresis, and parasomnias (Table 139.2). Commonly witnessed parasomnias include confusional arousals, sleep walking, and night/sleep terrors; however, the presence of these symptoms does not necessarily correlate with the presence of SDB in children. Caregivers may also report daytime symptoms including frequent mouth-breathing, chronic nasal obstruction, poor school performance, hyperactive behavior or attention deficit disorder, aggression, and less frequently, daytime somnolence (Table 139.2). Although hypersomnolence is present in some children with OSA, it is more commonly seen in adolescent and adult patients. For children with hypertrophic tonsils, caregivers may also report eating habits including avoidance of bulky foods such as meat.

While sleep questionnaires can be used in the office as a screening tool to identify children most at risk of having OSA and to acquire information about common symptoms associated with SDB and OSA (29–31), their use as a single tool to diagnose OSA has not been supported, thus they should only be used as an aid when pursuing a thorough sleep history. There are limitations to the accuracy of these data in differentiating SDB from OSA. In fact, parental reporting has been shown to be an inaccurate method of diagnosing OSA in children (30), and a recent meta-analysis of 12 articles that examined the accuracy of clinical assessment found that discrimination between primary snoring and OSA could not be precisely determined by parental reporting alone (32).

Physical Exam

Narrowing of the upper airway is the primary reason that children develop SDB and OSA. This may be the result of multiple factors including anatomic abnormalities, and thus, a complete head and neck exam is recommended. Identification of the anatomic location of the obstruction is necessary to tailor the appropriate treatment, especially in those children with multilevel obstruction.

A systematic approach to the physical examination is necessary so that no relevant findings are missed (Table 139.3). The exam should begin with evaluation of the general appearance of the patient, including height, weight, blood pressure, general craniofacial appearance, voice, and the presence or absence of mouth breathing. Voice abnormalities can be useful in identification of the location of

TABLE 139.3 SYSTEMATIC APPROACH TO THE PHYSICAL EXAMINATION IN A CHILD WITH OSA

General
- Vital signs including height, weight, blood pressure, BMI, and temperature
- General body habitus including obesity

Head and face
- Abnormal cephalic formation
- Abnormal facies

Nasal
- External deformity
- Nasal valve function
- Inferior turbinates
- Secondary areas of nasal obstruction
- Rhinorrhea
- Signs of allergic rhinitis

Oral cavity
- Dentition
- Tongue size and protrusion
- Hard and soft palate
- Uvula and posterior pharyngeal wall
- Tonsil grade
- Modified Mallampati score

Neck
- Neck size, including circumference
- Hyoid position, including submental-to-hyoid distance
- Tracheal position

Systemic
- Chest/lung exam including abnormal auscultation
- Cardiovascular examination
- Chest wall abnormalities

pathology. For example, a hyponasal voice can suggest enlarged adenoids, while a muffled voice can result from tonsillar hypertrophy. Care should be taken to perform a thorough cardiovascular exam including auscultation for any murmurs. Systemic findings including failure to thrive, cor pulmonale, and pectus excavatum should be considered (33). Special consideration is given to obesity and body habitus, especially in the adolescent patient. Finally, genetic and syndromal dysmorphisms should also be noted.

At the start of the exam, an overall assessment of head and neck shape and proportions should be performed. For example, midface hypoplasia is seen in Down syndrome and Crouzon syndrome, whereas mandibular hypoplasia is often seen in children with Treacher Collins or Pierre Robin sequence. Extensive cervical adipose tissue and increased neck circumference may be seen in children with obesity. Examination of the nasal cavity should include details regarding the mucosa, septum, inferior turbinates, nasal valve, and presence of polyps or masses. The nasal mucosa may be erythematous, suggesting chronic inflammation, or dusky, as is seen with allergic rhinitis. Anterior rhinoscopy can assist in identification of septal deviation and abnormalities of the inferior turbinates such as turbinate hypertrophy, contributing to nasal obstruction. Often, chronic rhinorrhea is seen in children with chronic sinusitis or adenoid hypertrophy. Functional nasal valve collapse can be seen in children during deep inspiration through the nose and can contribute to obstructed flow through the nasal passages. The presence of nasal polyps is rare except in children with cystic fibrosis. Patency of the nasal cavities, information often useful in the newborn, can be determined by passing an 8 French catheter through the nose and into the oropharynx. Finally, nasal endoscopy can be used in children to evaluate multiple anomalies of the nasal cavity, such as choanal atresia or stenosis, pyriform aperture stenosis, posteriorly positioned polyps or masses, or adenoid hypertrophy.

Examination of the oral cavity and oropharynx is one of the most useful portions of the head and neck exam in a child with suspected SDB and OSA. The oropharynx, and specifically the retropalatal region, is one of the most narrow portions of the airway in normal children (34). Initial exam should assess for size and position of the mandible and dentition, including malocclusion. Tongue size and position, especially macroglossia and glossoptosis, may have a significant contribution to SDB if present. Evaluation of the palate should include inspection for overt or submucosal clefting of the hard and soft palate, a high arched or narrow palate, and palatal masses, as well as presence of a bifid uvula. The tonsils are graded based on a four-point scale as described by Brodsky et al. (35) (Fig. 139.1): 0 for surgically absent tonsils, 1 for tonsils that lie within the anterior and posterior pillars, 2 for tonsils seen just beyond the pillars, 3 for tonsils that reach beyond 50% towards the midline,

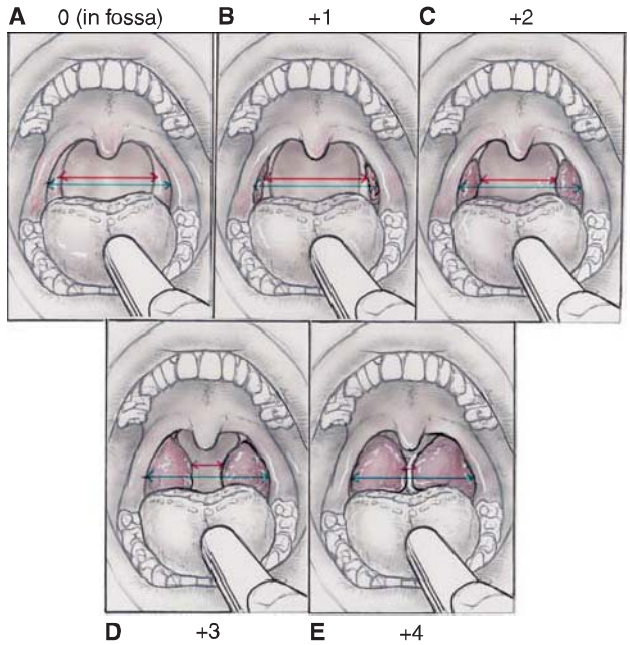

Figure 139.1 Brodsky grading of tonsil size. Tonsils are graded as: Grade 0—surgically absent (**A**), Grade 1—within the tonsillar pillars (**B**), Grade 2—just to/beyond the tonsillar pillars (**C**), Grade 3—beyond the tonsillar pillars, but not to midline (**D**), and Grade 4—touching in the midline (**E**).

and 4 for tonsils that "kiss," or approximate, in the midline. An assessment using the modified Mallampati score (36–38) can also be performed by evaluating the view of the uvula and posterior pharyngeal wall while asking the child to open his/her mouth completely while the tongue is in a resting position. Scoring is grade I when the entire uvula is visible, grade II for a partial view of the uvula, grade III when none of the uvula is visible but some of the soft palate is visible, and grade IV for a view of the hard palate only. Flexible laryngoscopy is recommended in all children under 1 year of age with OSA and when further evaluation is needed in older children. Flexible laryngoscopy allows direct visualization of the base of tongue, pharyngeal walls, vallecula, epiglottis, hypopharynx, vocal folds, and potentially, a portion of the subglottis. This procedure is useful in the evaluation of possible laryngomalacia, lingual tonsil hypertrophy, and persistent OSA despite previous tonsils and adenoids (T&A), and is also useful to document vocal cord mobility and to rule out pharyngeal/hypopharyngeal masses.

Additional Studies

Lateral neck films can be used in children that do not tolerate nasopharyngoscopy or flexible laryngoscopy. This film is most commonly used to identify adenoidal size but can also identify structural abnormalities within the nasal cavity, as well as lingual tonsil hypertrophy (39). Cine magnetic resonance imaging (MRI) has been described as a tool for assessment of the child with persistent sleep apnea despite surgical treatment with an adenotonsillectomy (40). In recent years, both pediatricians and pediatric otolaryngologists have deferred the use of airway fluoroscopy and computed tomography (CT) unless absolutely necessary, given the long-term risks of early radiation exposure. In those patients with a higher likelihood of associated cardiovascular complications from OSA, such as children with underlying congenital cardiac anomalies, electrocardiograms and echocardiograms should be considered in the workup of OSA.

Polysomnography

Polysomnography (PSG) is currently considered the traditional, and preferred, method in the evaluation and diagnosis of OSA in children (28). PSG includes the recovering of a number of different simultaneous recordings during sleep as noted in Table 139.4 (41). The results of this test provide objective measurements regarding the severity of airway obstruction in children during sleep. The apnea–hypopnea index (AHI) is obtained by averaging the number of apneas and hypopneas per hour of sleep, and this number is used to categorize the severity of OSA. Obstructive events/apneas in children are defined by continued respiratory effort with an absolute termination of airflow through the nose and mouth. A reduction in airflow of ≥30% to 50% along with either an arousal or an oxygen desaturation ≥3% from the baseline is considered a hypopnea (42).

TABLE 139.4 PARAMETERS RECORDED DURING NOCTURNAL PSG

Measurement Parameters	Electroencephalography (EEG)
	Electrooculography (EOG)
	Chin electromyography (EMG)
	End tidal CO_2
	Leg EMG
	Airflow performance
	Effort parameters
	Oxygen saturation
	Body position
Polysomnography Output	REM vs. non-REM sleep
	Apnea–hypopnea index (AHI)
	Respiratory disturbance index (RDI)
	Peak-end tidal CO_2
	Time with $CO_2 > 50$

In addition, the definition of flow limitation of apnea in children only requires an event to last for two or more consecutive breathing cycles, versus the 10-second criteria necessary for adults (42). Similar to adult evaluation, multiple series have demonstrated that the test–retest reliability, comparing multiple nights of PSG in the same child, is consistent and that PSG serves as a valid test for OSA in children (43–46).

The categories for OSA in adults are well-established; however, a standard definition of SDB disease severity does not exist for pediatric OSA, thus study interpretation may differ in their criteria used for mild, moderate, or severe OSA. One series that evaluated nonsnoring children defined a normal PSG as ≤1 obstructive apnea per hour, ≤0.9 central apneas per hour, an oxygen saturation nadir of 89% or higher, and an end tidal CO_2 greater than 45 mm Hg for 10% of the total sleep time (47). Current research definitions for OSA commonly define mild OSA when obstructive AHI is between 1 and less than 5 events per hour, moderate OSA if the AHI is 5 to less than 10, and severe OSA when the AHI is greater than 10.

While the use of PSG to diagnose OSA is widely accepted for adults, some controversy exists regarding the use of PSG in the diagnosis of pediatric OSA. It is not universally accepted that all otherwise healthy children with suspicion of OSA should undergo PSG. Issues include the fact that there are not enough sleep centers to test children in a reasonable time frame and that many sleep centers are not designed to accommodate children (i.e., with extra beds for caregivers, CO_2 monitoring, and staff specifically trained to work with children). If the PSG for a child is done in an "adult" sleep center, it is important to confirm that pediatric definitions are used in the scoring of the study. The extra cost and time to obtain a sleep study is questioned if adenotonsillectomy is planned, regardless of the PSG result.

Two recent guidelines were published in 2011 to address some of these issues. The first, by the American Academy of

Sleep Medicine (AASM), recommends that PSG is indicated when OSA is suggested by clinical assessment, and all children being considered for adenotonsillectomy for OSA should undergo PSG (48). These guidelines also recommend that PSG be used prior to decannulation in children that required tracheostomy placement, be used postoperatively in children with symptoms of persistent OSA after adenotonsillectomy as well as those with moderate to severe preoperative OSA, and those with high risk for persistent disease such as those with obesity or craniofacial abnormalities (48).

Alternatively, practice guidelines released by the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) recommend that all children with obesity, Down syndrome, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidoses be referred for PSG, since these children are at the highest risk of having OSA (49). In addition, PSGs are recommended in order to determine which otherwise healthy children should be admitted after adenotonsillectomy, specifically those with severe OSA and thus high risk for respiratory distress after surgery (50). They also recommend PSGs when the need for surgery is uncertain or if the size of the tonsils found on physical exam does not correlate with the reported symptoms of SDB (49,50).

TREATMENT OF OSA

Medical Treatment

Data on the use of medicine for the treatment of OSA are relatively limited. Both nasal and oral steroids have been studied for the treatment of snoring and OSA in children. In one series looking at OSA in children, the 6-week use of nasal steroids caused a mean reduction in the respiratory disturbance index (RDI) of 25 children from 11 events per hour to 6 events per hour (51). No reduction in symptoms or the AHI by PSG was seen when children were treated with a short course of oral steroids (52). Leukotriene modifiers, such as Montelukast, may be helpful in the treatment of enlarged adenoid tissue. One study on children with mild OSA showed improvement in hypercarbia, a decrease in the AHI, and a reduction in the size of the adenoid tissue after a 16-week course of Montelukast (Fig. 139.2) (53).

Weight loss has been shown to decrease the severity of OSA, particularly in those with mild to moderate disease. In those with severe OSA, weight loss by diet and bariatric surgery can lead to a decrease in the severity, but not necessarily a full cure (54,55). Weight loss could also lower CPAP requirements, leading to better compliance of the positive pressure therapy (56).

Continuous Positive Airway Pressure

Positive airway pressure (PAP) has become a commonly accepted treatment option for children with OSA in specific circumstances. Nasal continuous positive airway pressure (CPAP) is effective in treating OSA in children, and it has been approved for use in children since 2006. It is primarily used as an adjunct therapy, especially in children that have persistent OSA after adenotonsillectomy, but it is also used in patients in whom surgery is contraindicated. CPAP is composed of a source for warm humidified air or oxygen, a generator that creates positive pressure, and a patient delivery system (for children with OSA, it is in the form of a nasal mask) (57). Ideally, CPAP titration is performed during PSG, with a minimum starting pressure of 4 cm H_2O and a maximum of 15 cm H_2O for children under the age of 12 years old (58). The goal of titration is to eliminate obstructive events with positive airflow in order to maintain airway patency (58). A large series showed that RDI was reduced and oxygen saturation increased in children aged 2 to 16 years using CPAP for OSA; however, at least 30% stopped the use of CPAP in less than 6 months (59).

As with PSG, there are certain limitations with CPAP for the treatment of OSA in children. A national survey of sleep centers found that protocols for titration varied widely between institutions, and 22% of the centers do not utilize written protocols (60). The continued use of CPAP also carries with it certain risks. Many children discontinue the use of CPAP due to the discomfort of the mask or the noise that is created by the machine. Long-term use of the mask can also lead to skin defects or potentially harmful craniofacial abnormalities, with 68% experiencing global facial flattening, 37% with maxillary retrusion, and 48% resulting in damage of the skin (61).

Leukotriene modifier therapy for mild sleep-disordered breathing in children. *Am J Respir Crit Care Med* 2005;172(3):364–370, Figure 1, with permission.)

Surgical Treatment

Adenotonsillectomy

Adenotonsillectomy is currently the first-line treatment of OSA in children. In 2009, approximately 530,000 outpatient adenotonsillectomies were performed in children in the US (62). A meta-analysis from 2006 found that resolution of OSA, defined by a postoperative RDI of less than 1 or less than 5 depending on the study, was achieved in 83% of cases (63). However, the success rate of an adenotonsillectomy is variable depending on the patient population and confounding morbidities. For example, children with morbid obesity, craniofacial abnormalities, or those with syndromes often have difficult-to-treat OSA and have incomplete resolution after adenotonsillectomy. A large study from 2009 found an overall success rate in curing OSA in 66.3% of children treated with adenotonsillectomy, but cure rates varied widely between complicated (39%) versus uncomplicated (74%) children (64). QOL measures also seem to be different after an adenotonsillectomy in obese versus normal-weight children. In a recent series, both normal-weight and obese children had overall improvements in AHI and QOL, but obese children were more likely to have persistent OSA and poor QOL scores even after adenotonsillectomy (65).

Over the years, many methods have been used and developed for the removal of the adenoids and tonsils. However, there is no universally preferred method. Common methods for performing adenotonsillectomy include "cold steel" and electrocautery, but newer techniques include coblation (Fig. 139.3), Harmonic scalpel (Ethicon, Cincinnati, OH), CO_2 laser, and microdebrider intracapsular tonsillectomy (Medtronic, Jacksonville, FL) (66). The development of these and other alternate techniques for adenotonsillectomy have been aimed at reducing postoperative pain while minimizing bleeding rates.

Although adenotonsillectomy is one of the most common surgical procedures performed in the US, the rate of complications is quite low. Potential operative and postoperative complications include hemorrhage, negative reactions to anesthesia, airway complications, electrosurgical fires, nasopharyngeal stenosis, velopharyngeal insufficiency (VPI)/incompetence, and atlantoaxial subluxation (67). Other common postoperative complications that can result in hospitalization include nausea, vomiting, and dehydration. A recent series compared postoperative complications after microdebrider, coblator, or monopolar electrocautery, and major complications, including posttonsillectomy hemorrhage requiring an emergency department visit or surgical intervention, were studied (66). The overall major complication rates were 2.8% with coblation, 3.1% with monopolar electrocautery, and 0.7% with microdebrider (66); however, these results were confounded by multiple surgeons performing a number of different techniques (68).

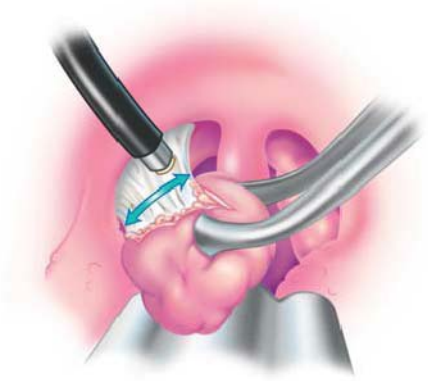

Figure 139.3 Tonsillectomy as performed with a Coblation wand (ArthroCare Corp., Sunnyvale, CA. Reprinted with permission from ArthroCare Corp.)

Adenoidectomy

Although adenoidectomy is routinely performed with a tonsillectomy for treatment of OSA in children, some studies have looked at the use of adenoidectomy alone for OSA. Indications for adenoidectomy alone include instances where adenoids are found on either nasopharyngoscopy exam or by lateral neck x-ray to be enlarged and causing nasal obstruction, but palatine tonsils are not enlarged. Studies have shown that clinically significant regrowth of the adenoids, with recurrence of obstructive symptoms, is rare, occurring in approximately 3% of children (69,70). Regrowth is felt to be more common in younger children or in cases where "blind" adenoidectomy techniques are used with residual adenoid tissue left behind, bulging into the posterior choanae (69,71). On the other hand, another retrospective analysis of children who underwent adenoidectomy found that 38% of the children who underwent adenoidectomy alone for obstructive symptoms required subsequent surgery (72). These study results must be weighed with the risks and benefits of doing both the tonsillectomy and adenoidectomy compared to just the adenoidectomy alone.

Methods for performing adenoidectomy include curette, electrocautery, microdebrider, and coblation, but, similar to tonsillectomy, no single method is universally used. Postoperative hemorrhage requiring surgical intervention is rare and generally only seen with a tonsillectomy, and pain associated with adenoidectomy is significantly less than that seen with tonsillectomy. Less common, but concerning, risks include postoperative VPI, nasopharyngeal stenosis, and injury to the soft palate. Many suggest only removal of the superior adenoids in children at risk for postoperative VPI, including those with submucous and overt cleft palates.

PRE-, PERI-, AND POSTOPERATIVE MANAGEMENT

The preoperative evaluation of any child with OSA should include questions about a family or personal history of bleeding disorders, easy bruising, excessive bleeding during

dental procedures, or any problems with anesthesia. If a bleeding risk is suspected, a more significant hematologic workup should be performed. In a recent study of children presenting with post-tonsillectomy bleeding, 19% of the children presented with abnormally elevated prothrombin time, partial thromboplastin time, or platelet function assays, and 4% were diagnosed with a coagulopathy (73). For those children who have other medical co-morbidities, the preoperative evaluation should be tailored to the individual. For example, for children with a higher risk of cardiovascular abnormalities/complications, including those children with long-term severe OSA, preoperative evaluation by cardiology, and/or preoperative electrocardiogram or an echocardiogram, should be considered.

Previous guidelines from the American Academy of Pediatrics note an increased risk of anesthetic complications in children with OSA (28). The AAO-HNS also advocates for detailed communication between the surgeon and anesthesiologist regarding the severity of OSA and PSG findings before surgery so that appropriate intraoperative decision making can be made (49).

Postoperatively, children with OSA should be closely monitored for hypoxemia and hypercarbia as they are at greater risk for complications compared to healthy children. Due to an increased risk of pulmonary complications, children under the age of 3 years should be monitored overnight after adenotonsillectomy (74). The 2002 AAP recommendations include postoperative admission and observation for all children in "at-risk" groups. This includes children younger than 3 years; those with severe OSA by preoperative sleep study, cardiac complications of OSA, failure to thrive, obesity, prematurity, recent respiratory infection, craniofacial anomalies; and those with neuromuscular disorders (28). The 2011 AAO-HNS recommendations include postoperative observation for children younger than 3 years of age and those with severe OSA. These recommendations also suggest that children in the "at-risk" groups "may be considered" for postoperative admission, with "at-risk" groups including those with obesity, neuromuscular or craniofacial disorders, Down syndrome, mucopolysaccharidoses, and sickle cell disease (75).

Children should have adequate pain control, either with acetaminophen, ibuprofen, or narcotics, although studies suggest that children with OSA are more sensitive to the respiratory-depressant effects of opioids, and should thus be used judiciously (76).

PERSISTENT OSA DESPITE PREVIOUS T&A

Although traditional teaching suggested that removal of the T&A successfully treated OSA and symptoms of upper airway obstruction in children who present with large T&A, studies now show that this does not occur in a significant percentage of children (63,77–79). Tauman et al. (78) showed that in a group of 110 children, only 25% had an AHI of ≤1 and 29% of the children still had an AHI greater than 5 after T&A. Obrien et al. showed in a group of 69 children, using a definition of "success" as an RDI less than 5, that only 77.5% had success after T&A. For a subgroup of obese children in this study, only 45% had success after surgery (77). Mitchell's results were somewhat better but also found a higher than expected failure rate, with 29% of the children in his study (n = 79) failing to have an AHI of ≤1 after T&A surgery. Risk factors identified in these studies include obesity, older age at the time of surgery, and severe preoperative OSA (79).

A multicenter study evaluated 560 children who underwent T&A for treatment of their sleep apnea. All children had preoperative and postoperative sleep studies. After surgery, only 27% had an AHI of less than 1, and over 21% continued to have an AHI greater than 5. Risk factors for failure included obesity, age older than 7 years, asthma in nonobese children, and more severe sleep apnea preoperatively (80).

Other populations at risk for continued OSA after T&A are those with craniofacial and mandibular anomalies. These include children with Pierre Robin sequence, cleft palate, Crouzon, Treacher Collins, achondroplasia, as well as children with cerebral palsy and genetic disorders such as Down syndrome (11,81–83). Merrell et al. showed in group of 37 children with Down syndrome who underwent T&A for treatment of sleep apnea, with an average age of 3.5 years, that only 43% had a normal AHI of ≤1 after surgery. If the persistence of hypoxemia and hypercarbia are also included in the evaluation of the postoperative sleep study, then only 29% of the children had a normal postoperative sleep study (84). Shete et al. (85) showed in a study of 11 children with Down syndrome, with an average age of 8.4 years, that only 18% had an AHI less than 2 postoperatively, significantly worse results than those seen in a group of nonsyndromic children matched for age, BMI, and degree of sleep apnea.

Evaluation of Site of Obstruction in the Oropharyngeal Airway

A PSG continues to be the most commonly used test to diagnose residual SDB after T&A. In addition to children with known higher risk factors and those with PSG-proven OSA preoperatively, PSGs should be considered for any child who continues to have persistent snoring, obstructive breathing, or oxygen desaturations following T&A (48).

If OSA is still present despite previous T&A surgery, other treatment options must be explored. Although the PSG can identify SDB and provide objective data regarding the severity of the obstruction, it does not identify at what level or levels of the airway the obstruction is occurring. Diagnosing the site(s) of obstruction in children can be more difficult compared to adults. The Mueller maneuver and the various grading systems used in adults, such as the Friedman Palate Position Grading system, the Fujita, and/or the modified Mallampati scoring methods, are not

easily achieved in the pediatric population. Children are not always able to fully cooperate, and the oral cavity exam is often challenging and rarely consistent (37). The lack of sensitivity even for the oral cavity exam in evaluating tonsil size and possible OSA was recently addressed by Nolan and Brietzke. Their review assessed the association between subjective tonsil size using the 0 to 4+ scale and objective PSG data and found little, if any, association between the two, stressing the poor reliability of the physical exam in the uncooperative pediatric patient (86). In addition, even if cooperation is possible, in their critical review of the techniques of airway evaluation, Stuck and Mauer point out that the sites of obstruction detected in awake patients by the Mueller maneuver and these grading systems do not always correlate with sites of obstruction during sleep (87).

There are four anatomic sites where obstruction can potentially occur: the nose and nasopharynx, the posterior oropharynx, the lateral pharyngeal walls, and/or at the level of the hypopharynx with obstruction at the base of the tongue.

Persistent nasal airway obstruction may result from a deviated nasal septum, enlarged nasal turbinates, or polypoid changes. Studies have shown that the use of nasal steroid sprays can have a significant improvement in the severity of OSA (51). Nasal polyps are less common in children, but a proper examination should be done to rule these out. The hard palate should also be examined. Since the hard palate also represents the floor of the nose, a high arched palate may have a significant effect on nasal resistance and obstruction. Lateral wall collapse of the posterior oropharynx has also been shown to contribute to OSA (88). Edema of the posterior oropharyngeal wall, lateral banding, and/or granular pharyngitis may suggest gastroesophageal reflux, contributing to a decrease in the airway size.

Flexible endoscopy, examining the nasopharynx, posterior oropharynx, base of tongue, the lingual tonsils, and the larynx, can be performed in the office setting or in the operative room under light sedation. A study by Revell and Clark (89) showed the contribution of "late-onset" laryngomalacia to persistent OSA after T&A. Whereas the office exam does not take into account the collapsibility of the airway that occurs with muscle relaxation during sleep, the exam in the operating room may be associated with false positives because of too much muscle relaxation secondary to the anesthesia (e.g., glossoptosis is common in all undergoing general anesthesia). Drug-induced sleep endoscopy (DISE) has more routinely been used for evaluation in adult patients with OSA; however, recent studies have used sleep endoscopy in the evaluation of late-onset laryngomalacia as a means to determine the collapsibility of the airway in pediatric patients (89,90). DISE has also been used for airway evaluation during lingual tonsillectomy in pediatric patients with OSA (91). Although not prevalent in the literature, DISE is becoming a more frequently used method to characterize the specific anatomic location and pattern of obstruction in pediatric patients with SDB.

Yellon has described a staging system for epiglottic and base of tongue prolapse using flexible endoscopy. Grade 0 is normal when the entire supraglottic larynx is visible with no base of tongue prolapse. Grade 1 occurs when the epiglottis falls against the posterior pharyngeal wall but the base of tongue is not pushing up against the epiglottis. Grade 2 has both prolapse of the base of tongue and the epiglottis together, with only the tip of the epiglottis visible. Grade 3 occurs when the base of tongue prolapse is so severe that the epiglottis is no longer visible on endoscopic exam (92).

Radiographic studies can also be useful to evaluate possible sites of obstruction. A lateral neck x-ray can show regrowth of the adenoid tissues and identify enlarged lingual tonsils (93). Radiographic studies are also used for dynamic evaluations of the airway (94–96). Videofluoroscopy was initially used, but due to the high level of exposure to ionizing radiation and the poor sensitivity due to overlapping structures seen on the lateral views taken for this technique, this is rarely done today. In children with craniofacial disorders and bony abnormalities of the facial skeleton, CT scans offer better bony definition. Dynamic cine CTs can also be performed, but due to concerns of exposure to high levels of ionizing radiation, they are not commonly used (97).

Cine MRI is increasingly being utilized to provide a high-resolution examination of the dynamic airway and more accurately identify sites of upper airway obstruction in children, without the added risk of radiation exposure. It is particularly helpful in evaluation of children with multiple sites of obstruction, such as is seen in children and adults with Down syndrome and those with craniofacial anomalies. Cine images are obtained with mild sedation administered by an anesthesiologist such as dexmedetomidine, an alpha-2 agonist that works similarly to clonidine but with a higher sensitivity to the alpha-2 receptors. It mimics natural sleep with minimal respiratory depression. Other anesthetic agents that have been used include propofol, pentobarbs, and midazolam, but these drugs have a greater effect on the pharyngeal airway muscle tone (98).

In the cine MRI, 128 consecutive images are captured over 2 minutes during episodes of airway obstruction and/or oxygen desaturation. The images can then be displayed in a cine format, creating a real-time "movie" of the airway motion. Dynamic motion of the airway is evaluated in three main anatomic locations: the nasopharynx, the oropharynx, and the hypopharynx (Fig. 139.4) (99). Donnelly et al. (100) studied children with and without known OSA and found that the frequency and degree (mean change in airway diameter) of dynamic motion or collapse were statistically greater in the nasopharynx and hypopharynx in the patients with OSA. Due to the increased brightness of lymphoid tissue compared to surrounding soft tissue and muscle on T2-weighted images, the cine MRI clearly delineates adenoid regrowth or recurrence as well as lingual tonsil hypertrophy (Fig. 139.5). Adenoid enlargement

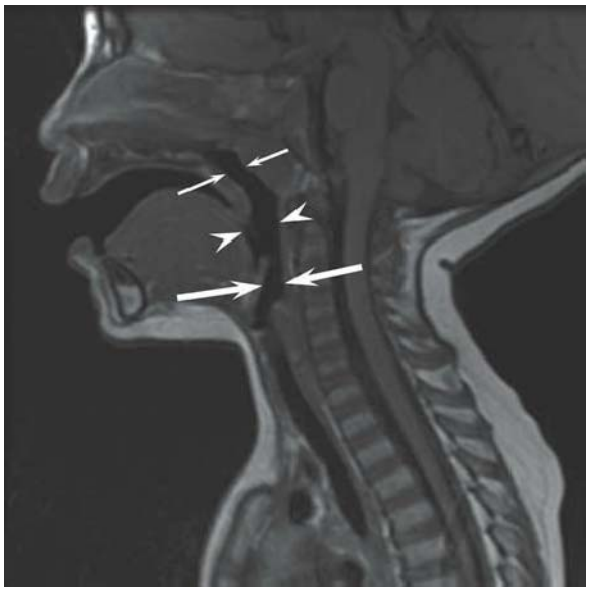

Figure 139.4 Sagittal T1-weighted MR demonstrates the anatomic regions of the supraglottic airway. The hypopharynx is behind the epiglottis (*large arrows*). The nasopharynx is between the soft palate and the adenoid tonsils (*small arrows*). The oropharynx is between the tongue base and the posterior oropharyngeal wall (*arrowheads*). (Reprinted from Shott SR, Donnelly LF. Cine magnetic resonance imaging: evaluation of persistent airway obstruction after tonsil and adenoidectomy in children with Down syndrome. *Laryngoscope* 2004;114(10):1724–1729, Figure 1, with permission.)

is reported if residual adenoid tissue is greater than 12 mm in thickness and if there is intermittent obstruction of the posterior nasopharynx seen on the sagittal cine MRIs (40). Lingual tonsil hypertrophy has been defined as tissue being thicker than 10 mm in diameter and abutting both the posterior border of the tongue and the posterior pharyngeal wall (101).

Figure 139.5 Due to increased brightness of lymphoid tissue compared to surrounding soft tissue and muscle on T2-weighted images, the cine MRI also clearly delineates adenoid regrowth (☆) or recurrence as well as lingual tonsillar hypertrophy (✦).

Unlike endoscopic examination of the airway, cine MRI allows for simultaneous assessment of multiple levels of the airway, identifying both primary and secondary sites of obstruction (40). Dynamic sagittal cine sequences can demonstrate glossoptosis, with abnormal posterior motion of the tongue during sleep (Fig. 139.6). Cine MRI axial views of the hypopharynx allow one to characterize the pattern of obstruction in either an anterior to posterior direction or more of a lateral wall movement and collapse. If there is both anterior–posterior and lateral wall collapse, a circumferential pattern of collapse is present (Fig. 139.7).

In a study evaluating 29 children with Down syndrome who had persistent OSA after T&A, cine MRIs were used to evaluate for the site(s) of residual obstruction (Table 139.5). The base of tongue, with both macroglossia and glossoptosis, was the major site of obstruction along with recurrent adenoids, each occurring in 63% to 74% of the children. Thirty percent of the children had enlarged lingual tonsils contributing to their airway obstruction (102).

TREATMENT OF PERSISTENT OSA AFTER T&A IN CHILDREN

Identification of an ideal management plan for children with residual OSA after T&A can be difficult as there is no specific treatment strategy available that is consistently effective. A multidisciplinary approach is often needed that includes sleep medicine, otolaryngology, pulmonology, and behavioral psychology to help with behavior modification and compliance issues. Many of the surgical interventions currently practiced are procedures that have been done for many years in adults, but only recently in children, thus there are few outcome studies available. Results are frequently reported via parental satisfaction reports without objective data, such as that provided by postoperative sleep studies (78).

Positive Airway Pressure Therapy

CPAP therapy continues to be a primary treatment for persistent OSA after T&A and should be offered if no obvious anatomic issue is identified. CPAP has proven to have successful therapeutic results if they are used, but unfortunately compliance is problematic in children, especially those with developmental delays or the very young. Finding appropriately sized masks can be difficult in younger children, and one study evaluating CPAP compliance in children showed that 30% stopped using within 6 months. For those who continued to use it, parents overestimated the nightly length of use by 1.8 hours (59). If CPAP is used in children, yearly retitration evaluations may be needed. One of the more serious adverse effects limiting long-term use of this treatment modality in children is the potential for craniofacial changes due to the mechanical forces applied to the maxilla from the nasal masks (61).

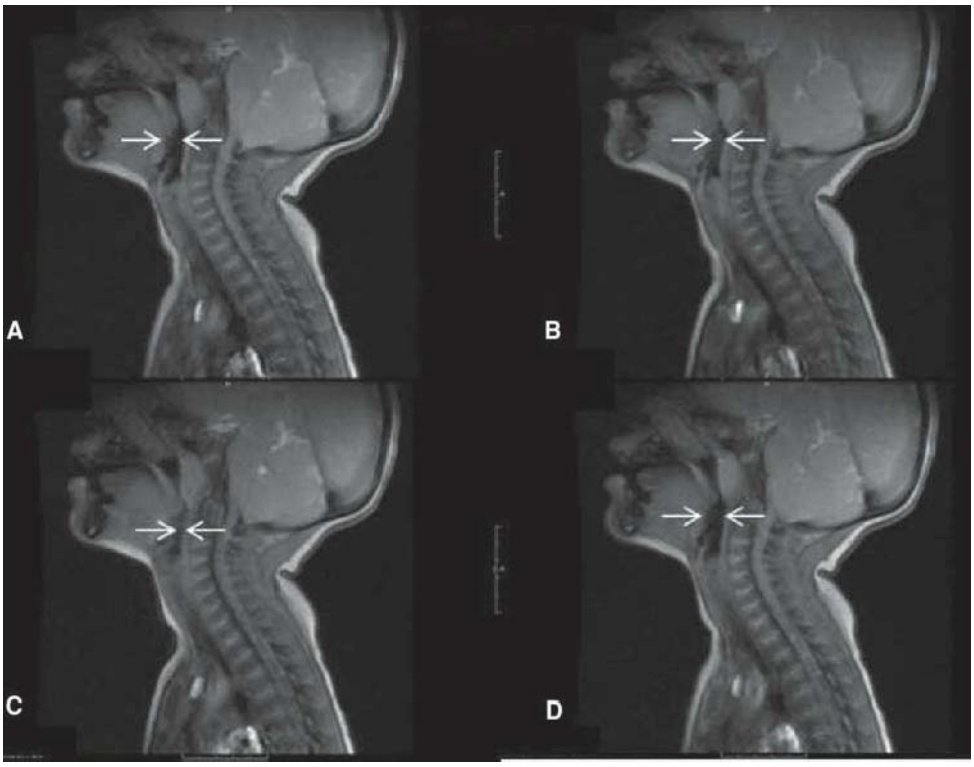

Figure 139.6 Cine MRI consecutive sagittal views showing glossoptosis. *Arrows* show area of movement of base of tongue and airway collapse (**A–D**).

Oral Appliances

Oral appliances are one of the newer advances in the treatment of pediatric OSA (103). These devices enlarge the pharyngeal airway using mechanical forces (104). The use of dental appliances to achieve nighttime mandibular advancement can be considered in older children who have all secondary dentition in place and mild OSA (105). Outcome studies on the use of oral appliances have been mainly in adults with variable success. Better results are seen in those who have mild to moderate OSA, those who are thinner, those who have a greater protrusion range, and those who have positional apnea (104). Studies have also shown a subset of patients who are better able to tolerate CPAP with the combined use of an oral appliance (106). Although useful for certain patients, these appliances, similar to the masks used for CPAP, can result in craniofacial abnormalities due to prolonged mechanical forces to the maxilla and mandible.

In children with high arched palates and mild residual OSA, rapid maxillary expansion or palate expanders are another option of treatment. In addition to the increased nasal resistance associated with a high arched palate and maxillary constriction, there can also be associated alterations in tongue posture that contribute to retroglossal airway narrowing (107). In one study evaluating 14 children undergoing rapid maxillary expansion, snoring was reduced and the AHI was decreased from a mean average of 5.8 to 1.5 events per hour (108). A recent study also showed improvement that persisted up to 24 months after treatment (109).

Weight Loss, Positional Therapy, and Medical Therapy

With the increasing number of young children and adolescents who are obese, weight loss must also be incorporated in the treatment of children with persistent OSA.

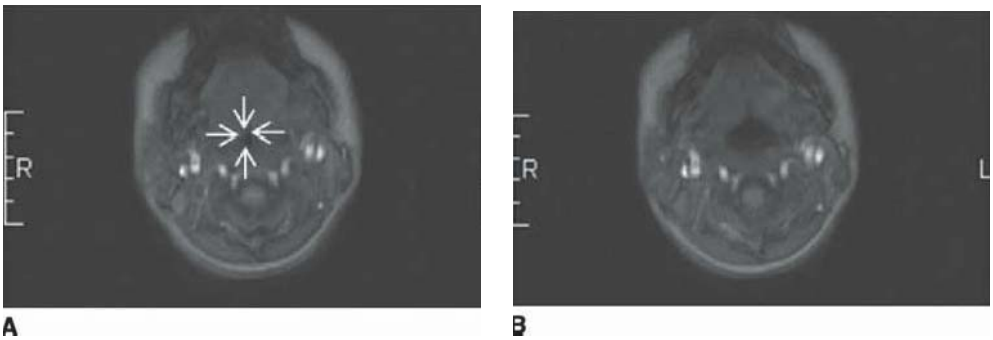

Figure 139.7 Axial view of cine MRI showing circumferential hypopharyngeal collapse of the airway with both lateral wall and anterior–posterior wall collapse (**A,B**). *Arrows* show area of collapse (**A**).

TABLE 139.5 CAUSES OF PERSISTENT OSA DESPITE PREVIOUS T&A IN CHILDREN WITH DOWN SYNDROME AS DEPICTED ON STATIC AND DYNAMIC CINE MRI

Causes of Persistent OSA in Children with Down Syndrome

Macroglossia	74%
Glossoptosis	63%
Recurrent adenoids	63%
Enlarged lingual tonsils	30%
Hypopharyngeal collapse	22%

From Donnelly LF, Shott SR, et al. Causes of persistent obstructive sleep apnea despite previous tonsillectomy and adenoidectomy in children with down syndrome as depicted on static and dynamic cine MRI. *AJR Am J Roentgenol* 2004;183(1):175–181.

The medical treatment reviewed earlier such as nasal steroids and leukotriene inhibitors may also be considered in children with residual mild OSA (53). Positional therapy, using special shirts, pillows, or belts, is intended to keep the child sleeping on his/her side or stomach and has been shown to be effective in a subset of patients who have positional sleep apnea. Figure 139.8 shows an example of a positional belt (110).

Surgical Treatments

Patients with moderate to severe OSA will frequently obstruct at several levels. The impulse is to therefore address multiple sites at a single surgical setting, as has been advocated in the adult population (111,112). However, a study by Prager et al. (113) showed an 8.2% incidence of oropharyngeal scarring and stenosis in 48 children who underwent multilevel surgery that included lingual tonsillectomy for OSA in children. Because of this, staged surgeries are recommended. In addition, significant improvements in airway size can be accomplished with solitary surgical procedures, result in augmented airway dynamics, and reduce Bernoulli and Starling effects causing collapse at other levels (114).

The various anatomic locations of upper airway obstruction in pediatric OSA and their recommended surgical management are listed in Figure 139.9 (115). All of these surgeries have been traditionally performed in adults with varying degrees of success that rarely reach above 50% to 60% for those with moderate and severe OSA. While complete cure may not be achieved, surgery usually leads to significant improvement in the degree of OSA and may also allow for decreased CPAP pressures, facilitating improved tolerance and compliance of this treatment modality.

Nasal Surgery

Nasal obstruction that is not altered by adenoidectomy, such as seen with a deviated nasal septum or enlarged nasal turbinates, can contribute to residual OSA. Further, enlarged nasal turbinates are especially important as contributors to SDB in prepubertal children. If nasal steroid sprays or allergy treatment are not effective, surgical treatment using radiofrequency reduction of the inferior turbinates has been shown in adults to improve nasal obstruction and CPAP compliance (116). Sullivan et al. (117) evaluated children with SDB and found that children that had enlarged inferior turbinates who underwent adenotonsillectomy plus radiofrequency treatment of inferior turbinates had a significant decrease in postoperative AHI compared to children with enlarged turbinates that underwent adenotonsillectomy alone. Although nasal obstruction is not always a component of airway obstruction and SDB in children, it is an important anatomic region that requires appropriate evaluation.

Uvulopalatopharyngoplasty

Uvulopalatopharyngoplasty (UPPP) has been used in adults with variable success, ranging from 40% to 80% (118). Higher success is seen in patients with mild OSA or Stage 1 patients using the Friedman scale (119). The traditional UPPP includes submucous resection of the musculus uvulae and a portion of the distal and lateral soft palate, in addition to tonsillectomy with closure of the anterior and posterior tonsillar pillars. The concern that aggressive removal of the soft palate may lead to increased rates of postoperative VPI is elevated in children who may already

Figure 139.8 An example of a sleep belt to encourage positional treatment of OSA. (Reprinted from Permut, I, Diaz-Abad M, et al. Comparison of positional therapy to CPAP in patients with positional obstructive sleep apnea. *J Clin Sleep Med* 2010;6(3):238–243, with permission.)

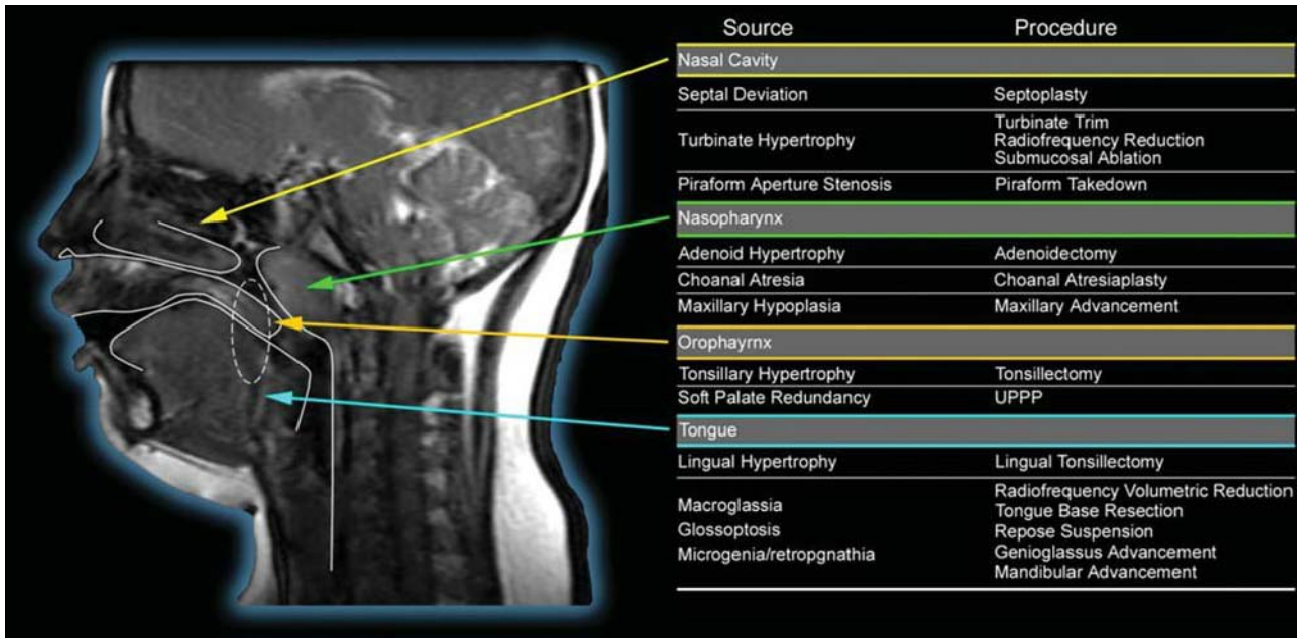

Figure 139.9 Various anatomic locations of upper airway obstruction in pediatric OSA and their recommended surgical management. (Reprinted from Shott SR, Richter GT. Chapter 8: Oral and oropharyngeal obstruction. be prone to hypernasality, such as those with submucous clefts and Down syndrome. In these cases, a more conservative excision of the soft palate, as described in the Z-pharyngoplasty procedure by Friedman, may be appropriate (120). If the exam shows more lateral wall collapse contributing to the patient's OSA, the expansion sphincter pharyngoplasty, as described by Pang and Woodson, should also be considered (88). Some have suggested the combined procedures of T&A and UPPP as first-line treatment for children in "at-risk" populations. However, no studies have shown the effectiveness of this approach with postoperative PSG data (121–125).

Lingual Tonsil Surgery

Enlarged lingual tonsils are a common site of residual obstruction in children with persistent OSA after T&A (102). Removal was initially performed with electrocautery, using an insulated blade and/or suction cautery, but this was complicated by significant postoperative pain. The use of the microdebrider allows for faster surgery but requires the use of electrocautery to control bleeding. On the other hand, the use of the coblation technique provides a good balance of speed, minimal tissue damage to surrounding areas, the ability to cauterize bleeding with the same instrument, and decreased postoperative pain. Lin and Koltai (91) reported that lingual tonsillectomy using an endoscopic coblation technique decreased the mean RDI from 14.7 to 8.1 in 26 patients, aged 3 to 20 years. This suggests that while lingual tonsils may be a significant contributor, other levels of obstruction may remain in children with residual OSA.

Base of Tongue Surgery for Macroglossia and Glossoptosis

As seen in Table 139.5, the tongue base, with associated macroglossia and glossoptosis, represents one of the most common sites of obstruction in children with Down syndrome who have persistent OSA despite previous T&A. Procedures on the base of tongue strive to either decrease the bulk of the tongue tissue or help to immobilize the tongue base in an attempt to prevent collapse of the tongue base during sleep.

The Repose system of genioglossus suspension was introduced in 1997. This is a minimally invasive technique that provides a supporting sling to the tongue base as a treatment for glossoptosis (126–129). Although originally described with a transoral approach, a submental incision and approach is much more facile in the pediatric population (Fig. 139.10). Wootten and Shott (130) reported their experience with the Repose genioglossus advancement in 31 children, with an average age of 11 years old, in 2010. Nineteen of the thirty one patients had Down syndrome. Using a "success" definition of a postoperative AHI of less than 5, no hypercarbia, and no hypoxemia less than 90%, an overall success rate of 61% was achieved. Success was higher in the children who did not have DS (66%) compared to those with DS (58%) (130).

Another method of genioglossus advancement is the midline segmental osteotomy technique (Fig. 139.11). Bone cuts through the anterior mandible create a full-thickness mandibular segment with attached genioglossus muscle. The bone is advanced anteriorly and rotated and then secured to the surrounding mandibular bone, applying anterior traction to the genioglossus muscle. Complications can

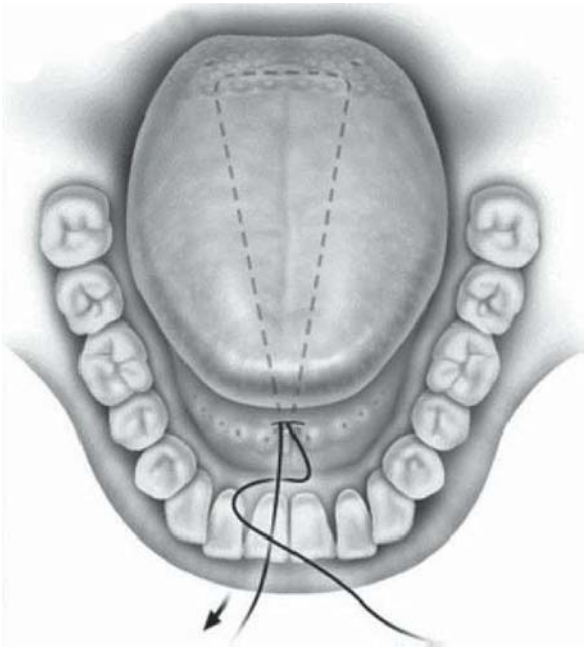

Figure 139.10 The Repose genioglossus tongue suspension applies a sling-type support to the base of the tongue to prevent hypopharyngeal collapse. (Reprinted from Pang KP, Terris D. Tongue suspension in obstructive sleep apnea. *Oper Tech Otolaryngol-HN Surg* 2006;17:252–256, Figure 6, with permission.)

include hematoma, dental and lower lip numbness, permanent injury to tooth roots and mental nerve, and infection (131). Clinical results in children have not been reported, and this surgery can only be done in older children who have already had eruption of their secondary teeth.

7. Periosteum
8. Mental foramen

Figure 139.11 Midline osteotomy genioglossus advancement. Bone cuts through the anterior mandible create a full-thickness mandibular segment with attached genioglossus muscle (**A**). The bone is advanced, pulling the tongue anteriorly (**B**). The window through the anterior mandible is located between the mental foramen (**C**). The bone window is anchored in place with screws (**D**).

The midline posterior glossectomy focuses on removal of tongue base muscle to decrease tissue volume that is obstructing the posterior oropharynx and hypopharynx in patients with macroglossia and glossoptosis. Techniques include midline wedge resections as well as submucosal excisions. Mickelson and Rosenthal (132) describe removal of a wedge of posterior tongue mucosa and muscle from 1 cm anterior to the posterior circumvallate papilla to the base of the epiglottis.

Because of the prolonged recovery associated with the open wound created by the wedge excision technique, submucosal excision of the tongue musculature has been described. Coblation excision is used in either open or closed techniques. For the open midline posterior glossectomy, mucosal flaps are raised after making a midline incision, and underlying muscle is then removed (Fig. 139.12). Dissection continues posteriorly into the vallecula. The mucosal incision is then closed anteriorly. Because the incision is closed, there is less pain than what is seen with the wedge resection technique.

A closed, submucosal posterior excision of the base of tongue has also been described. In the *s*ubmucosal *m*inimally *i*nvasive *l*ingual *e*xcision, or "SMILE" procedure,

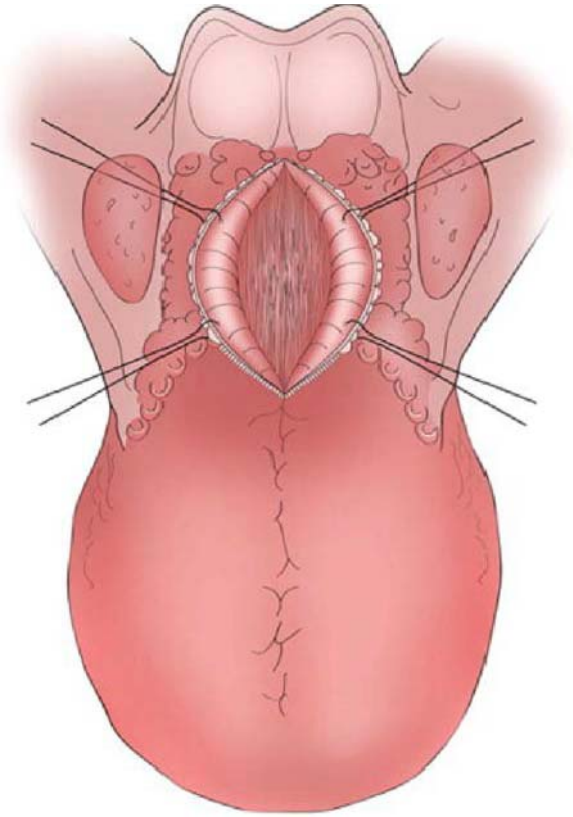

Figure 139.12 Midline posterior glossectomy: mucosal flaps are raised and posterior tongue muscle is removed with coblation wand using location of lingual arteries as margins of dissection. (Reprinted from Shott SR, Richter GT. Chapter 8: Oral and oropharyngeal obstruction. In: Haver K, Brigger M, Hardy S, Hartnick C, eds. *Pediatric aerodigestive disorders.* San Diego, CA: Plural Publishing, 2009, Figure 8-13, page 136, with permission.)

a midline incision is made on tongue dorsum, and a submucosal tunnel is made as the tongue muscle tissue is removed (133).

In both of these techniques, Doppler ultrasound is helpful to locate the lingual arteries on both sides of the midline of the tongue, providing margins for surgical safety from the more laterally sitting hypoglossal nerve. In adults, a reduction in AHI by 50% has been reported with the midline posterior glossectomy (134). Clinical studies in children are just starting to become available. Clark et al. (135) presented their initial experience with posterior midline glossectomy for treatment of macroglossia/glossoptosis at the Annual Meeting of the American Society of Pediatric Otolaryngology in 2011. In 22 patients, the success rate was 59%. Rare but reported complications include dysphagia, taste disturbances, and minor bleeding (136). Bleeding from the lingual artery, as well as the potential for hypoglossal nerve damage, should also be discussed as potential risk factors (137).

Craniofacial Surgery

In children with significant craniofacial anomalies, craniofacial surgery with mandibular and/or maxillary advancement surgery may be recommended as the primary surgical treatment.

Tracheotomy

In children with severe OSA, particularly those with associated complications of OSA such as pulmonary hypertension or cor pulmonale, tracheotomy must be considered. This may also be advisable in those with severe OSA where multilevel, staged surgeries are needed, with a recommendation to plan decannulation once surgical treatment is completed. In addition, OSA in children under 1 year old without other obvious anatomic solutions may be best treated with a tracheostomy tube.

CONCLUSION

Pediatric sleep science continues to develop and evolve while the diagnosis and management of OSA in children remain routinely debated. Because of this, clinicians must establish their own evaluation protocol with the understanding that residual OSA after T&A can be a result of obstruction at multiple sites. Endoscopic exams and radiologic evaluations, such as cine MRI, are helpful to identify the sites of obstruction. Alternatively, CPAP and BiPAP remain viable treatment options and can be successful, but compliance is difficult to achieve in the pediatric population. Despite the technique used to manage pediatric OSA, more outcomes research is needed, and currently identified surgical outcome limitations must be presented to the patients and their families. Lastly, because of the changing body size and shape that is inherent in the growing child, there is a need for continued vigilance for recurrence of the airway obstruction as the child ages.

HIGHLIGHTS

- Estimates suggest that 1% to 4% of children in the United States have OSA with snoring in 3% to 40%.
- OSA is more common in children with obesity, craniofacial anomalies, black race, and male gender.
- OSA in children commonly presents with poor school performance, snoring, daytime behavior issues, gasping and choking at night, witnessed apneas, and less frequently, daytime sleepiness.
- OSA can also result in hyperactivity, attention-deficit disorders, aggression, and poor socialization, and long-term complications include cardiovascular and pulmonary complications.
- PSG currently remains the gold standard for diagnosing OSA in children.
- The evaluation of a child with suspected OSA should include a thorough history, including a sleep history, as well as a complete head and neck exam.
- Practice Guidelines from the AAO-HNS state that PSG is recommended in children when there is a discordance in OSA severity and physical exam characteristics or is suggested by the clinical assessment, or in high-risk populations such as those with obesity, craniofacial abnormalities, sickle cell disease, and Down syndrome.
- Adenotonsillectomy is the primary treatment for OSA.
- Additional therapies to treat OSA include oral appliances, position belts, weight loss, and nasal steroids with or without leukotriene inhibitors.
- For those patients in whom surgery is contraindicated or significant OSA persists after surgery, CPAP is an appropriate alternate therapy.
- Persistent OSA occurs in a significant number of children despite a previous adenotonsillectomy.
- Children at risk for persistent OSA include those with obesity, Down syndrome, and craniofacial anomalies.
- Cine MRI is increasingly being utilized as a means to provide high-resolution examination of the dynamic airway and to identify further sites of obstruction in children with persistent OSA.
- No single specific treatment is advocated for persistent OSA in children, and often a multidisciplinary approach is appropriate.
- An array of staged surgeries, including nasal surgery, UPPP, lingual tonsil surgery, base of tongue surgery, and craniofacial surgery, can be utilized to treat persistent OSA.
- For children with severe OSA, especially in those with complications associated with OSA, a tracheotomy may be considered.

Development of the Ear

140

Michael John Wareing *Anil K. Lalwani* *Abbas A. Anwar* *Robert K. Jackler*

The development of the structures necessary for transmission of sound information from the environment to the auditory cortex is a complex and interwoven process. An understanding of the major developmental steps and their interrelations is desirable because therein lies the key to understanding many conditions encountered by otolaryngologists. Awareness of the developmental process alerts the surgeon to anatomic associations and explains important departures from normal.

Abnormal development is important for its clinical effects, but it also has a role in unraveling the complexities of normal development. The critical period of ear development begins in the third week after fertilization, the inner ear appearing first. The inner, middle, and outer portions of the ear have different embryologic origins, and development can be arrested at any stage. The result is a range of abnormalities from mild to severe. In view of the different origins, a disorder in one part does not necessarily signify a disorder in another, but proximity in terms of time of development, originating tissue, anatomic characteristics, and function does mean that multiple malformations are possible. The disorders can be caused by an inborn genetic error, either inherited or spontaneous, or by a teratogenic influence during organogenesis. The tissues of the head and neck are derived from all three layers of the embryo—ectoderm, mesoderm, and endoderm. The neural crest cells play a special role in the head and neck, where they constitute most of the skeletal and connective tissue. These cells arise from the ectodermal layer at the junction where the neural tube begins to fold. All divisions of the ear contain some neural crest tissue. The mesodermal proportion in the head and neck is less than in the rest of the body.

The story of ear development goes back to the time life itself was in its infancy. Fish seem to be the first hearing organisms, with development of a hearing organ from an internal balance organ. Even at this early evolutionary stage, the hair-cell design now so widespread was in use. Both amphibians and reptiles inherited the balance labyrinth of fish but went on to develop auditory labyrinths of their own, having branched from the line of fish before acquisition of a hearing organ. The need to hear in air resulted in development of a conductive apparatus to correct the impedance mismatch of sound arriving in air but having to be transmitted into the liquid of the labyrinth. Mammalian design continued from the basic reptilian design with, in particular, the addition of rows of hair cells, an independent cochlear nerve, changes in the middle-ear conduction system, and protective external auditory canals (1). Throughout this chapter, we separate development of the ear into its component parts as an aid to understanding. It is important, however, to remember that these changes occurred in a simultaneous manner. An overview of ear development is presented in Table 140.1.

AURICULAR DEVELOPMENT

In keeping with its recent evolutionary appearance, the auricle of the external ear begins its development later than do other components of the ear. From the fifth week of gestation, three hillocks arise on the first branchial (mandibular) arch (hillocks 1, 2, and 3) and three arise on the second branchial (hyoid) arch (hillocks 4, 5, and 6) on either side of the first branchial cleft (Fig. 140.1). Hillocks 1 and 6 are the first to be identifiable separately, but by the sixth week, all are distinct. The lobule also can be identified on the second arch. By the eighth week, the auricle has an identifiable structure, and the contributions of the hillocks to the adult form can be recognized: hillock 1, tragus; hillock 2, crus helicis; hillock 3, ascending helix; hillock 4, horizontal helix, upper portion of scapha, and antihelix; hillock 5, descending helix, middle portion of the scapha, and antihelix; and hillock 6, antitragus and inferior aspect of the helix (2). Although this is the majority view, there is uncertainty about the origin of the crus helicis and

TABLE 140.1 OVERVIEW OF EAR DEVELOPMENT

Fetal Age (wk)	Outer Ear	Middle Ear	Inner Ear
3			Otic placode develops. VC ganglia appear
4	EAC begins	Tubotympanic recess is apparent	Otocyst present
5	Hillocks become evident	Ossicles begin to condense in mesenchyme	Otocyst begins to divide into vestibular and cochlear areas Semicircular canals begin to outpouch; VC ganglion divides
6	All hillocks are distinct	Malleus and incus are identifiable as cartilaginous models	Superior SCC completed. Utricle and saccule are present; cochlear duct begins
7			Maculae present; sensory ridges in the cochlea appear
8	Auricle has identifiable structure; deep meatus is apparent as epithelial strand	Incudomalleolar and incudostapedial joints form	Ductus reuniens is identifiable; 1.5 cochlear turns; cristae present Vacuoles develop in vascular precartilage surrounding membranous labyrinth; cartilaginous model of otic capsule forms
9		Tympanic membrane has trilaminar structure	Nerve fibers enter sensory epithelium; oval window develops
10		Stapes loses annular form; facial nerve runs through middle ear	2.5 cochlear turns
11			Hair cells present in cochlea; synaptic connections are present
12		Tympanic ring begins to ossify	Otoconial membrane is present; cochlear duct changes to triangular shape
16		Malleus, incus, and stapes begin to ossify	Ossification of the otic capsule begins
18	Auricle has adult form		
20	Meatal plug begins to disintegrate	Tympanic cavity begins to open	Cochlear duct reaches full length; membranous labyrinth is full size
22		Antrum begins to develop	Tunnel of Corti present at all levels; basal turn of cochlea is functional
23			Otic capsule ossification is complete
24			Perilymphatic space is completed
26		Facial nerve makes second genu in adult position	
28	EAC is fully open		
30		Malleus and incus are ossified	
34		Ossicles lie within open middle ear space Mastoid air cells begin to develop	

VC, vestibulocochlear; SCC, semicircular canal; EAC, external auditory canal.

ascending helix; some believe that these structures can arise from the second arch (3). By approximately 18 weeks' gestation, the auricle has achieved essentially adult form, although it continues to grow in childhood with changes continuing into late adult life.

DEVELOPMENTAL ANOMALIES

A wide spectrum of pinna deformity exists, from anotia, in which there is no development, to a small but normally formed pinna. Microtia encapsulates the wide spectrum between anotia and normality. The superior portion of the auricle usually is severely malformed or absent. The presence of a deformity of the pinna can indicate further defects of the auditory system. Although this is less common with some minor deformities, severe cases of microtia and anotia are almost always associated with atresia of the external auditory canal and defects of the middle ear (see later).

The etiology of auricular abnormalities remains unclear, but evidence has implicated both environmental and genetic factors. Environmental risk factors for microtia are numerous and include anemia, advanced maternal or paternal age, male gender, race, and multiple births. In addition, mothers with chronic type I diabetes are at significantly higher risk for having children with microtia (4). Microtia may also have genetic risk factors, as autosomal recessive and dominant forms of the deformity

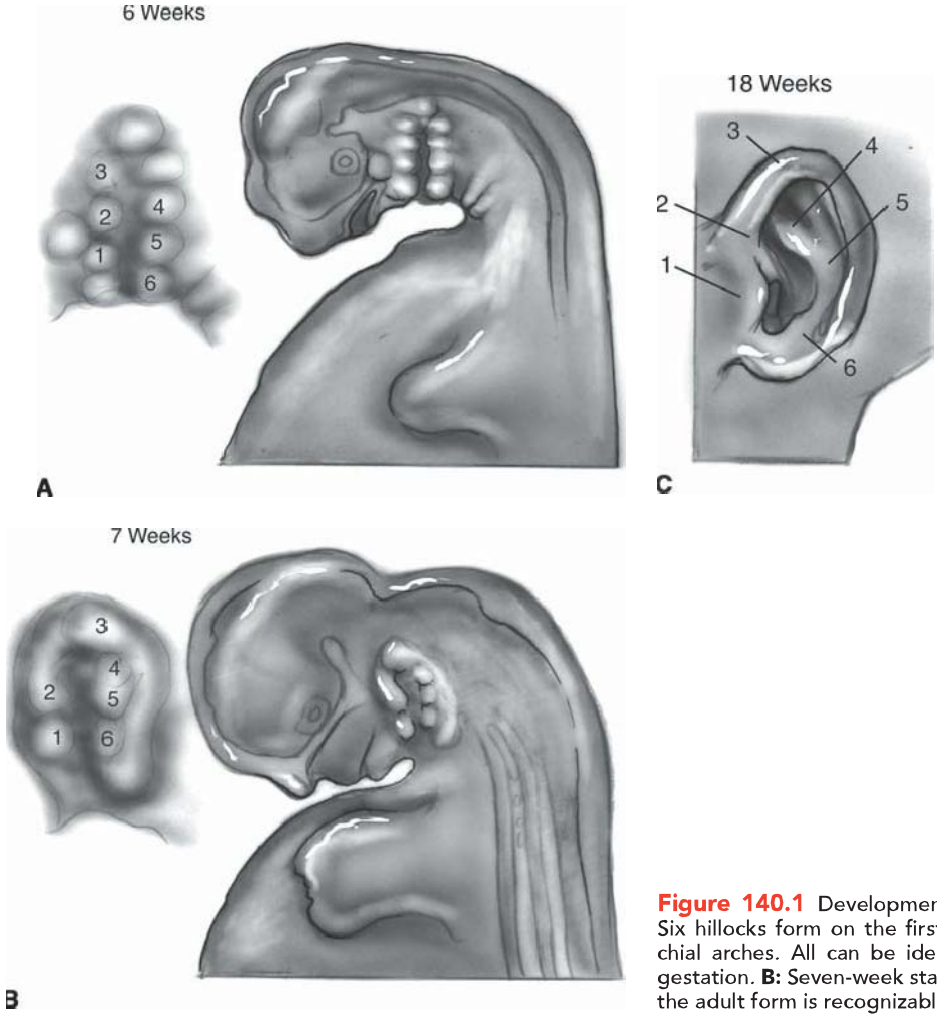

Figure 140.1 Development of the auricle. **A:** Six hillocks form on the first and second branchial arches. All can be identified at 6 weeks' gestation. **B:** Seven-week stage. **C:** By 18 weeks, the adult form is recognizable.

with variable expression and incomplete penetrance have been reported. More recently, specific genes, such as the *Gsc* homeobox gene and the *BMP5* maternal peptide gene, have been implicated as possible predisposing genes for microtia (5). Auricular abnormalities also are present in all the common chromosomal abnormalities, including trisomy 13, 18, and 22 as well as chromosomal translocations and microdeletions, and thus, are useful markers of these conditions. Classification of deformities of the pinna and treatment are discussed in Chapters 190 and 191.

DEVELOPMENT OF THE EXTERNAL AND MIDDLE EAR

External Auditory Canal

The external auditory canal begins to form in the fourth week of gestation (Fig. 140.2). The first branchial cleft, between the first and second branchial arches, widens, and the ectoderm proliferates to form a pit, which comes into apposition with the endoderm of the first pharyngeal pouch. This pit is the forerunner of the cartilaginous external auditory canal. This arrangement is temporary because mesenchymal growth separates the cleft and the pouch. The deep portion of the external auditory canal is apparent from the eighth week of gestation as a strand of epithelial cells running down to the disc-shaped precursor of the tympanic membrane (3). At approximately 28 weeks' gestation, this epithelial core has canalized from the medial to the lateral aspect to allow communication with the tympanic membrane. The epithelial core is the precursor of the bony external auditory canal.

Tympanic Membrane

The tympanic membrane has a trilaminar origin of ectoderm from the floor of the first branchial cleft laterally as the epidermal layer, endoderm of the first pharyngeal pouch medially as the mucosal layer, and neural crest mesenchyme with cephalic mesoderm interposed as the fibrous layer (6). It is almost horizontal initially but gradually tilts to lie in the adult position at approximately 3 years of age. The bone of the tympanic ring, derived from neural crest mesenchyme, begins to ossify at approximately 3 months.

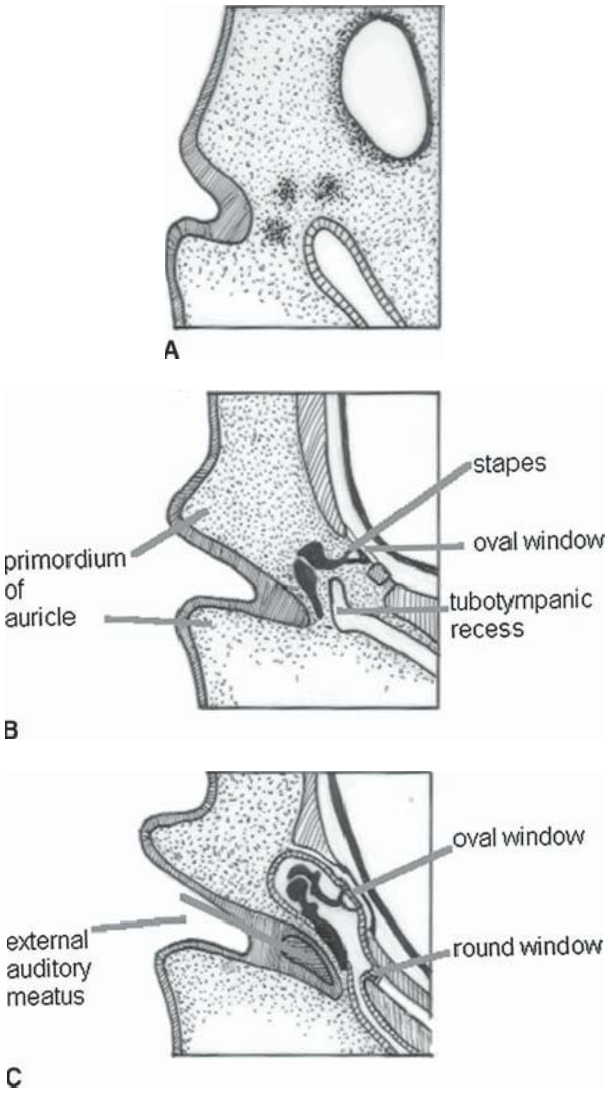

Figure 140.2 Development of the middle ear and ear canal. **A:** Week 5. **B:** Week 10. **C:** Week 27.

Middle Ear Cavity

The cavity and lining of the middle ear and eustachian tube develop from the expanding terminal end of the first pharyngeal pouch with a small contribution from the second pharyngeal pouch. This is apparent in the fourth week of gestation as the tubotympanic recess, which is positioned against the ectoderm of the infolding branchial groove. In the fifth and sixth weeks, the mesenchyme between the branchial cleft and the developing inner ear has condensations destined to become the ossicles. The tympanic cavity continues to develop as the continuing expansion of the endodermal pouch surrounds the ossicles and their supporting structures. It remains a slit-like structure until the fifth month but begins to expand such that the ossicles lie within an open tympanic space by the eighth month (7). Continuation of the tympanic cavity from the epitympanum into the antrum begins at 22 weeks and is complete at birth. Formation of the mastoid air cell system begins late in fetal life, the antrum is present at birth, and continues throughout childhood. The pattern and extent of pneumatization are highly variable. Pneumatization of the petrous pyramid, present in 30% of temporal bones, does not begin until the third year of life (8). At birth, the mastoid tip is not developed but expands through the tractional effect of the sternocleidomastoid attachment.

Ossicles

The exact origin of the ossicles has long been debated. It is certain that the main source is the neural crest mesenchyme of the first and second branchial arches—Meckel cartilage (first arch) and Reichert cartilage (second arch). The otic capsule has a role in formation of the stapes footplate (9). It is generally agreed that the head of the malleus and the body and short process of the incus are formed from Meckel cartilage and are initially continuous with the cartilaginous mandible. The mandibular branch of the trigeminal nerve is the nerve of the first arch; thus, it supplies the tensor tympani muscle, also a derivative of the first branchial arch. The long process of the incus, handle of the malleus, stapes superstructure, and tympanic surface of the stapes footplate are derived from the Reichert cartilage. The facial nerve is the nerve of the second arch; this supplies the stapedius muscle. The vestibular surface of the footplate is a derivative of the mesoderm of the otic capsule, as is the anular ligament (3) (Fig. 140.3).

The malleus and incus are first formed as cartilaginous models from the sixth week of gestation. They begin to ossify in week 16, and ossification is almost complete by week 30. The stapes appears slightly before the malleus and incus. It is initially ring shaped and penetrated by the stapedial artery, the artery of the second arch, which regresses. By 10 weeks, the stapes has already started to assume the familiar stirrup shape. By the time ossification begins from a solitary center at 16 weeks, the structure is a model of the future stapes. It is reduced in bulk throughout fetal life to develop its slender architectural form.

Maldevelopment

The spectrum of abnormal development in congenital atresia of the external auditory canal parallels the fact that the canal is present, albeit short, then is absent before achieving the adult form. In the most severe cases of atresia, a bony mass replaces the tympanic ring and forms the lateral wall of the middle ear cavity, the condyle of the mandible lying more posteriorly. In membranous atresia, which is less common, a fibrous mass replaces the external auditory canal. The mildest form of abnormality is stenosis of the external auditory canal, common in Down syndrome, which can be difficult to diagnose unless complications such as proximal cholesteatoma caused by trapped debris supervene. Congenital atresia is unilateral in 70% of cases (10).

A further consideration with atresia is the presence of coexisting abnormalities of either the pinna or the middle

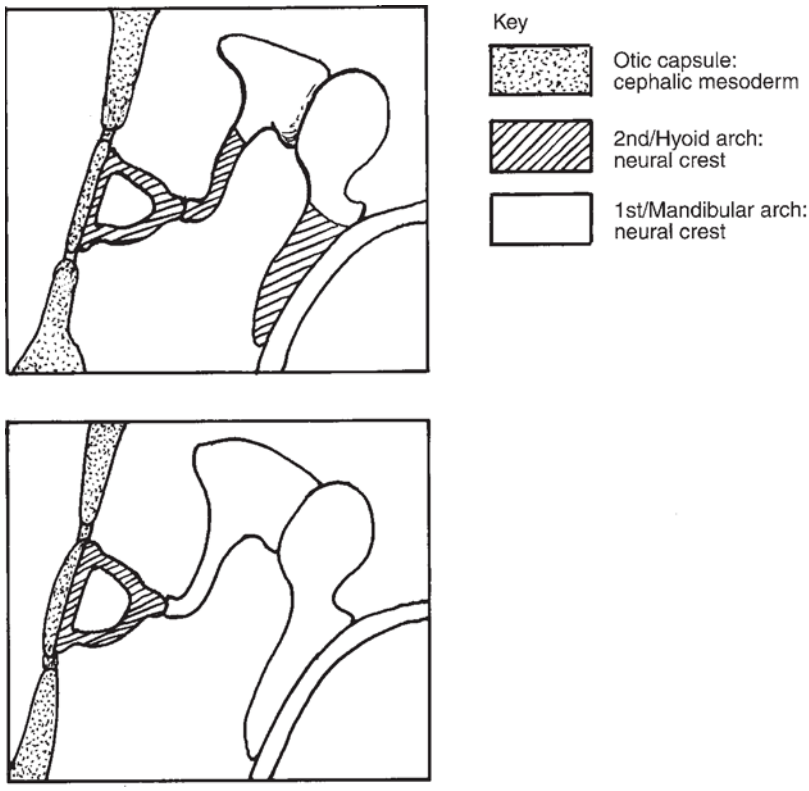

Figure 140.3 Origin of the ossicles—two interpretations.

ear. Associated auricular abnormality exists in 94% of cases of atresia, and the middle ear is frequently deranged (11), in part because all these structures are derived from the first two branchial arches and the intervening branchial cleft. Consequent are further abnormalities of branchial arch derivatives, such as the mandible. Among children with microtia or anotia, 20% to 40% have an identifiable syndromal malformation, such as hemifacial microsomia, Treacher Collins syndrome (mandibulofacial dysostosis), or Goldenhar (oculoauriculovertebral) syndrome (5,12). These syndromal malformations are discussed in Chapter 86.

Ossicular abnormalities also encompass a wide spectrum, from a rudimentary ossicular mass to minor morphologic defects. Middle ear deformities without coexisting outer ear defects are unusual, occurring among fewer than 10% of children with congenital conductive defects (13). This may, however, be an underrepresentation with cases undiagnosed or ascribed to acquired causes. The malleus is always fixed to a bony atretic plate if present, and incudomalleolar fusion or fixation is a common defect. Stapedial abnormalities are less common. In particular, the footplate can have normal mobility, even with a severe coexisting abnormality, because of its separate development from the otic capsule (14).

Persistent stapedial artery is a condition with an interesting embryologic background, although only approximately 50 cases have been reported worldwide. The stapedial artery is the remnant of the second arch artery, which courses from the aortic sac to the dorsal aorta. This artery regresses at approximately 10 weeks' gestation, and its role is assumed by the precursors of the internal and external carotid arteries. When the artery persists, a vessel arises from the internal carotid artery in the hypotympanum, which courses through the crura of the stapes to the fallopian canal. It enters the fallopian canal and courses forward to the geniculate ganglion and to the dura. If present, a persistent stapedial artery often manifests as a pulsatile mass in the middle ear cavity, pulsatile tinnitus, and rarely, as conductive hearing loss due to stapes ankylosis. The clinical interest is in cases in which middle ear surgery has been undertaken to manage presumptive otosclerosis or for cochlear implantation, as there is an increased risk of bleeding (15). Another condition with an embryologic basis is congenital cholesteatoma. This condition is caused by failure of atrophy of epidermoid formation in the anterior mesotympanum.

Although the inner ear develops separately, there is still an approximately 10% incidence of coexisting inner and middle-outer ear abnormalities (14). Careful assessment of the auditory system is mandatory if one is alerted to problems by maldevelopment of the auricle or ear canal Classification and management of congenital atresia are discussed in Chapter 137.

DEVELOPMENT OF THE FACIAL NERVE

The facial nerve is extremely important in surgical anatomy of the ear. The complex course of the nerve is a result of development of the structures that surround it. The facioacoustic primordium appears in the third week of gestation and has split into distinct seventh and eighth cranial nerves by the fifth week. The facial nerve supplies second arch structures, in particular the muscles of facial

expression. There also are secretomotor and special sensation fibers derived from the nervus intermedius, which is distinct by the seventh week. The chorda tympani has appeared in the fourth week, running to the first arch, before supplying sensation to the anterior two-thirds of the tongue. The greater superficial petrosal nerve appears in the sixth week. The nerve to the stapedius is identifiable by the seventh week (16). The first genu can be considered the result of the nerve's being pushed forward by the developing otic capsule. The fallopian canal is derived from the mesoderm of the otic capsule. More distally, the fallopian canal is formed partly by the Reichert cartilage (9). In the 10th week, the facial nerve makes its second genu in the middle ear, and its relation to the structures of the external and middle ear is far more anterior than in adults. By week 26, there is partial closure of the fallopian canal by bone, and the nerve has moved posteriorly, coming to lie in a position comparable with that in adults. In a manner similar to its being pushed forward by the otic capsule proximally, the nerve is pulled posteriorly by the growing tympanic ring and structures of the posterior tympanum and pulled inferiorly by the developing meatus and mastoid system. The facial nerve comes to lie between the tympanic and mastoid portions of the temporal bone. Even at birth, the facial nerve, which exits through the superficially positioned stylomastoid foramen, is more superficial than it is in the final adult position, which is attained by means of growth of the mastoid tip.

Maldevelopment

In ears with congenital defects of the outer or middle ear, the implication of this pattern of development is that the facial nerve lies more anteriorly and superficially in the lateral temporal bone. Often this means that the expected position of a new external meatus is crossed by the facial nerve (Fig. 140.4). In atretic ears, the facial nerve is abnormal in as many as 50% of cases (14).

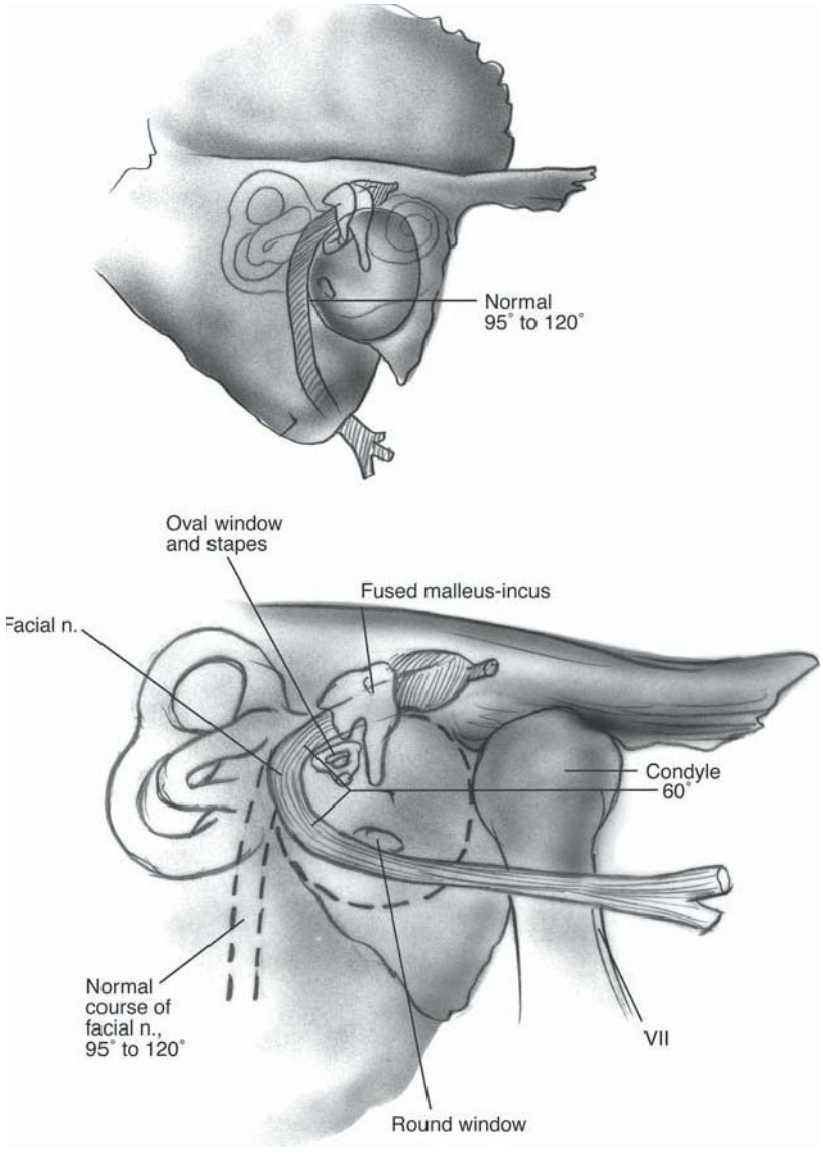

Figure 140.4 The facial nerve is anterior and superficial in atretic ears.

Some congenital disorders of the stapes are related to abnormal development of the facial nerve. Anterior displacement of the nerve at the 6-week stage can prevent the developing stapes from coming into contact with the otic capsule; the result is rudimentary formation (17). The facial nerve also can divide around the stapes. Dehiscence of the fallopian canal is common enough for it to be considered a normal variant, present in approximately 25% of temporal bones. The most common site is above the oval window, although sufficient dehiscence to allow prolapse over the oval window is much less common.

DEVELOPMENT OF THE INNER EAR

Membranous Labyrinth

The internal ear phylogenetically predates the other components of the ear and is accordingly the first part to develop. At the end of the third week of gestation, the otic placode can be differentiated on the lateral surface of the cephalic end of the embryo as a thickening of ectoderm in contact with hindbrain portion of the closing neural tube. The neural tube, also derived from ectoderm, is destined to become the central nervous system. This contact is short-lived. By the time the neural tube closes, a layer of thin ectoderm separates it from the neural epithelium. The placode invaginates itself to become a pit and a closed sac, the otocyst or otic vesicle, the precursor of the membranous labyrinth (Fig. 140.5). Positioned between the second and third branchial arches, it is predictable that the otocyst is supplied by the eighth cranial nerve. It migrates inward, changing shape and growing dramatically so that it achieves adult form by the 10th week and adult size by 20 weeks (18) (Fig. 140.6).

The otocyst lengthens more than it widens. The cranial portion becomes marked off as the developing endolymphatic duct. The caudal portion is destined to become the cochlear duct and the intermediate portion, the utriculosaccular area, is the vestibular precursor. These distinctions are discernible in the fifth week of gestation. The vestibular portion begins to take shape slightly before the cochlear portion, in keeping with its older phylogenetic status. From the utricular part of the vestibular pouch, three outpocketings appear, which are converted, through fusion of the central epithelium, into semicircular canals. The superior canal is completed first, in the sixth week. The posterior canal is next to be completed, and the lateral canal is last. The utricle and saccule start to develop in the sixth week and form the utriculosaccular duct. The cochlear duct also begins to grow from the saccule in the sixth week with recognizable narrowing of the communication; the ductus reuniens is visible by the eighth week. The cochlear duct grows rapidly, having 1.5 turns at 8 weeks and the full 2.5 turns at 10 weeks, although it does not reach full length until 20 weeks (2).

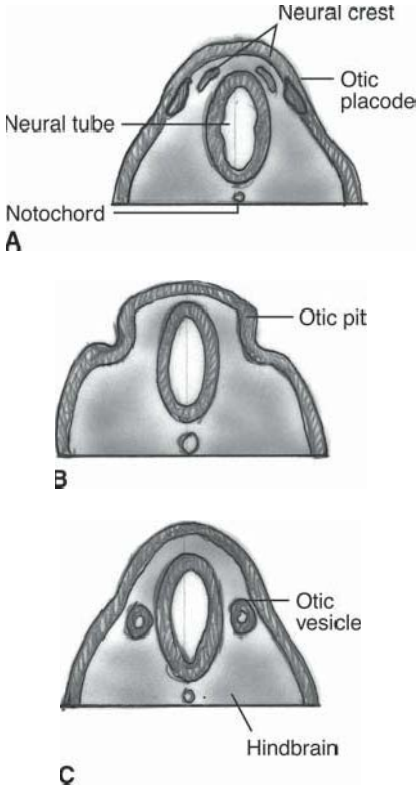

Figure 140.5 **A–C:** Early development of the inner ear in the third and fourth weeks of gestation—formation of the otocyst from the otic placode.

The sensory epithelia of the vestibular system, the three cristae and two maculae and the organ of Corti in the cochlea, are derived from the ectodermal epithelium of the otocyst. These six areas, which initially are close together, develop in the wall of the membranous labyrinth (3). The maculae develop in the seventh week of gestation by means of intense proliferation of the epithelium accompanied by cell differentiation. The distinctive cells and otoconial membrane are apparent by week 12. Development of the cristae parallels this event; they are distinguishable at 8 weeks and have reached adult in form at 23 weeks.

The sensory epithelium of the cochlea begins to develop in the seventh week as the duct itself grows and begins to coil. Lying on the medial wall, the layers of the epithelium organize into two ridges and spiral along the length of the cochlea. The supporting cells arise from both ridges. The larger inner ridge differentiates into the inner hair cells and tectorial membrane. The smaller outer ridge differentiates into the outer hair cells (19). *Atoh* has been identified as the earliest hair-cell-specific gene required for definitive hair cell development, as *Atoh* knockout mice show no hair-cell differentiation (20). Once differentiation begins, the hair cells become identifiable by about week 11, the inner hair cells appearing marginally before the outer hair cells at the same position along the basilar membrane (7). Hair-cell development is initially apparent in the midbasal region of the cochlea and moves

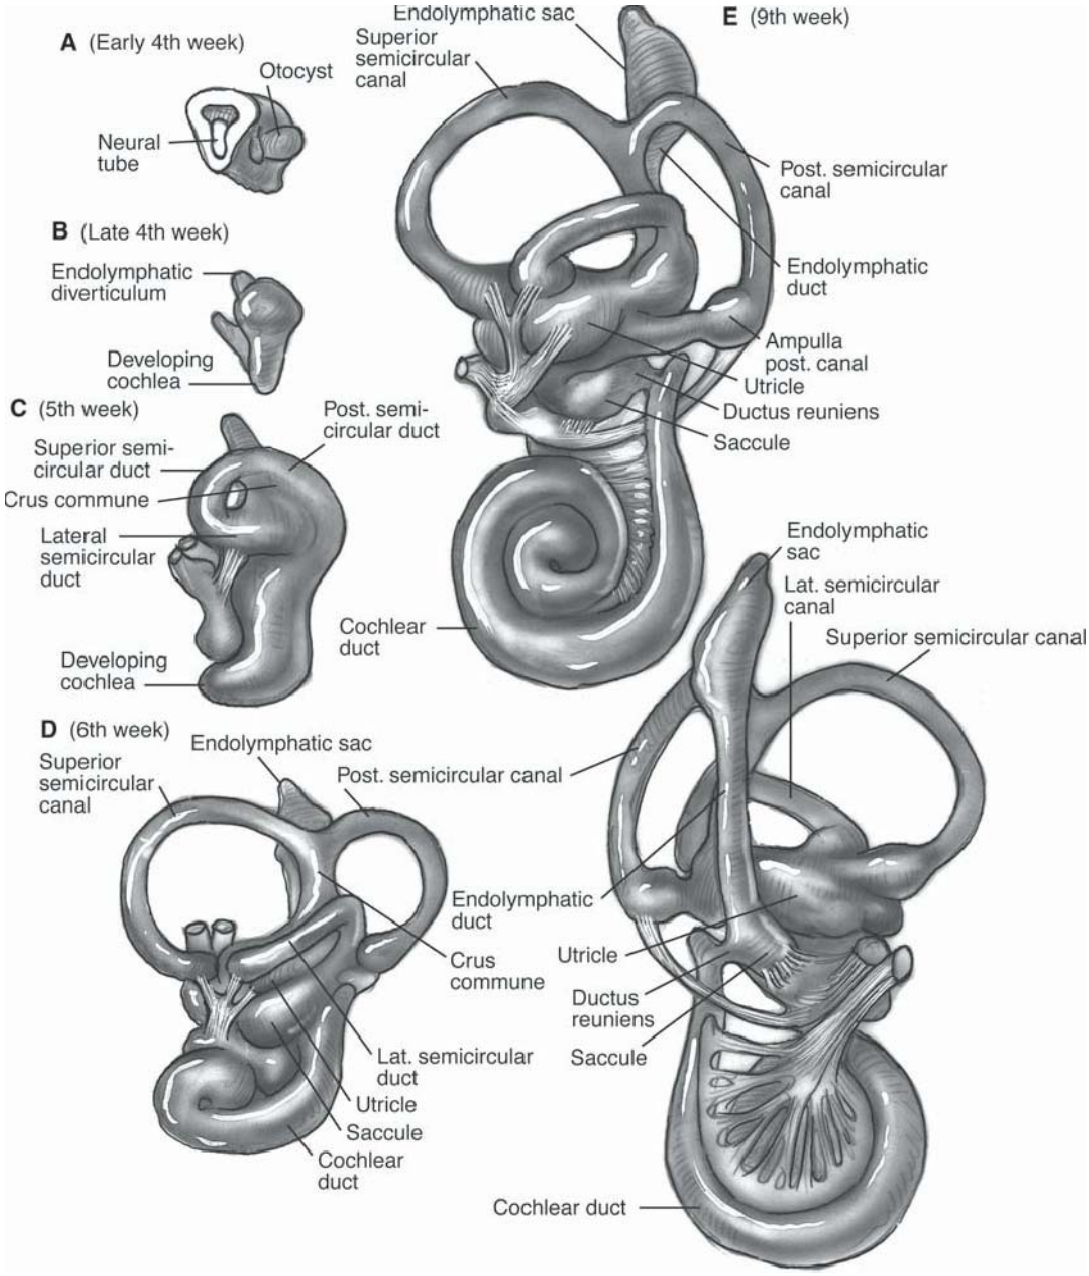

Figure 140.6 **A–E:** Development of the membranous labyrinth from gestational weeks 4 through 9.

toward the apex, maturation of the base preceding that of the apex by 1 to 2 weeks, although the most basal portion of the cochlear lags slightly behind the midbasal portion. The supporting cells develop in the same direction, and at the 21-week stage, the tunnel of Corti is present at all levels. At approximately this time, the organ of Corti becomes functional, at least in its basal turn (2). The shape of the cochlear duct starts changing at approximately week 12 from oval to triangular, the changes first happening in the basal turn. The surrounding mesoderm of the osseous labyrinth participates in this process. The endolymphatic duct and sac are the only parts of the inner ear that continue to grow into the third trimester. Full size is not attained until adulthood (21).

DEVELOPMENT OF INNERVATION OF THE MEMBRANOUS LABYRINTH

The facioacoustic primordium appears in the third week of gestation. It does not, however, have a uniform origin. The vestibulocochlear ganglia arise from ectoderm of the primitive otocyst, having split away from the epithelium in the third week. Although destined to innervate different portions of the inner ear, the vestibulocochlear ganglia appear to arise from a common site on the otic epithelium. The neural crest is a small additional source of supporting cells of the ganglion (6).

From the vestibulocochlear ganglia, fibers grow toward their destined target organs, the inductive process driven

by the target organs and nearby tissues. While the otocyst is dividing into its vestibular and cochlear portions, the vestibulocochlear ganglion divides into a superior and an inferior division. The fibers of the superior division pass to innervate the superior and lateral ampullae of the semicircular canal and the utricle. The inferior division sends fibers to the posterior ampulla and the saccule. The remaining portion becomes the spiral ganglion of the cochlea (2). As the cochlear duct grows and coils, the ganglion follows it to give it its characteristic configuration. Recent studies have shown that, while the hair cells are the final target for the auditory fibers of the spiral ganglion, many other nonsensory tissues that are present along the pathway, such as Kolliker organ and Schwann cells, may actually provide the earliest guidance cues and survival molecules needed to direct axon growth toward the sensory epithelium. The exact signals and molecules that provide this guidance remain unclear, but there is significant evidence that *neurotrophin-3* (*NT3*) and *brain-derived neurotrophic factor* (BDNF) may play an integral role in the process, as they are required for normal innervation of the cochlea (22). Eventually, by about the ninth week, auditory nerve fibers grow to enter the sensory epithelium, and synaptic connections are identifiable as the hair cells begin to differentiate in week 11. Although differentiated hair cells are not required to successfully target auditory fibers to the sensory epithelium of the cochlea, they do appear necessary for later auditory circuit assembly, synapse formation, and ultimately, auditory neuronal survival (23). Once the hair cells differentiate, the inner hair cells are innervated before the outer hair cells, afferent innervation precedes efferent innervation, and the basal turn precedes the apex in development (19).

DEVELOPMENT OF THE OSSEOUS LABYRINTH

The most important aspect of development of the perilymph-filled osseous labyrinth is a resorptive process in the mesoderm that separates the membranous labyrinth from the developing bony otic capsule. In the eighth week of gestation, the vascular precartilage that surrounds the membranous labyrinth develops vacuoles in its structure that coalesce to leave the perilymphatic space. This process begins around the utricle and saccule and progresses outward from there. The part around the cochlear duct destined to be the scala tympani precedes the scala vestibuli, and development is farther advanced in the basal turn than in the apical turn. The perilymphatic space is completed by week 24 (9). The origin of the precartilage is cephalic mesoderm with a small contribution from neural crest cells. The cephalic mesoderm contributes to the basilar membrane, Reissner membrane, and the stria vascularis, which also has cells derived from the neural crest (24,25).

DEVELOPMENT OF THE OTIC CAPSULE

It is remarkable that the bony otic capsule achieves its adult size by week 22 of gestation. Arising from cephalic mesoderm, a precartilaginous precursor appears in the seventh week. From week 8 to week 16, the developing labyrinth is surrounded by an enlarging cartilaginous model, which ossifies in three layers over 7 weeks from a total of 14 centers (8,9). Solidification is completed in the early postnatal stage; the petrous (stony) nature of the otic capsule results from the compactness of the bone of the original ossification centers. The oval (vestibular) window is formed where the developing stapes abuts the cartilaginous model of the otic capsule in the ninth week. This section becomes the vestibular surface of the footplate. The rim of the footplate and the facing rim of the window, derivatives of the otic capsule precursor, do not turn into bone but remain cartilage; the intervening tissue becomes the annular ligament. The round (tympanic) window forms adjacent to the basal turn of the cochlea, where cartilage is not turned into bone but is converted into the fibrous tissue of the secondary tympanic membrane.

The vestibular aqueduct forms around the endolymphatic duct and sac but is late in achieving full ossification (9). The cochlear aqueduct forms in the mesoderm, which ossifies to become the otic capsule, and is first apparent as an outpouching of the subarachnoid space. Progressive ossification causes curving and lengthening of the cochlear aqueduct, which has two sections. The otic capsule section, which has a narrow cochlear opening just inside the round window membrane, becomes progressively narrower from its appearance in the fourth month to the ossification of the otic capsule at week 23. The medial petrous apex portion enlarges throughout the third trimester, and it is in this section that postnatal elongation of the cochlear aqueduct takes place. The length in a newborn infant is 3.5 mm; the average length in an adult is 10 mm (26). The internal acoustic meatus forms around the vestibulocochlear nerve and internal auditory blood vessels as well as the facial nerve. The facial nerve, however, is cranial to the eighth nerve, and its path is deflected by the growing otic capsule, although the bony fallopian canal proximal to the second genu is of otic capsule derivation. The adult position of the facial nerve in the internal acoustic meatus is in the anterosuperior quadrant.

Maldevelopment

A practical categorization divides inner ear anomalies into those affecting the osseous and membranous labyrinth and those affecting the membranous labyrinth alone (27). As many as 20% of patients with congenital sensorineural hearing loss fall into the first category, which can be identified with radiologic techniques

TABLE 140.2 CLASSIFICATION OF CONGENITAL INNER EAR MALFORMATIONS

Malformations limited to the membranous labyrinth
- Complete membranous labyrinthine dysplasia (Bing-Siebenmann)
- Limited membranous labyrinthine dysplasia
  - Cochleosaccular dysplasia (Scheibe)
  - Cochlear basal turn dysplasia

Malformations of the osseous and membranous labyrinth
- Complete labyrinthine aplasia (Michel)
- Cochlear anomalies
  - Cochlear aplasia
  - Cochlear hypoplasia
  - Common cavity
  - Incomplete partition (Mondini)
- Labyrinthine anomalies
  - Semicircular canal dysplasia
  - Semicircular canal aplasia
- Aqueductal anomalies
  - Enlargement of the vestibular aqueduct
  - Enlargement of the cochlear aqueduct
- Internal auditory canal abnormalities
  - Narrow internal auditory canal
  - Wide internal auditory canal

TABLE 140.3 NOTABLE GENES IMPLICATED IN THE DEVELOPMENT OF THE INNER EAR

Structure	Genes
Cochlea	*TGF-β2, HOXA1, N-myc, Pax2, Ildr1, Tbx, Wnt, Lgr5, Six1, Eya1, Sonic hedgehog (Shh), Fgf3, Gbx2*
Vestibular labyrinth	*HOXA1, SLC4A11, GRHL2, DAN, Bmp2, Bmp4, Dlx, Hmx, Wnt, Msx1, Lmo4, Six1, Pax2, Eya1, Otx1, Fgf3, Gbx2, Lmx1a, Mafb, Foxg1, Fgfr-2*
Endolymphatic sac	*DAN, Pax2, Six1, Pds, Foxi1, Fgf3, Mafb, Otx2*
Auditory neurons	*NT3, BDNF, GDNF, Neurod1, Sox2, Npr2, Shh, TrkB, TrkC, Fgf10*
Hair cells	*GDNF, Atoh, Neurog1, Neurod1, Tbx1, Math1, Brn-3c, Tekt2, Gfi1, Lmod1, Hes/Hey, Eya1, IsK, Jag2, Lfng, Myo6, Myo7a, Tecta*

Human genes—entire gene name is in uppercase letters.
Mouse genes—first letter capitalized followed by all lowercase letters.

(28,29). In absence of histologic confirmation however, accurate categorization ultimately reflects the sensitivity of the contemporary imaging modality (30). Inner ear abnormalities can be caused by arrested or aberrant development (Table 140.2). The variable but frequent coexistence of deformities involving the component parts of the labyrinth suggests that a number of different factors can be involved: The anomaly can be genetically predetermined, an insult can occur before the fifth week, or the separate portions of the developing system can be variably susceptible to teratogenic insult; the contribution of a host of genes to the development of the inner has been determined using the modern tools of molecular genetics and mouse model of deafness (Table 140.3).

The most common histopathologic finding in congenital deafness is cochleosaccular dysplasia due to incomplete development of the caudal portion of the otocyst, the pars inferior, first described by Scheibe in 1892 (28). The organ of Corti typically is partially or completely missing, the cochlear duct and saccule are collapsed, and the stria vascularis is degenerated. The utricle and semicircular canals are normal. The normality can be explained in part by the earlier development of the vestibular system. Basal turn dysplasia is the mild end of this spectrum. Complete membranous labyrinthine dysplasia (Bing-Siebenmann) is rare and is the most severe membranous abnormality.

Most combined membranous–osseous labyrinth abnormalities appear to be caused by arrested development between the fourth and eighth weeks of gestation. The appearance of most malformed ears is in accord with the stages of labyrinthine development (Fig. 140.7). The most severe abnormality, complete aplasia (Michel malformation), is extremely rare and presumably is caused by failure

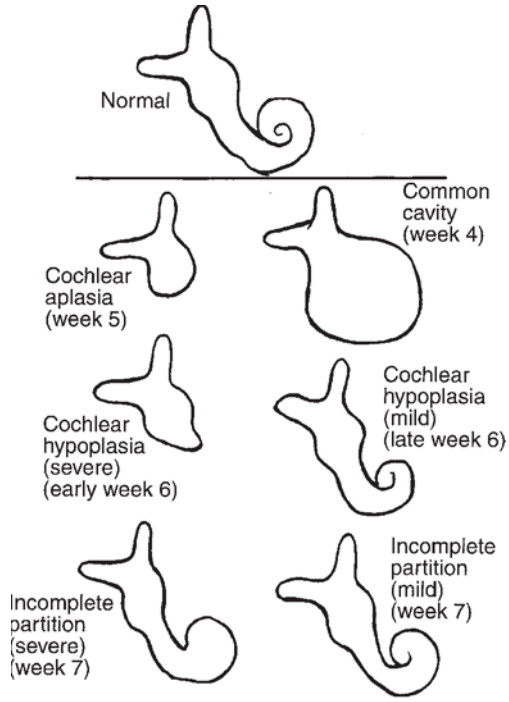

Figure 140.7 Coronal computed tomographic scan shows stages of cochlear maldevelopment.

of the otic vesicle to develop. Cochlear aplasia, hypoplasia, and incomplete partition are a spectrum occurring from arrest at gestational weeks 5, 6, and 7. The common cavity can arise from arrest at 4 weeks or can be caused by later aberrant development. Dysplasia of the semicircular canals is caused by failure of central epithelial fusion and is four times as common as aplasia of the semicircular canals. The lateral semicircular canal (LSCC) is most commonly affected because it develops later, and lateral dysplasia of the semicircular canals can occur as the sole abnormality. Approximately 40% of ears with osseous cochlear abnormalities have concomitant abnormalities of the semicircular canals (27). Bilateral involvement with osseous inner ear deformities is the rule, the same morphologic abnormality occurring in both ears (27).

An enlarged vestibular aqueduct is the most common radiologically detectable abnormality of the inner ear and may be due to acquired or genetic influences (31). The vestibular duct may be abnormally broad and short due to premature arrest of development or as a consequence of increased cerebrospinal fluid pressure. As part of the genetic Pendred syndrome, large vestibular aqueduct can be associated with disturbance of thyroid organification resulting from mutations in *SLC26A4*, a chloride–iodide transporter gene (32). In addition, recent studies have also linked mutations in *KCNJ10*, a potassium channel gene, and *FOXI1*, a transcriptional activator of *SLC26A4*, with Pendred syndrome associated with enlarged vestibular aqueduct, suggesting that it is a multigenic and complex disease (33).

Whereas the vestibular aqueduct forms around an ectodermal structure, the cochlear aqueduct is a secondary structure around a mesodermal derivative. Developmental aberrations of the otic capsule are expected to cause absence of rather than enlargement of the cochlear aqueduct. In fact, a recent study examining 400 temporal bone CT scans found no patients with enlargement of the cochlear aqueduct, suggesting that this is an exceedingly rare or even nonexistent malformation (34). Absence of the cochlear aqueduct is as yet unreported.

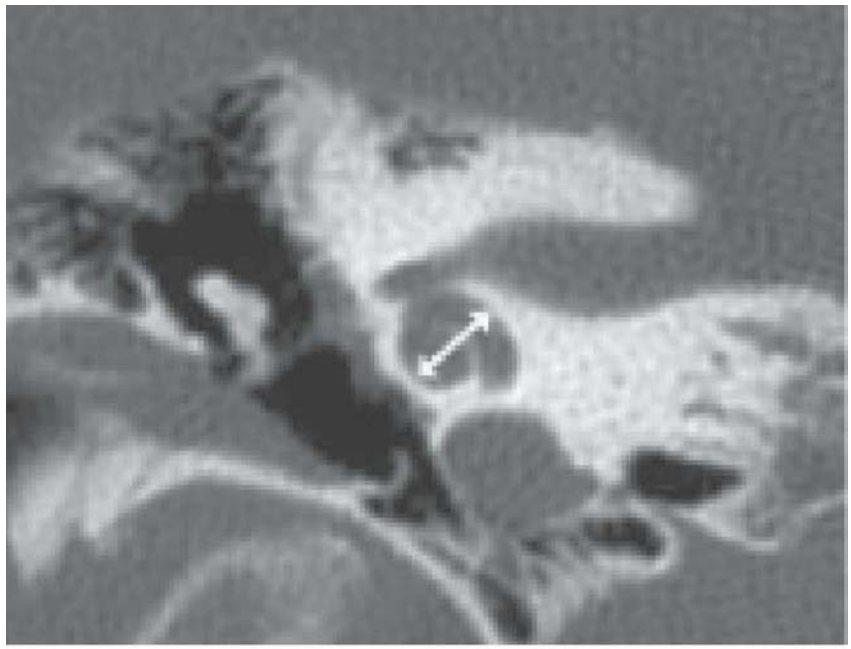
Of all the inner ear structures, the internal auditory canal is most variable in size, length, and configuration. Absence of bony partition between a large bulbous lateral end of the canal and the inner ear is associated with stapes gusher (DFN3). Due to a mutation in a developmental transcription factor gene POU3F4, this finding contraindicates stapedectomy for congenital stapes fixation. A narrow internal auditory canal can indicate failure of development of the eighth cranial nerve. If the internal auditory canal has a diameter less than 3 mm and there is normal facial function, it is likely that only the facial nerve is present. This condition is a contraindication to cochlear implantation (35).

The ability to identify maldevelopment of the inner ear is dependent on the sensitivity of radiologic imaging and experience of the clinician reviewing the images (36). Morphologic abnormalities of the bony labyrinth are identified in approximately 20% to 40% of patients with childhood SNHL undergoing temporal bone computerized tomography (CT) scan. While the identification of severe morphogenetic malformations such as complete labyrinthine aplasia or Michel deformity and common cavity deformity is not difficult (accounting for only 1% of abnormalities), the detection of milder radiologic abnormalities is dependent on the experience of the clinician. Nearly one-third of these less severe dysplasias are missed by simple visual inspection of the radiologic images. Introduction of standardized measurements of inner ear structures, such as the dimension of the vestibular aqueduct and the internal auditory canal, and more recently, the vertical height of the cochlea on coronal scan and of the central bony island within the LSCC on axial scan on temporal bone CT can complement visual analysis and greatly aid in the identification of inner ear malformations (Fig. 140.8) (36).

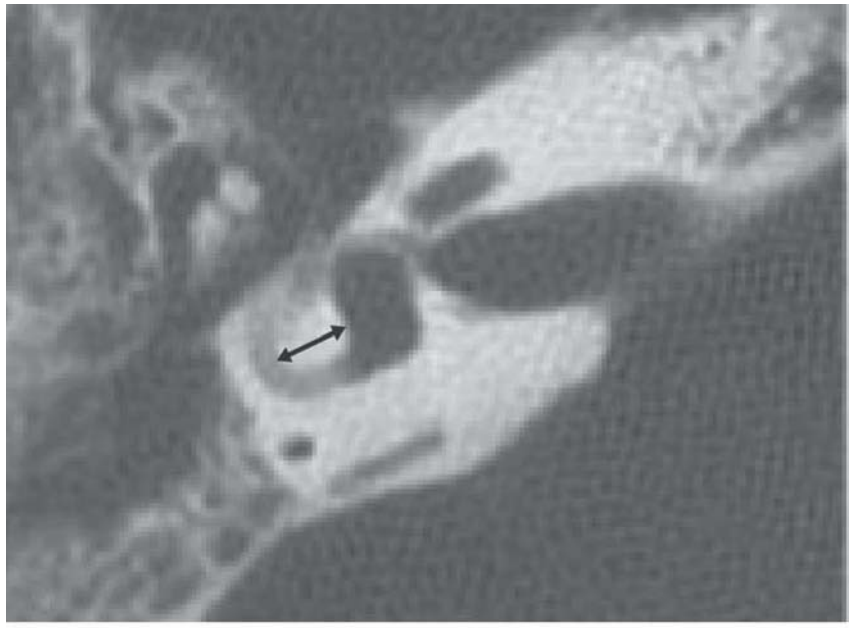
CONTROL OF EAR DEVELOPMENT

Molecular-genetic techniques with knockout and mutant animals have helped to elucidate the development of the ear. Development of both the outer and the middle ear is controlled by genes that affect first and second branchial arch identity as well as hindbrain segmentation and identity. Genetic defects range from the complete absence of structural elements to hypomorphism or duplication. The *HoxA2* gene, which is a type of developmentally critical homeobox gene, is expressed by neural crest cells that populate the first and second branchial arch and encodes a transcription factor that appears to be critical for the development of the external and middle ear. In fact, *HoxA2* knockout mice have been shown to have abnormal ear phenotypes, including transformations of middle ear bones and ectopic or duplicate malleus and incus (37). In addition, PACT, which is an RNA-binding protein expressed in the pinna, middle ear, and cochlea, may also play a crucial role in the development of the outer and middle ear, but not the inner ear, as *Pact* knockout mice express smaller external auditory canals, malformed ossicles, but normal cochlea (38). New cartilage elements can also arise from genetic defects. The phenotypes are not neatly arranged by branchial arch, reflecting functional redundancy in the system.

Invagination and inward movement of the otocyst are under control of external tissue interactions, particularly the hindbrain. Information from knockouts and mutants shows that the genes that control hindbrain segmentation, especially rhombomeres 5 and 6, and genes expressed in neural crest cells influence inner ear development. The inner ear consequently has an indirect requirement for neural genes also expressed in ear tissue. Absence of these genes can cause dramatic changes in inner ear development. For example, inactivation of the transcription factor



A



B

Figure 140.8 **A,B:** Routine measurement of the cochlear height on coronal scan and the axial measurement of the bony island of the lateral semicircular canal on CT of the temporal bone will complement visual analysis and greatly aid in the identification of inner ear malformations.

gene *Hoxa1* results in the complete absence or severe reduction in rhombomere 5 and produces a primitive cystic inner ear with defects of the semicircular canals and the cochlea. Furthermore, the transcription factor Pax2 also appears to be essential for inner ear development, as *Pax2* knockout mice have been shown to often lack a distinct saccule and have a fused endolymphatic duct and common crus. And although a rudimentary cochlea is always present in *Pax2* knockout mice, the organ of Corti is often absent and the formation of the spiral ganglion is frequently delayed or truncated (39). Recent studies have even shown that the proto-oncogene *N-myc* may also play an integral role in the growth, morphogenesis, and patterning of the inner ear. For example, *N-myc* knockout mice frequently show fusion of the cochlea with the sacculus and utriculus, stunted growth of the cochlea, and absence of the LSCC (40). The LSCC seems particularly sensitive to genetic perturbations, which is in accord with it being the most commonly abnormal semicircular canal. The various structural elements of the otic vesicle are under independent genetic control for specification, morphogenesis, or both (41).

HIGHLIGHTS

- The auricle develops from six ectodermal hillocks arising from the first and second branchial arches. Most of the adult pinna is of second arch origin.
- The ectoderm of the first branchial cleft forms the external auditory canal. The cartilaginous canal forms first and the bony canal later, from medial to lateral, at 28 weeks. The outer layer of the tympanic membrane is derived from this source.
- The tympanic cavity is derived from the first pharyngeal pouch and develops from the fourth week of gestation. It remains a slit-like structure as the endodermal pouch surrounds the ossicles and their supports to the fifth month and expands so the ossicles lie in a cavity in the eighth month.
- The ossicles develop from the neural crest mesenchyme of the first and second branchial arches, except for the vestibular surface of the footplate and the annular ligament, which arise from the mesoderm of the otic capsule.
- The facial nerve only comes to lie in its adult position late in fetal life. It consequently is anterior and superficial in ears with congenital malformations of the middle or outer ear.
- The membranous labyrinth develops from the otic placode. It invaginates to become the otocyst, subdivides into vestibular and cochlear compartments, and grows and dramatically changes shape to achieve adult form at 10 weeks and adult size at 20 weeks of gestation.
- The organ of Corti becomes functional in its basal turn at approximately 20 to 24 weeks.
- The vestibulocochlear ganglia are derived from the otic placode. They innervate six areas of neuroepithelial ectoderm on the wall of the membranous labyrinth that become the three cristae, two maculae, and the spiral organ of Corti.
- The perilymphatic space forms by means of resorption of precartilage from week 8 to week 24. The cartilage model of the bony otic capsule ossifies from 14 centers between week 16 and week 23. It is adult size at 22 weeks.
- Congenital inner ear abnormalities are divided into those affecting the membranous labyrinth alone and those affecting both the bony and membranous labyrinths. The latter appear to be caused by arrested development between weeks 4 and 8 of gestation. They account for only 20% of cases of abnormality but can be diagnosed with imaging techniques.
- Molecular-genetic techniques with knockout and mutant animals have helped to elucidate the development of the ear. Specific homeobox genes and other transcription factors appear to be critical for this process. Further research may help to more clearly illustrate the roles of these genes and their specific contribution to ear development.

Anatomy and Physiology of Hearing

141

Peter C. Weber *Samir Khariwala*

This chapter provides a brief summary of the most basic features of the anatomy and physiology of the ear. It is divided into sections on the external and middle ear, cochlea, and central nervous system (CNS). The focus is on the anatomic and physiologic bases of audition with an effort directed at functional features. Surgical anatomy, vasculature, and eustachian tube function are not discussed.

EXTERNAL EAR

The external ear consists of the pinna (auricle) and the external auditory canal (EAC) from the meatus to the tympanic membrane (Fig. 141.1). The pinna of humans is composed mostly of cartilage and has no useful muscles. The center of the pinna, the concha, leads to the external auditory meatus, which is about 2.5 cm long. The lateral third of the canal is the cartilaginous portion. It contains cerumen-producing glands and hair follicles. The remaining medial two-thirds is the bony portion, including an epithelial lining over the tympanic membrane (1).

The external ear and the head have a passive but important role in hearing because of their acoustic properties. The concha, or bowl of the auricle, has a resonance of about 5 kHz, and the irregular surface of the pinna introduces other resonances and antiresonances. These acoustic features are useful to help differentiate whether sound sources are in front of the listener or behind.

The EAC is essentially a tube that is open at one end and closed at the other; thus, the EAC behaves like a quarter-wave resonator. The resonant frequency (f_0) is determined by the length of the tube; the curvature of the tube is irrelevant. For a tube of 2.5 cm, the resonant frequency is approximately 3.5 kHz:

$$f_0 = \text{Velocity of sound @ 350 m/s}/(4 \times 2.5\ \text{cm})$$

A flat, wide-band sound measured in a sound field is changed considerably by the acoustic properties of the head and external ear. As Figure 141.2 demonstrates, a gain of about 15 dB occurs in the 3-kHz range of the human, cat, and chinchilla, and 10 dB between 2 and 5 kHz. The acoustic properties of the external ear are one of the reasons noise-induced hearing losses occur first and most prominently at the 4-kHz frequency region (boilermaker notch).

In addition to the prominence of noise-induced hearing loss in the 4-kHz region, the acoustic properties of the head and external ear have an important role in several hearing functions. In localization of sound sources, the head acts as an attenuator at frequencies at which the width of the head is greater than the wavelength of the sound. Thus at frequencies greater than 2 kHz, a *head shadow effect* occurs, in which interaural intensity differences of 5 to 15 dB are used to localize sound sources. At lower frequencies, at which the wavelength of the sound is larger than the width of the head, little attenuation is provided by the head. Interaural time differences (~0.6 ms for sound to travel across the head) are the salient cues for localization. The head-shadow effect is the reason right-handed hunters using rifles and shotguns have larger hearing losses in their left ears than in their right ears and vice versa. The muzzle of the gun, where the acoustic energy is greatest, is closer to the left ear, and the right ear is protected by the head-shadow effect.

The 10- to 15-dB gain provided by the external ear in the 3- to 5-kHz region is useful for improving the detection and recognition of low-energy, high-frequency sounds such as voiceless fricatives. The importance of the acoustic properties of the external ear and head is reflected in hearing-aid design and evaluations. Finally, the resonance of the external canal is approximately 8 kHz in infants and decreases to adult values after approximately 2.5 years of age. This developmental feature has several clinical implications, especially for sound-field testing and for hearing-aid design and evaluation of infants.

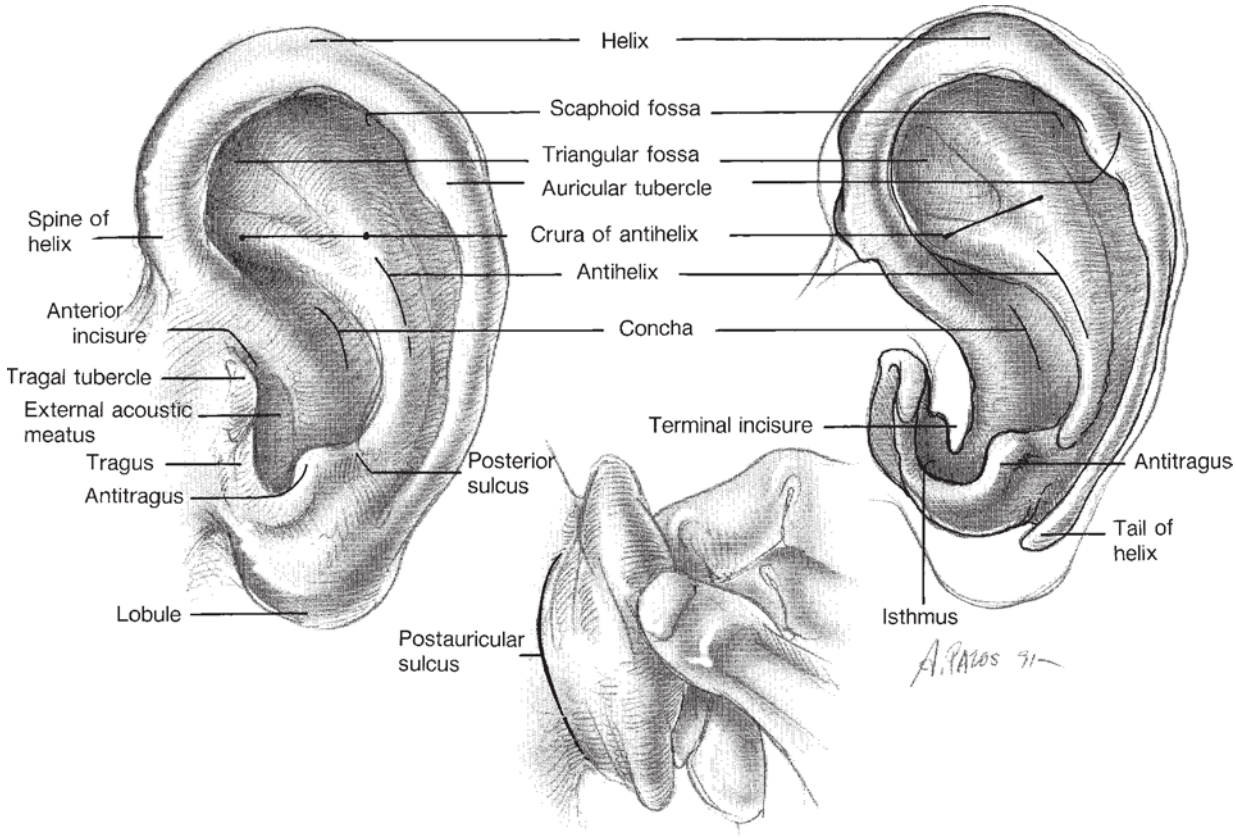

Figure 141.1 External ear.

MIDDLE EAR

The middle ear transmits acoustic energy from the air-filled EAC to the fluid-filled cochlea. It functions as an impedance-matching device inasmuch as it couples the low impedance of air to the high impedance of the fluid-filled cochlea. The impedance match is achieved in three ways. The first and most important factor is that the effective vibratory area of the tympanic membrane is approximately 17 to 20 times greater than the effective vibratory area of the stapes footplate (Fig. 141.3). A second factor involves the lever action of the ossicular chain. The arm of the long process of the incus is shorter, by a factor of 1.3, than the length of the manubrium and neck of the malleus. A third and minor factor is the shape of the tympanic membrane. The combined result of these three factors is a pressure gain of approximately 25 to 30 dB. The variance in published

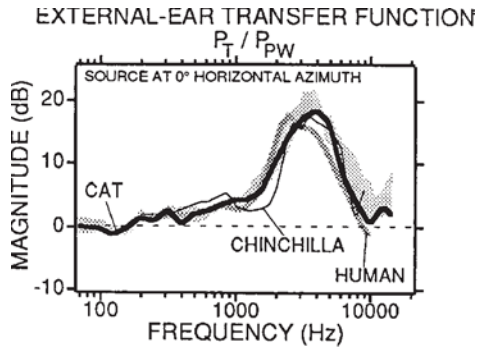

Figure 141.2 Ratio of sound pressure measured at the tympanic membrane to sound pressure measured in a sound field. Acoustic properties of the head, pinna, and external auditory meatus in three species (cat, chinchilla, and human). (From Rosowski JH. The effects of external and middle ear filters on noise-induced hearing loss. *J Acoust Soc Am* 1991;90:124, with permission.)

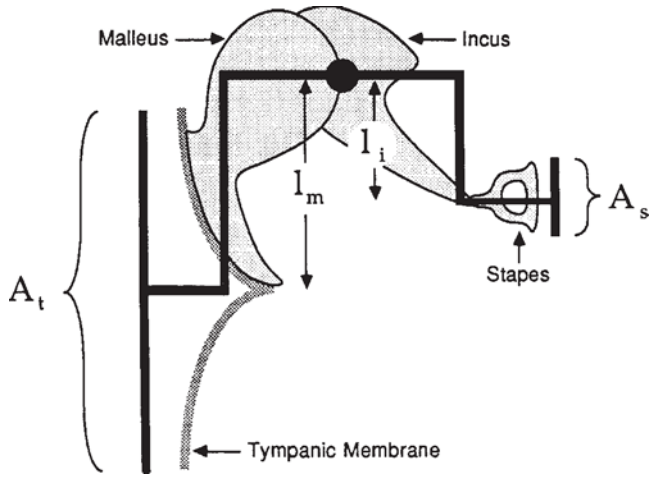

Figure 141.3 Schematic of ossicular chain and tympanic membrane shows the differences in area and vibratory pattern of the ossicles. (From Relkin EM. Introduction to the analysis of middle ear function. In: Jahn HF, Santos-Sacchi J, eds. *Physiology of the ear*. New York: Raven Press, 1988:103, with permission.)

measurements of the transformer ratio is noteworthy. With the exception of studies of acoustic impedance of the ear, most data are from studies of human cadavers, with all of their shortcomings, or of animals, usually cats. In addition to its role in the transfer of power to the inner ear, the tympanic membrane protects the middle ear space from foreign material of the ear canal and maintains the air cushion that prevents insufflation of foreign material from the nasopharynx though the eustachian tube.

The vibratory behavior of the ossicular chain is described in Figure 141.3. The transformer action of the tympanic membrane and ossicular chain provides for relatively efficient transfer of power to the inner ear, and the fidelity of sound transmission across the middle ear is outstanding. Distortion of sound signals does not occur in the middle ear, even for input signals with sound levels greater than 130 dB sound pressure level (SPL).

The middle ear, including the tympanic membrane, ossicular chain with supporting ligaments, and middle ear space, can be viewed as a passive mechanical system with both mass and compliant elements and therefore resonant properties. This linear system is coupled to the cochlea, which contributes a large resistance. The result is a middle ear system that is highly damped and linear and has a wide frequency response. The input–output function or transfer function of the middle ear is shown in Figure 141.4A. The ratio of the volume velocity of the stapes to sound pressure at the tympanic membrane increases in humans to approximately 800 to 900 Hz, which is the resonant frequency of the middle ear, and decreases at higher frequencies. Phase shift or time lag between movement of

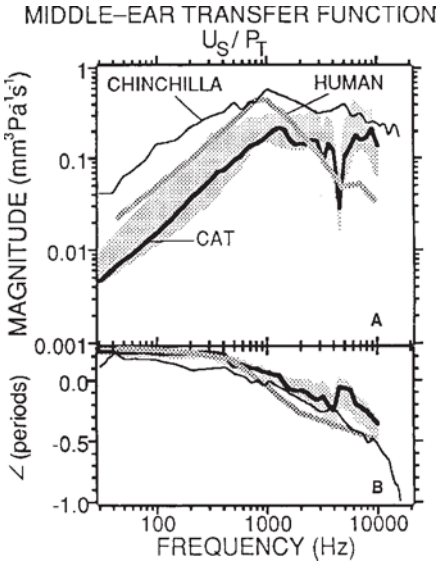

Figure 141.4 **A:** Transfer function of the middle ear in chinchilla, cat, and human. *Ordinate* is the ratio of the volume velocity of the stapes to sound pressure at the tympanic membrane. **B:** Phase shift of stapes footplate in relation to tympanic membrane. (From Rosowski JH. The effects of external and middle ear filters on noise-induced hearing loss. *J Acoust Soc Am* 1991;90:124, with permission.)

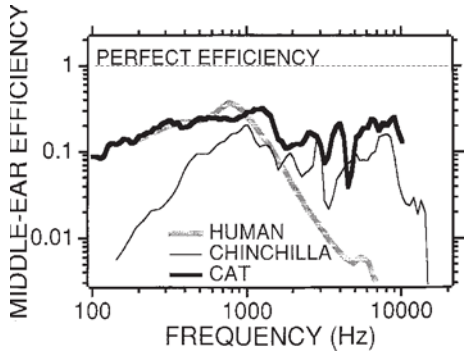

Figure 141.5 Efficiency of the transfer of power through the middle ear. For all species shown, less than half the power that enters the middle ear actually reaches the cochlea. Energy loss is caused by absorption by the tympanic membrane, ossicular ligaments, and middle ear. (From Rosowski JH. The effects of external and middle ear filters on noise-induced hearing loss. *J Acoust Soc Am* 1991;90:124, with permission.)

the tympanic membrane and the stapes generally increases with frequency (Fig. 141.4B). Although the middle ear is an impressive system in terms of frequency response, linearity, and transformer properties, considerably less than half of the power entering the middle ear actually reaches the cochlea because of the absorption of energy by the ligaments and middle ear. As shown in Figure 141.5, the human middle ear is particularly inefficient at frequencies greater than 2 kHz, especially in comparison with the ears of cats and chinchillas. It also is important to recall that a 50% loss of power is a loss of only 3 dB.

Auditory function is profoundly affected by cochlear impedance as well as the combined acoustic effects of the head, external ear, and middle ear. The combined effects of the acoustic properties of the head, external ear, and middle ear, as well the input impedance of the cochlea, have a profound effect on auditory function. For example, these factors determine the shape of the audibility curve and therefore the frequency range of human hearing (Fig. 141.6). For example, humans do not detect and recognize sounds greater than approximately 20 kHz because such high-frequency sounds are not transmitted efficiently through the middle ear to the cochlea. A second example of this sound transformation is shown in Figure 141.7, in which the spectrum of a cannon measured in a sound field is compared with the spectrum by the time it is transformed and shaped by the acoustic properties of the external ear, head, middle ear, and input impedance of the cochlea. Low-frequency energy is not transmitted to the cochlea, and the frequency region of greatest energy concentration is 3 to 4 kHz. Thus, these acoustic properties are primarily responsible for the ability of intense low-frequency sounds (measured in a sound field) to produce high-frequency hearing losses and injuries in the basal region of the cochlea.

Two striated muscles, the tensor tympani and the stapedius, are located in the middle ear. The former attaches to

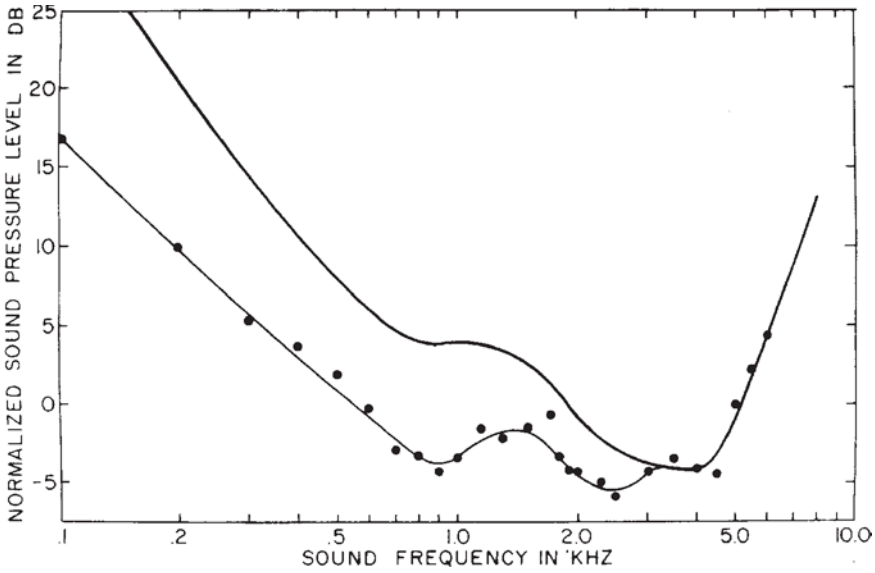

Figure 141.6 Comparison between overall outer and middle ear transfer function (*circles, lower curve*) and median threshold of audibility. (From Zwislocki JJ. The role of the external and middle ear in sound transmission. In: Turner D, ed. *The nervous system, human communication and its disorders.* Vol 3. New York: Raven Press, 1975:45, with permission.)

the malleus and is innervated by the trigeminal nerve. The stapedius muscle attaches to the stapes and is innervated by the stapedial branch of the facial nerve. Noticeably the stapedius and tensor tympani muscles are the smallest striated muscles in the body and also have a high innervation ratio, that is, nerve fibers per muscle fiber. Although no question remains that contraction of these muscles affects sound transmission through the middle ear, the details of the effect and the extent of the influence of the middle ear muscles are still not fully understood. A number of disparate functions have been attributed to the middle ear muscles.

One function of the middle ear muscles is to protect the cochlea from loud sounds (2). When sounds louder than approximately 80 dB SPL are presented monaurally or binaurally, consensual (bilateral) reflex contraction of the stapedius muscle occurs. This contraction increases the stiffness of the ossicular chain and tympanic membrane, attenuating sounds less than approximately 2 kHz. Although the tensor tympani contracts as part of a startle response, acoustic reflex data from human subjects with neurologic involvement of cranial nerves V and VII suggest that the tensor tympani does not normally respond to intense acoustic stimulation. Laboratory and field studies of noise-induced hearing loss have shown convincingly that the stapedial reflex protects the cochlea, particularly from low-frequency (<2 kHz) sounds in excess of 90 dB. Inasmuch as the latency of the acoustic reflex is greater than 10 ms, the cochlea may be unprotected from short-duration, unanticipated impulsive sounds.

The following functions have been attributed to the middle-ear muscles. Some of these functions include providing strength and rigidity to the ossicular chain; contributing to the blood supply of the ossicular chain; reducing physiologic noise caused by chewing and vocalization; improving the signal-to-noise ratio for high-frequency signals, especially high-frequency speech sounds such as voiceless fricatives, by means of attenuating high-level, low-frequency background noise; functioning as an automatic gain control and increasing the dynamic range of the ear; and smoothing out irregularities in the middle-ear transfer function.

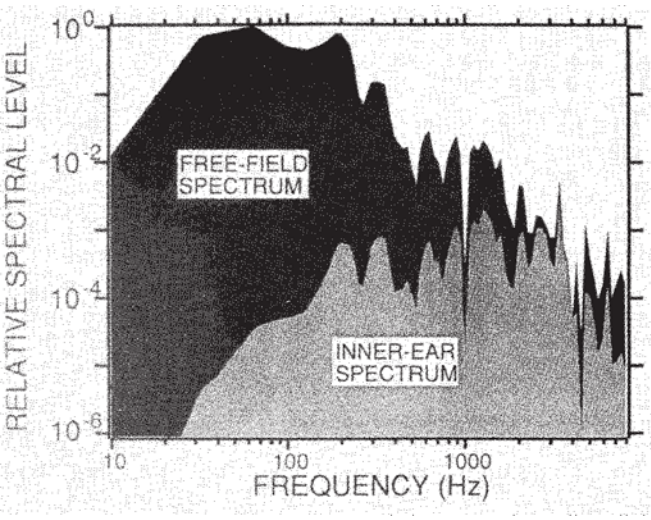

Figure 141.7 A comparison of the relative power spectra of impulses produced by a cannon and measured in a free field with the power that actually reaches the cochlea of a cat. (From Rosowski JH. The effects of external and middle ear filters on noise-induced hearing loss. *J Acoust Soc Am* 1991;90:124, with permission.)

COCHLEA

The human cochlea is a coiled, bony tube approximately 35 mm long, divided into the scala vestibuli, scala media, and scala tympani (Fig. 141.8). The scalae vestibuli and tympani contain perilymph, an extracellular fluid-like material with a potassium concentration of 4 mEq/L and a sodium concentration of 139 mEq/L. The scala media

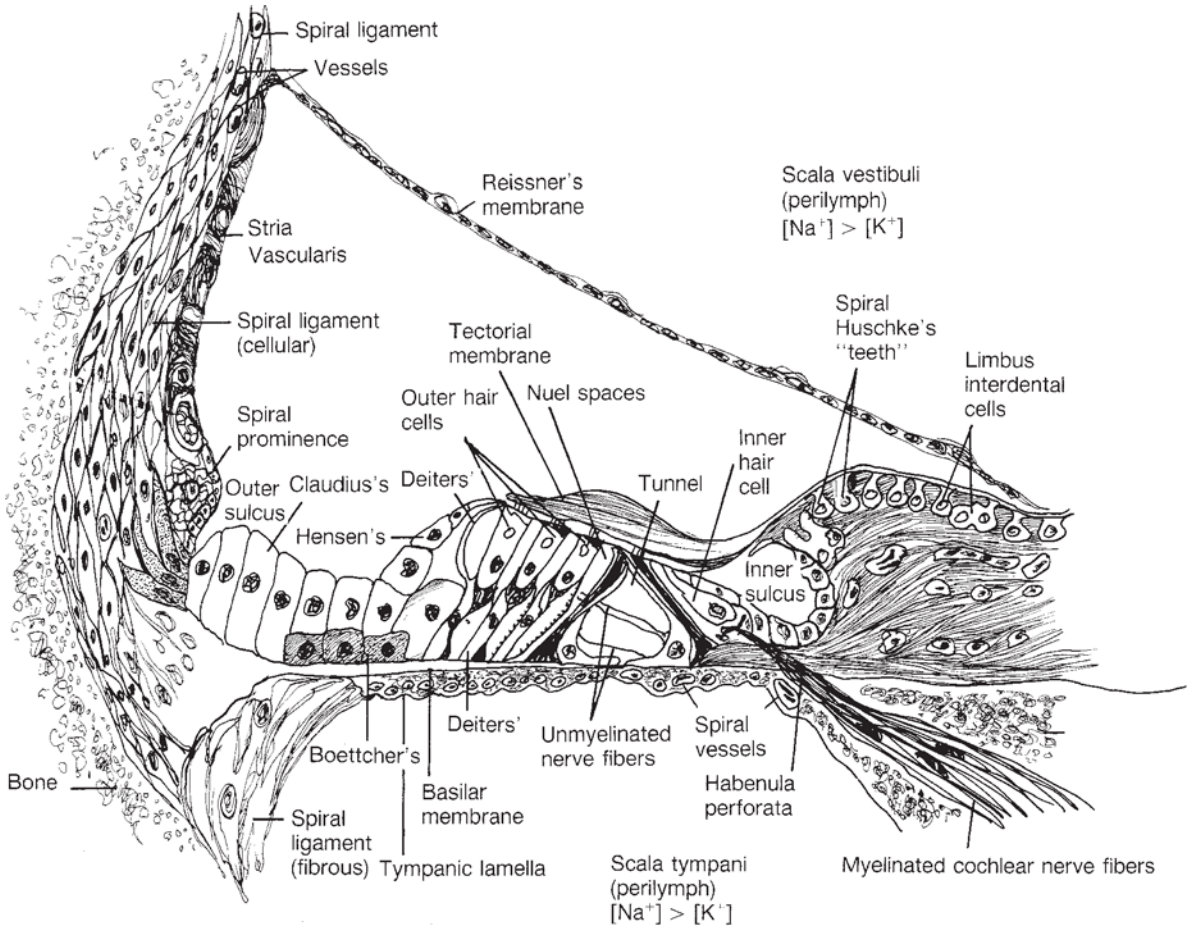

Figure 141.8 Midmodiolar view of cochlear duct. (Redrawn from Hawkins JE Jr. Hearing: anatomy and acoustics. In: Best C, Taylor NB, eds. *The physiological basis of medical practice*, 8th ed. Baltimore, MD: Williams & Wilkins, 1966:347, with permission.)

is bounded by the Reissner membrane, the basilar membrane and osseous spiral lamina, and the lateral wall. It contains endolymph, an intracellular-like fluid with a potassium concentration of 144 mEq/L and a sodium concentration of 13 mEq/L. The scala media has a positive direct current (DC) resting potential of approximately 80 mV that decreases slightly from the base to apex. This endocochlear potential is produced by the heavily vascularized stria vascularis of the lateral wall of the cochlea. The sodium-potassium-adenosine triphosphatase (Na^+-K^+-ATPase) pumps in a number of specialized cells of the stria vascularis contribute to this potential (3).

Acoustic energy enters the cochlea through the piston-like action of the stapes footplate on the oval window and is coupled directly to the perilymph of the scala vestibuli. The perilymph of the scala vestibuli communicates with the perilymph of the scala tympani through a small opening at the apex of the cochlea known as the *helicotrema*. The organ of Corti rests on the basilar membrane and osseous spiral lamina (Fig. 141.9). The basilar membrane is approximately 0.12 mm wide at the base and increases to approximately 0.5 mm at the apex. The major components of the organ of Corti are the outer and inner hair cells, supporting cells (Deiters, Hensen, Claudius), tectorial membrane, and the reticular lamina–cuticular plate complex (Fig. 141.10). Supporting cells provide structural and metabolic support for the organ of Corti. The phalangeal processes of the Deiters cells form tight cell junctions of the reticular lamina.

Outer and inner hair cells of the organ of Corti are important in transduction of the mechanical (acoustic) energy into electrical (neural) energy. Outer hair cells are radically different from inner hair cells. Figure 141.11 and Table 141.1 detail these differences (4). In addition to the morphologic differences between outer and inner hair cells, neural innervation is different (Fig. 141.12). The spiral ganglion, the cell body of the auditory nerve, sends axons to the cochlear nucleus of the brainstem, whereas the dendrite projects through the osseous spiral lamina. Of the 50,000 neurons that innervate the cochlea, 90% to 95% synapse directly on inner hair cells. These are called *type I neurons*. Each inner hair cell is innervated by approximately 15 to 20 type I neurons. In contrast, 5% to 10% of the 50,0000 neurons innervate the outer hair cells (*type II neurons*). Each type II neuron branches to innervate approximately 10 outer hair cells. In addition to the

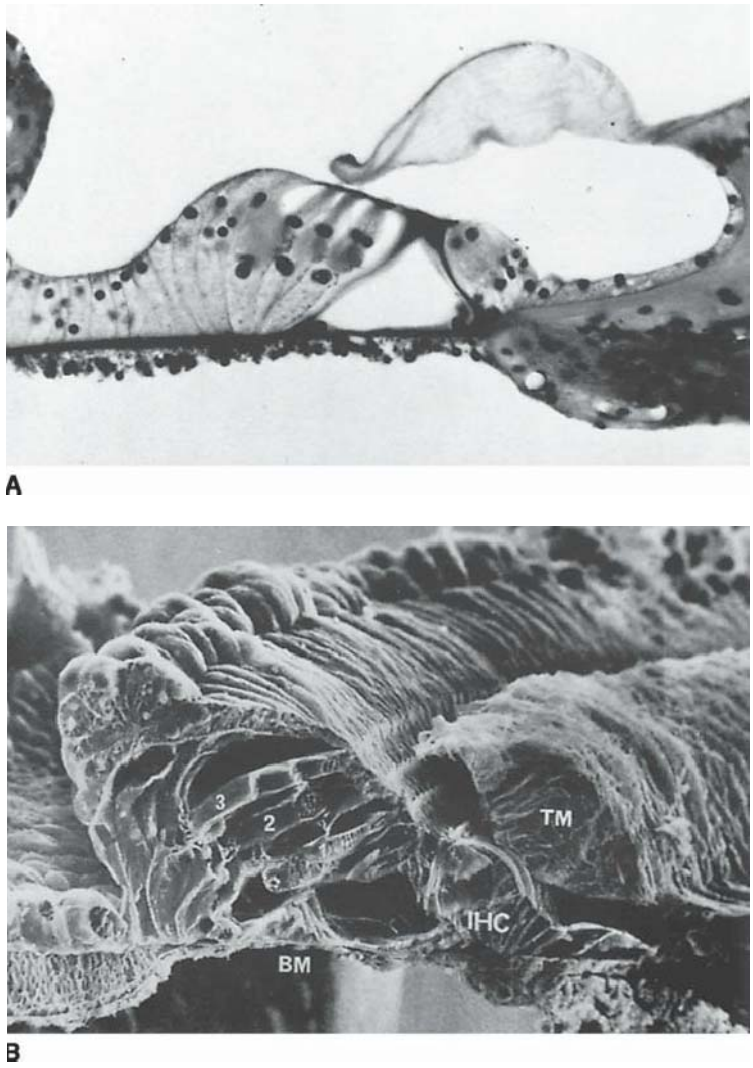

Figure 141.9 **A:** The organ of Corti of a cat in conventional midmodiolar section. Both sensory cells and supporting elements are evident. **B:** Photograph obtained through scanning electron microscope shows a corresponding specimen from a guinea pig. The inner hair cell (IHC) and three rows of outer hair cells (*1*, *2*, *3*) are visible. BM, basilar membrane; TM, tectorial membrane. (From Bredberg G, Ades W, Engstrom H. Scanning EM of the normal and pathologically altered organ of Corti: inner ear studies. *Acta Otolaryngol (Stockh)* 1972;301(suppl):48, with permission.)

afferent innervation pattern of the cochlea, approximately 1,800 efferent fibers, originating from the ipsilateral and contralateral superior olivary complex, project to the cochlea (Fig. 141.13).

Transduction is initiated by displacement of the basilar membrane in response to displacement of the stapes due to acoustic energy. The displacement pattern of the basilar membrane is a traveling wave (Fig. 141.14). The basilar membrane is stiffer at the base than in the apex. The stiffness component is distributed continuously. Therefore, the traveling wave always progresses from the base to apex. The maximal amplitude of basilar membrane displacement varies as a function of stimulus frequency. Traveling waves produced by high-frequency sounds (10 kHz) have maximal displacement near the base of the cochlea, whereas the waves to low-frequency sounds (125 Hz) have the maximum toward the apical region. Traveling waves generated by high-frequency sounds do not reach the apical regain of the cochlea, whereas waves to low-frequency sounds can travel the entire length of the basilar membrane.

In the past, the mechanical traveling wave was considered a broadly tuned response, with finer tuning introduced subsequently by transduction, the auditory nerve, and the CNS. Data obtained with sensitive recording and detection methods, however, have shown that the traveling wave has an extremely sharply tuned response (Fig. 141.15) and that many of the remarkable frequency-selective abilities of the ear can be explained by the mechanical properties of the cochlea.

The mechanism by which the sharply tuned peak is generated within the mechanical traveling wave involves an enhancement known as the *cochlear modifier*. This is an activity of the outer hair cells that enhances the motion of the basilar membrane at frequencies near the best frequency of the particular cochlear location. This enhancement contributes to the fine frequency-selective abilities of the ear and to the sensitivity of the ear and ability to detect extremely faint sounds. The notion of an active process in the cochlea, the cochlear amplifier, is supported by the phenomenon of *otoacoustic emissions*. That is, when a short-duration signal is presented to the ear, an echo emanating

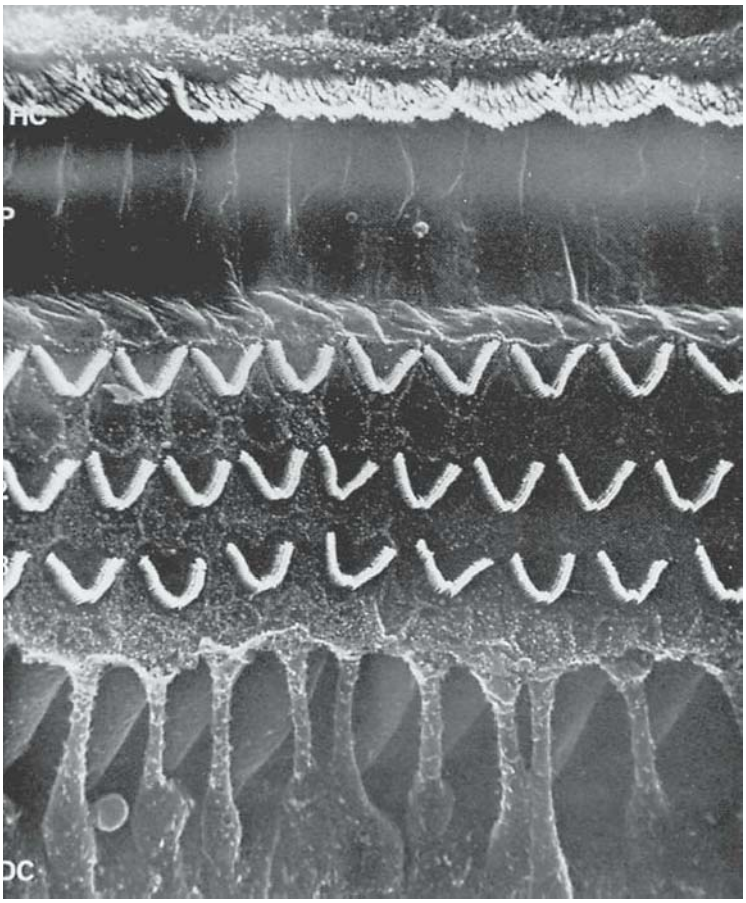

Figure 141.10 Scanning electron micrograph shows upper surface of organ of Corti with tectorial membrane removed. Modiolus is toward the *top*. Three rows of outer hair cells (*1, 2, 3*) with their characteristic V- or W-arranged stereocilia and a single row of inner hair cells (*IHC*) with slightly curved rows of stereocilia are visible. Inner and outer hair cells are separated by heads of pillar cells (*P*). Phalangeal processes of third row of Deiters cells (*DC*) are visible because Hensen cells have been removed. TABLE 141.1 STRUCTURE AND INNERVATION OF INNER AND OUTER HAIR CELLS

Characteristic	Inner Hair Cells	Outer Hair Cells
Number	3,500	12,000
Shape	Flask	Cylindrical
Stereocilia		
No. of hair cells	Few	Many
Arrangement	Three or four rows; rows slightly curved	Six or seven rows; rows arranged in V or W shape
Attachment to tectorial membrane	None or loosely connected	Longest stereocilia firmly embedded
Ultrastructure		
Position of nucleus cell body	Center	Base
Cytoplasmic organelles	Scattered	Adjacent to cell membrane
Presynaptic specializations	Large	Small or absent (synaptic bars and vesicles)
Glycogen content	Low	High
Relation to supporting cells	Completely surrounded	Supported only at surface and base
Afferent innervation		
Ganglion cells	Type I	Type II
Number of ganglion cells	27,000	2,100
Hair cell-to-ganglion cell ratio	1.8:1	5.7:1
Efferent innervation		
Source	Lateral superior olivary complex	Medial superior olivary complex
Postsynaptic target	Afferent dendrites	Base of hair cell

From Neely JG, Dennis JM, Lippe WR. Anatomy of the auditory end organ and neural pathways. In: Cummings CW, ed. *Otolaryngology–head and neck surgery*. St. Louis, MO: Mosby, 1986:2571, with permission.

from the cochlea can be recorded in the external auditory meatus. Because the energy of the echo can be greater than the energy of the short-duration signal, an active process, the cochlear amplifier, is assumed. Factors that may contribute to the cochlear amplifier include motility of outer hair cells and the mechanical properties of the stereocilia and tectorial membrane.

The stereocilia-hair cell complex is critical to transduction. Stereocilia are bundles of actin filaments that form tubes and are inserted into the cuticular plate. They also are cross-linked between themselves. Stereocilia of inner hair cells probably do not contact the tectorial membrane, but those of outer hair cells are in direct contact. Deflection of the stereocilia by the traveling wave opens and closes nonspecific ion channels at the tips of the stereocilia, resulting in a current flow (potassium) into the sensory cell. The flow of potassium ions into the sensory cell is modulated by the opening and closing of ion channels of the stereocilia. The potassium flux is caused by the endocochlear potential of +80 mV added to the negative intracellular

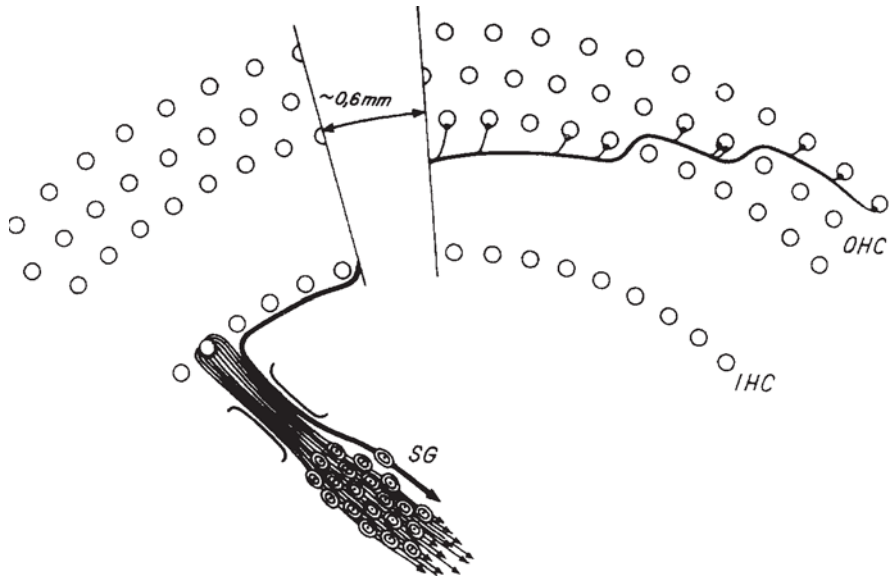

Figure 141.12 Schematic view from above shows the surface of the organ of Corti. The distribution of cochlear nerve fibers to inner (*IHC*) and outer (*OHC*) hair cells is evident. Basal end of cochlea is toward the *right*. Most spiral ganglion cells (*SG*) synapse with inner hair cells. Each ganglion cell innervates only one hair cell; many ganglion cells contact each hair cell. Only approximately 5% of spiral ganglion cells innervate outer hair cells. Each fiber travels basally for some distance before sending branches to several outer hair cells. (From Spoendlin H. The afferent innervation of the cochlea. In: Naunton RF, Fernandez C, eds. *Evoked electrical activity in the auditory nervous system*. New York: Academic Press, 1978:29, with permission.)

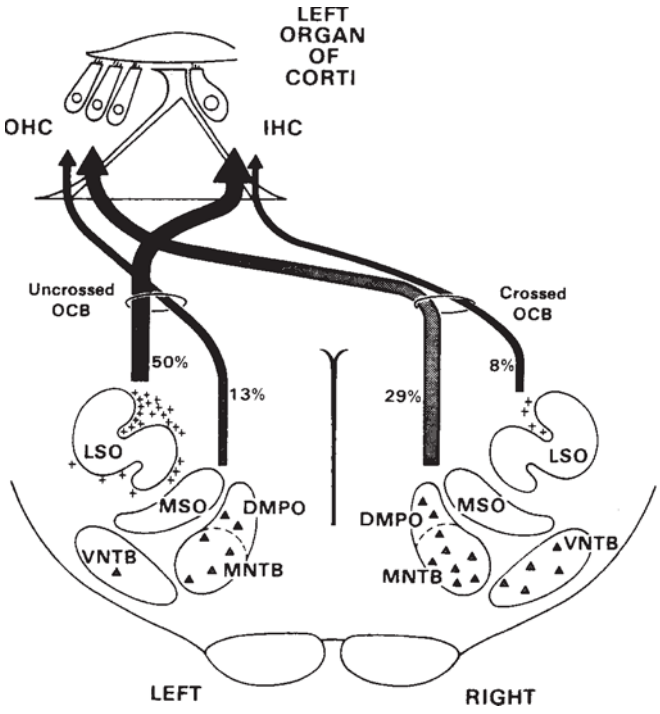

Figure 141.13 Schematic shows origin and distribution of efferent fibers of the olivocochlear bundle. *Crosses*, Small olivocochlear bundle neurons; *triangles*, large olivocochlear bundle neurons. The *number* of each kind of symbol, relative widths of *lines*, and *percentages* indicate the proportion of total olivocochlear projection to one cochlea that arises from each cell group. Efferent fibers to outer hair cells originate from large cells in the medial portion of the superior olivary complex. Approximately 70% of the projection to outer hair cells comes from the contralateral side of the brain. Projection to inner hair cells arises from small cells in the lateral region of the superior olive. Most of these fibers (85%) originate on the ipsilateral portion of the brain. Data are from studies with cats. DMPO, dorsomedial preolivary nucleus; IHC, inner hair cells; LSO, later superior olivary nucleus; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olivary nucleus; OCB, olivocochlear bundle; OHC, outer hair cells; VNTB, ventral nucleus of the trapezoid body. (From Warr B. The olivocochlear bundle: its origins and terminations in the cat. In: Naunton RF, Fernandez C, eds. *Evoked electrical activity in the auditory nervous system.* New York: Academic Press, 1978:60, with permission.)

potentials of hair cells. The resulting intracellular depolarization causes an enzyme cascade involving calcium. This ultimately leads to the release of chemical transmitters, and the subsequent activation of the afferent nerve fibers.

Although the notion of the cochlea as an active rather than a passive organ is no longer debated, specific details of the cochlear amplifier and the biologic basis of its operation are under active investigation. One point of view attributes the cochlear amplifier to the ability of hair cells to contract and lengthen in response to electrical signals, a property called *somatic electromotility*. A protein named *prestin* has been identified in outer hair cells and is considered to be the motor protein of outer hair cells and the driving force of electromotility of hair cells (5). Another point of view focuses on rapidly acting potassium and calcium ion channels presumed to be the basis of the cochlear amplifier and its regulation (6). A third approach suggests that a collection of motor proteins within a hair cell can generate oscillations that depend on the elastic properties of the cell (7). The foregoing approaches are nonlinear models that involve rapidly acting calcium channels. Specification of the biologic basis of the cochlear amplifier (nonlinearity) is important inasmuch as many forms of hearing loss involve loss of the cochlear amplifier.

The neurotransmitters of the afferent and efferent systems are the subject of intense study. In regard to the afferent system, analysis of excitatory amino acid receptor expression by the techniques of reverse transcriptase–polymerase chain reaction, in situ hybridization, and immunochemical analysis indicates that glutamate is the afferent neurotransmitter. Glutamate has been detected in both spiral ganglion cells and sensory cells (8). The principal transmitter substance of cochlear efferent fibers is acetylcholine. It is possible that the organ of Corti is mechanically modified by means of motility changes of outer hair cells under the influence of the efferent system. Acetylcholine acts on receptors to produce hyperpolarization of the cell membrane

Middle ear response in the chinchilla and its relationship to mechanics at the base of the cochlea. *J Acoust Soc Am* 1990;87:1612, with permission.)

and doubling of the input conductance of the cell. The acetylcholine receptor has both muscarinic and nicotinic features. In addition to acetylcholine, γ-aminobutyric acid and several neuroactive peptides are neurotransmitters for the efferent system (9–11).

GROSS COCHLEAR POTENTIALS

Four gross (extracellular) potentials can be recorded in the cochlea (12)—endolymphatic (endocochlear) potential, cochlear microphonic, summating potential, and whole-nerve action potential (Fig. 141.16). Unlike the other cochlear potentials, the endolymphatic potential is not generated in response to acoustic stimulation; rather, it is a DC potential of 80 to 100 mV recorded in the scala media. It arises from the stria vascularis of the lateral wall of the cochlea. The stria vascularis is considered to be the energy source, or "battery," of the cochlea, crucial for transduction. The nature of the energy source is the Na^+-K^+-ATPase pump. This pump has been localized to several types of cochlear cells, including marginal cells of the stria vascularis, outer sulcus cells, and fibrocytes near the attachment of the Reissner membrane and in the spiral ligament. Whereas Na^+-K^+-ATPase must play a significant role in ion transport in the cochlea, the nature of the energy source and the details of the ion exchange remain active research issues (3).

Malfunctioning of the mechanisms involved in production of endolymph and the endolymphatic potential can produce hearing loss, sometimes called *metabolic presbycusis*. When the flow of endolymph through the ductus reuniens is blocked, endolymphatic pressure increases, and hydrops occurs.

The cochlear microphonic is an alternating current (AC) voltage usually recorded within the cochlea or near

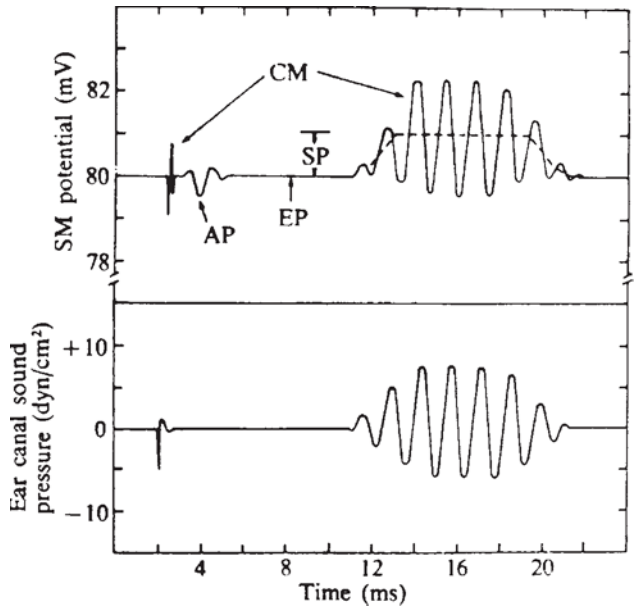

Figure 141.16 Schematic shows cochlear potentials recorded in the scala media in response to typical acoustic stimuli. All waveforms are approximately to scale. **Bottom:** Time waveforms of sound pressure in the ear canal for a click and a 750-Hz tone burst obtained with a probe-tube microphone. *Positive* and *negative* pressures refer to condensation and rarefaction, respectively, with the static value of atmospheric pressure subtracted out. An acoustic pressure of 5 dyne/cm² is equivalent to 88 dB SPL, referred to as 0.0002 dyne/cm² (20 Pa). **Top:** Resulting time waveform of the potential recorded in scala media by a single micropipette in the basal turn. The voltage is referenced to the neck of the animal. Ordinate is discontinuous to allow closer inspection of stimulus-related waveforms on the 80-mV endocochlear potential (*EP*), that is, the whole-nerve action potential (*AP*), the cochlear microphonic (*CM*), and the summating potential (*SP*). At low frequencies, the phase of the cochlear microphonic waveform leads that of the sound pressure at the eardrum. (From Schmiedt RA. Basic techniques for the measurement of cochlear potentials. In: Beagley HA, ed. *Auditory investigation: the scientific and technological basis.* Oxford: Clarendon Press, 1979:211, with permission.)

the round window. It represents the potassium ion current flow through mainly the outer hair cells; that is, the electrical resistance of outer hair cells is altered by the motion of the basilar membrane. When stereocilia are bent away from the modiolus, the resistance of the hair cells decreases. The result is an increase in current flow and a small decrease in endolymphatic potential. When stereocilia are bent toward the modiolus, resistance increases and current flow decreases with an accompanying increase in the endolymphatic potential. The corresponding voltage fluctuations, the cochlear microphonic, depend on the presence of outer hair cells. Unlike neural potentials, the waveform of the cochlear microphonic mirrors the motion of the basilar membrane. The summating potential is a DC potential recorded in the cochlea in response to sound. It follows the envelope of the stimulating sound. Recordings of this DC potential can be made in the scala tympani, media, or vestibuli and in some circumstances from a gross electrode in the human ear canal. The potential can be positive or negative, and it can reverse polarity, depending on electrode location or stimulus frequency and level. The summating potential probably has several origins, but it largely reflects the DC shifts caused by stimulus-driven intracellular potentials of outer hair cells. Inner hair cells contribute to these to a lesser extent.

The whole-nerve or compound action potential arises from the all-or-none discharge of auditory nerve fibers. The compound action potential is recorded most effectively with a gross electrode placed near the round window or auditory nerve and with high-frequency signals with rapid onsets. Such signals produce synchronous neural activity, which is summed to become the compound action potential waveform. The amplitude of the compound action potential increases with stimulus intensity over a 40- to 50-dB range, whereas latency decreases as stimulus intensity is increased. At high levels, a second peak sometimes is observed that probably reflects activity of the cochlear nucleus. The compound action potential can be clinically recorded with scalp electrodes or electrodes in the external meatus or by means of a transtympanic approach in which an electrode is placed near the round window niche. The ratio of the amplitude of the summating potential to the amplitude of the compound action potential has been used as an indicator of perilymphatic fistula, but the validity of this indicator is doubtful.

EIGHTH NERVE PHYSIOLOGY

The auditory nerve has approximately 30,000 fibers in humans and approximately 50,000 in cats. Perhaps one of the most important research findings in recent years was the observation that 90% to 95% of neurons (type I, radial fibers) innervate inner hair cells, whereas 5% to 10% (type II, outer spiral fibers) innervate to the outer hair cells (Fig. 141.12). Most, if not all, recordings from auditory nerve fibers are from the larger type I fibers in contact with inner hair cells. These radial fibers have bipolar cell bodies in the spiral ganglion. Outer spiral fibers are monopolar and unmyelinated. Most recordings of single units of the auditory nerve are obtained by means of inserting a microelectrode into the auditory nerve where it exits the internal auditory meatus. The most basic measures of auditory nerve function are spontaneous rates, tuning curves, and intensity (rate-level) functions.

Most auditory nerve fibers in mammals discharge in the absence of acoustic stimulation. The nerve fibers have been classified into three categories on the basis of rate of spontaneous discharge—high (18 to 120 spikes per second), medium (0.5 to 18 spikes per second), and low (0 to 0.5 spikes per second). Fibers with high rates of spontaneous activity respond to auditory signals at lower levels than do fibers with medium or low rates of spontaneous activity. In other words, the most-sensitive fibers have the most-spontaneous activity. Fibers with high spontaneous rates have thick dendrites that tend to terminate on the side of inner hair cells facing outer hair cells. Fibers with low and medium spontaneous rates have thin dendrites that terminate on the side of the inner hair cell facing the modiolus. Ongoing studies indicate that fibers with high rates of spontaneous activity have different terminations in the auditory CNS (cochlear nucleus) than do fibers with low rates of spontaneous activity. In other words, spontaneous activity of nerve fibers is not random but is proving to be anatomically and functionally significant (13–16). The tuning curve of a single auditory nerve fiber is perhaps the most basic measure of auditory nerve function. A tone burst controlled in frequency and level is presented. The level is adjusted until a criterion change (one or two spikes per second) in firing rate is detected. Tone bursts covering a wide range of frequencies are used, and the lowest level of signal is recorded for a given frequency that produces a specific rate of discharge. The resulting isoresponse curve is called a *tuning curve*.

Figure 141.17 shows tuning curves for six different fibers. The sharp tip of the tuning curve identifies the best, or characteristic, frequency of the fiber. Units with low characteristic frequency innervate inner hair cells in the apical region of the cochlea, fibers with high characteristic frequency innervate inner hair cells from the basal region, and so on. Tuning curves are described according to the frequency of the tip or characteristic frequency, the high- and low-frequency side, and the tail. Fibers with a characteristic frequency less than 1 kHz are roughly V shaped. Fibers with a higher characteristic frequency have an obvious tip at the characteristic frequency and a tail that extends to the low frequencies. The high side of a tuning curve is the frequency region greater than the characteristic frequency. As characteristic frequency increases, the high side of the tuning curve becomes steeper with a slope or rejection rate that can exceed 500 dB per octave. The characteristics of tuning curves of auditory nerve fibers are strikingly similar to isoamplitude curves of a mechanical traveling wave (Fig. 141.15).

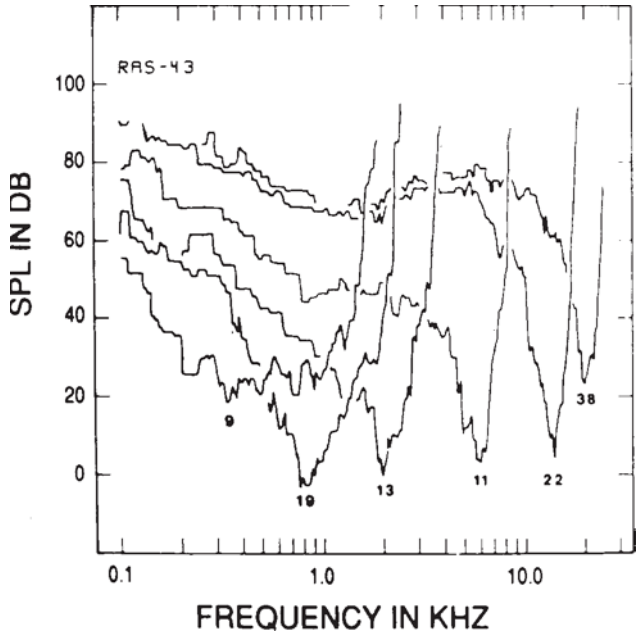

Figure 141.17 Tuning curves obtained from single fibers in the auditory nerve of a 6-month-old gerbil (CG-9) raised in quiet. Fiber numbers given in sequence during the experiment are at the *tips* of the curves. (From Schmiedt RA, Mills JH, Adams K. Tuning and suppression in auditory nerve fibers of aged gerbils raised in quiet or noise. *Hear Res* 1990;45:221, with permission.)

Injury or damage to sensory cells, including stereocilia, can alter the shape of tuning curves dramatically (Fig. 141.18). The lower right portion of the figure shows that when outer hair cells are destroyed, the tuning curve of auditory nerve fibers from normal inner hair cells is changed in several ways. The sensitive tip region is missing; that is, the threshold of the fiber is elevated by approximately 40 to 45 dB. The high-frequency side no longer has a steep slope, and the low-frequency side becomes slightly more sensitive, or hypersensitive. The characteristic frequency of the fiber appears to be much lower in frequency, and the band width of the fiber appears broader. The upper left portion of Figure 141.18 shows the consequences of partial injury to the stereocilia of outer hair cells. A threshold shift of approximately 30 dB occurs, but a short, sharply tuned tip remains, and the low-frequency tail is again hypersensitive. Irregularities in this tuning curve may explain monaural displacusis; that is, a tone in one ear (800 Hz) has two pitches, for example, one at 800 Hz and a second at approximately 2.8 kHz.

The upper left portion of Figure 141.18 shows a tuning curve in which stereocilia of inner hair cells are damaged or in disarray, whereas most of the stereocilia of outer hair cells appear normal or nearly so. The threshold of the unit is elevated approximately 30 dB, but the tuning curve is approximately normal. The lower left portion of the figure shows responses to signals in a narrow range of frequencies only at sound levels greater than 90 dB SPL. In this case, sensory cells are present, but stereocilia of inner hair cells are

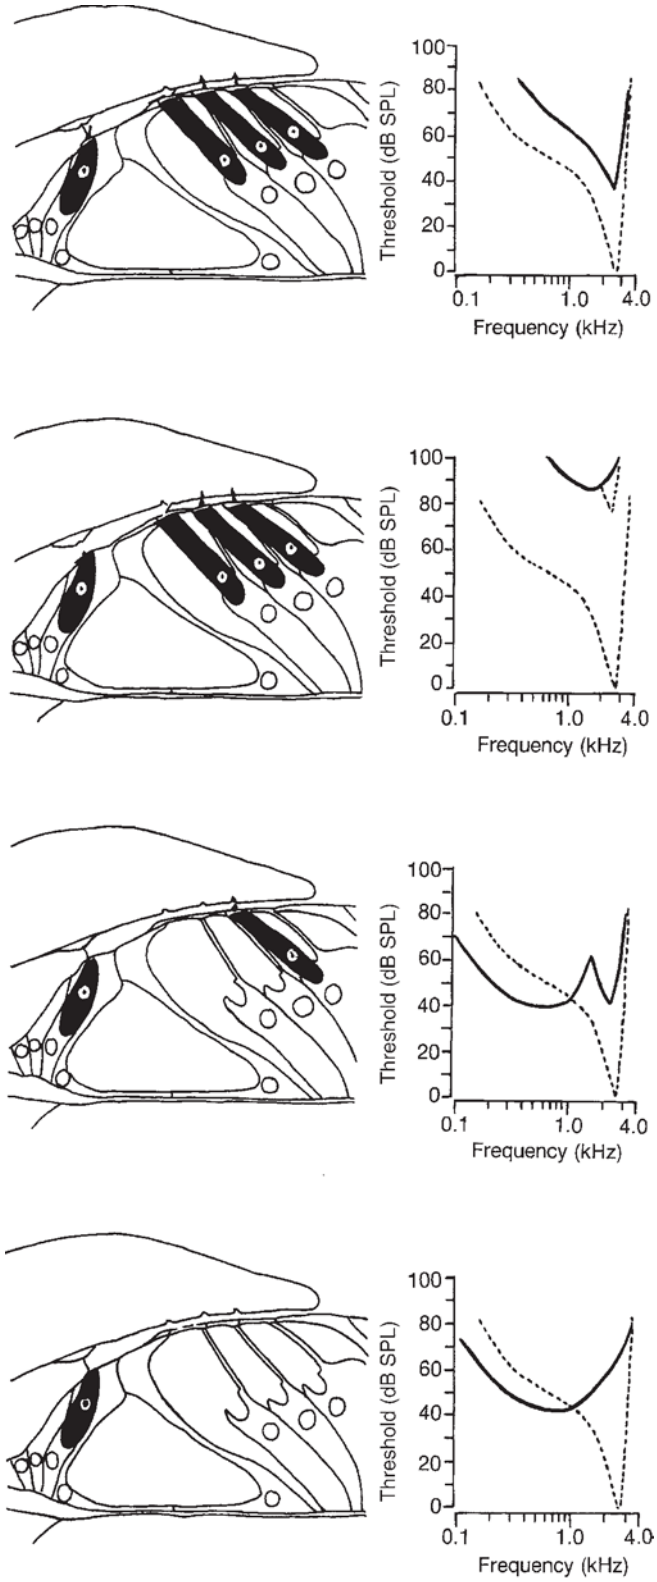

Figure 141.18 Tuning curves of single units of the auditory nerve with different degrees and types of acoustic injury to the sensory cells, including stereocilia. *Dotted line*, normal; *solid line*, after injury. (Redrawn from Liberman MC, Dodds LW. Single neuron labeling and chronic cochlear pathology III: stereocilia damage and alterations of threshold tuning curves. *Hear Res* 1984;16:55, with permission.)

destroyed, and those of outer hair cells are destroyed or in disarray. Thus normal neural activity, including sensitivity (detection of faint sounds) and frequency-resolving power, depends on intact outer hair cells and normal stereocilia.

Although thresholds of auditory nerve fibers are related to the rate of spontaneous discharge, most afferent nerve fibers (60%) have high spontaneous rates and thresholds within 20 dB greater than the thresholds for the animal. The remaining low-spontaneous fibers have thresholds that cover approximately 60 dB. The dynamic range of most auditory nerve fibers is approximately 30 dB from threshold to saturation (Fig. 141.19), although some low-spontaneous fibers have a much wider dynamic range. Given the dynamic range of human hearing (0 dB SPL to ≥100 dB SPL), the auditory system must have neurons the thresholds of which cover a wide range and have firing rates that also cover a wide range of intensities. The ability of the human ear to respond appropriately to sounds over a 120-dB range (10,13) is remarkable. One way is with low-spontaneous fibers; another is recruitment of fibers of characteristic frequency.

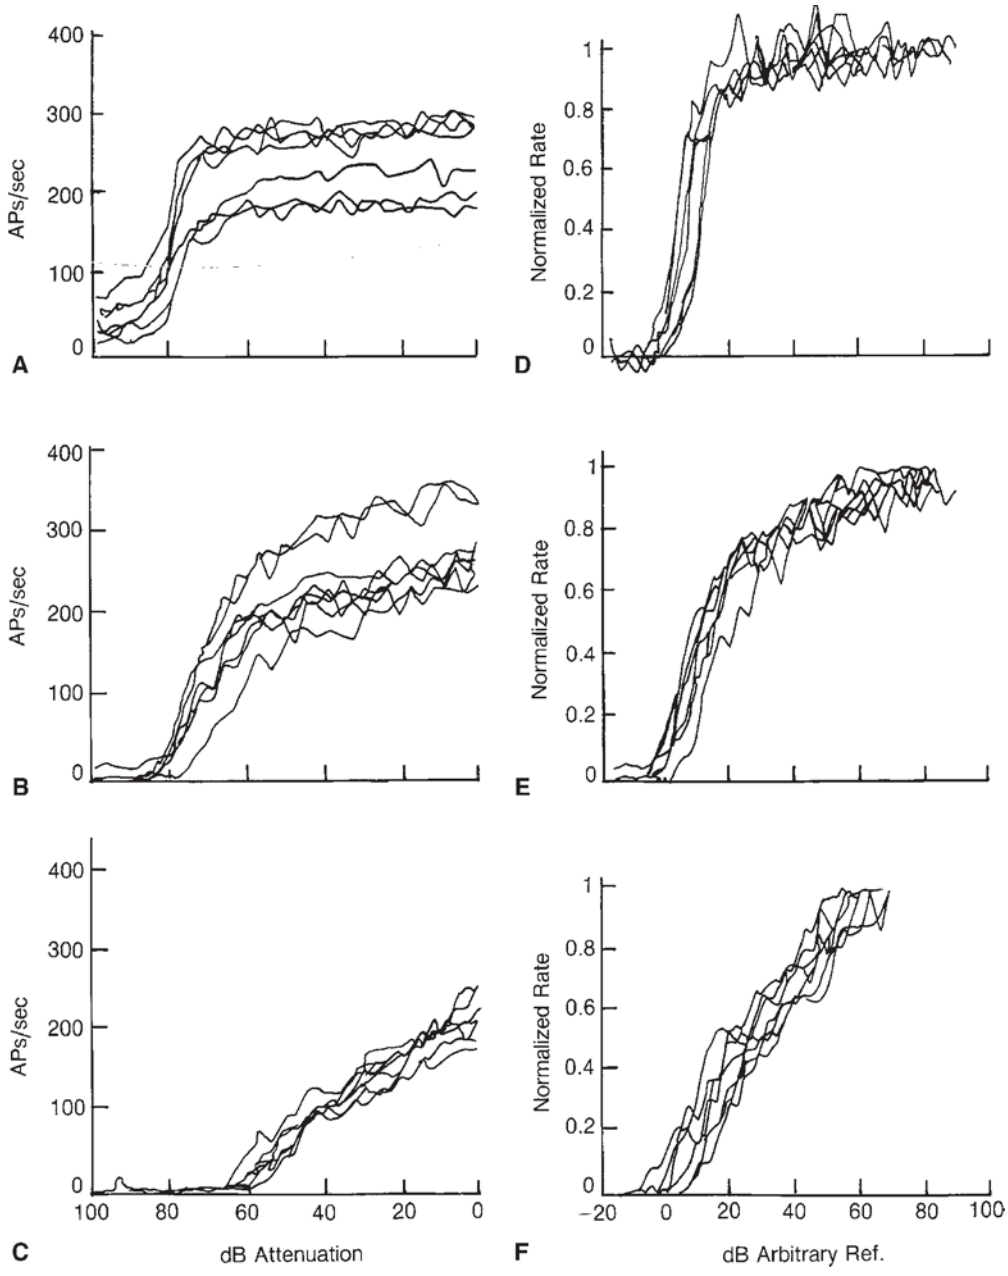

Figure 141.19 Examples of the three types of rate-intensity function. **A:** Saturating. **B:** Sloping saturation. **C:** Straight. For all units, characteristic frequency (*CF*) varies between 16 and 24 kHz, and maximum sound level varies between 104 and 115 dB SPL. **D–F:** Normalized rate–intensity functions for the fibers in **A, B,** and **C.** (Redrawn from Winter IM, Robertson D, Yabs GK. Diversity of characteristic frequency rate-intensity functions in guinea pig auditory nerve fibers. *Hear Res* 1990;45:191, with permission.)

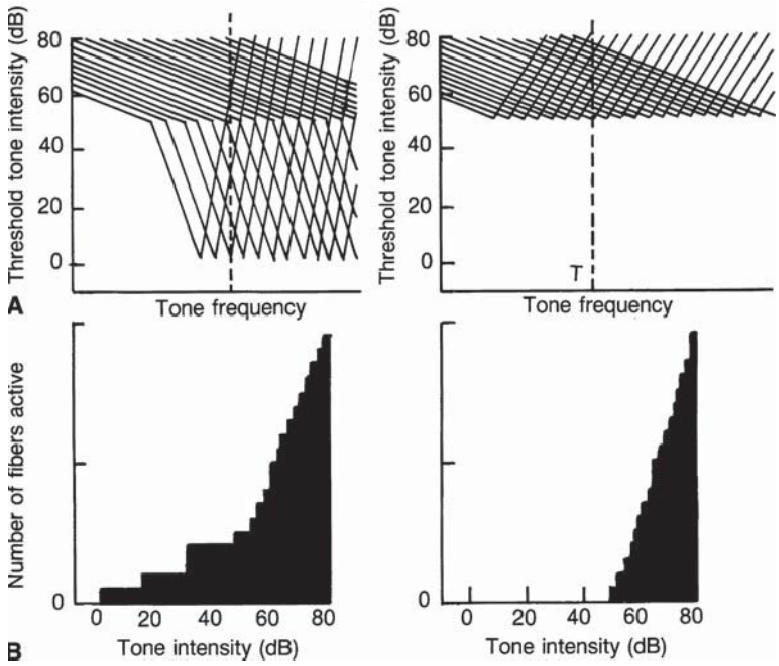

Figure 141.20 Neural explanation of one mechanism of loudness recruitment. **A:** Normal ear. **B:** Loudness in an abnormal ear grows abnormally quickly with intensity once the threshold is reached because the tips of the tuning curves are missing. (From Evans EF. The sharpening of cochlear frequency selectivity in the normal and abnormal cochlea. *Audiology* 1975;14:419, with permission.)

One of the most common features of sensorineural hearing loss is recruitment of loudness. Figure 141.20 gives an explanation. It is assumed that loudness depends on the total activity of the auditory nerve. As Figure 141.20A shows, the number of fibers activated increases slowly as intensity is increased, and only the tips of the tuning curves are activated. As the intensity increases further, the tails of the tuning curves are encountered, and the number of fibers activated increases rapidly. In the case of sensorineural hearing loss, the tips of the tuning curves are missing, and the fibers are not activated until the level of the signal is sufficient to reach the tails of the tuning curves. Abruptly, many fibers then are abruptly activated simultaneously.

NONLINEAR PROPERTIES OF THE EAR

Some of the outstanding features of the middle ear transformer are its linear properties, but the outstanding features of the cochlea and auditory nerve are the nonlinear characteristics. Perhaps the most studied nonlinearities are combination tones, described herein in relation to cochlear emissions, and two-tone rate suppression, as recorded in auditory nerve fibers.

Two-tone rate suppression is the reduction in firing rate produced by one tone when a second tone is introduced. Figure 141.21 shows a tuning curve with a suppression area outlined above the characteristic frequency of the nerve fiber and an area below the characteristic frequency of the fiber. Tones presented in the dotted or suppression areas in the figure reduce the firing rate caused by the probe tone. Both the excitor and suppressor tones are presented simultaneously, and because little or no time lag is associated with this phenomenon nor is any evidence available that it is neurally produced, the effect is called *suppression* rather than inhibition. Two-tone suppression in single units is reflected in the compound action potential. Figure 141.21 (right) shows tuning curves of the compound action potential with suppression areas shown in the dotted areas. In this case, the amplitude of the compound action potential is altered by the suppressing signal, whereas in the single-unit case (left), the firing rate of a neuron is reduced by an arbitrary amount (20%). The single-unit and compound action potential suppression areas are similar. Inasmuch as two-tone suppression can be observed in the DC intracellular response of inner hair cells, it is probable that two-tone suppression originates in the active nature of cochlear mechanics and before the inner hair cells.

In the presence of sensorineural hearing loss caused by exposure to noise or to ototoxic drugs, two-tone rate suppression is severely affected, if at all measurable. Two-tone rate suppression appears normal or nearly so in cases of cochlear hearing loss in which the sensory cells, including stereocilia, are normal or nearly so, but in the stria vascularis is affected. The latter scenario leads to presbycusis (17).

Otoacoustic emissions (OAEs) are sounds that are detected in the ear canal when the tympanum receives vibrations transmitted through the middle ear from the cochlea. OAEs provide support for the notion that the cochlea is not just a passive receiver of acoustic energy but can also generate or amplify sounds. Several different types of OAEs are found (18). *Spontaneous* OAEs occur in the absence of acoustic stimulation and are typically highly stable pure tones of −10 to 30 dB SPL, which are found in 30% to 40% of healthy young ears (19,20). The precise frequency of a spontaneous OAE does not imply an origin at a precise place in the cochlea, but only a particular

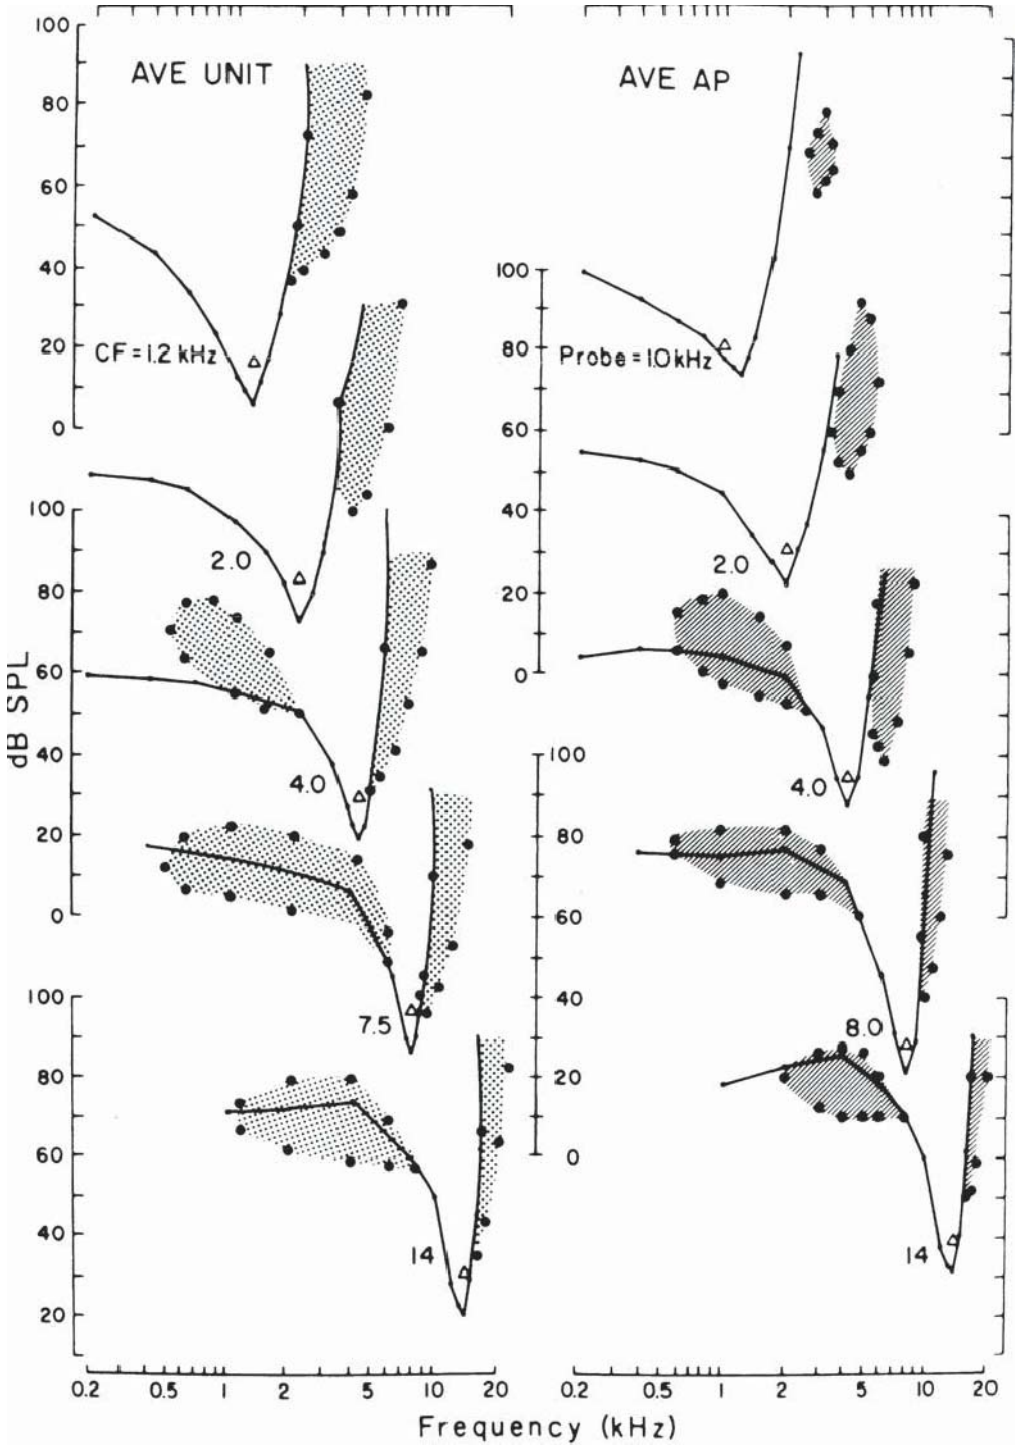

Figure 141.21 **Left:** Excitatory tuning curve (*circles*) and two-tone suppression areas (*shaded*) for a single auditory nerve fiber. Tones presented in the suppression areas decrease the firing rate to the excitatory tone. **Right:** Tuning and suppression of the compound action potential (CAP). (From Harris DM. Action potential suppression, tuning curves and thresholds: comparison with single fiber data. *Hear Res* 1979;1:133, with permission.)

coincidence of travel time and reflection from an ill-defined region of high outer cell activity. Spontaneous OAEs can be recorded over long periods with only minor but seemingly systematic variations in frequency and amplitude.

A second class of OAEs are produced after exposure to an acoustic signal. *Transient-evoked* OAEs (TEOAE) are made via a probe placed in the ear canal. The oscillatory sound pressure waveform seen in TEOAE responses actually corresponds to the motion of the eardrum resulting from pressure fluctuations generated within the cochlea (Fig. 141.22). Although stimulatory clicks excite the entire cochlea, TEOAE responses can be used to give frequency-specific

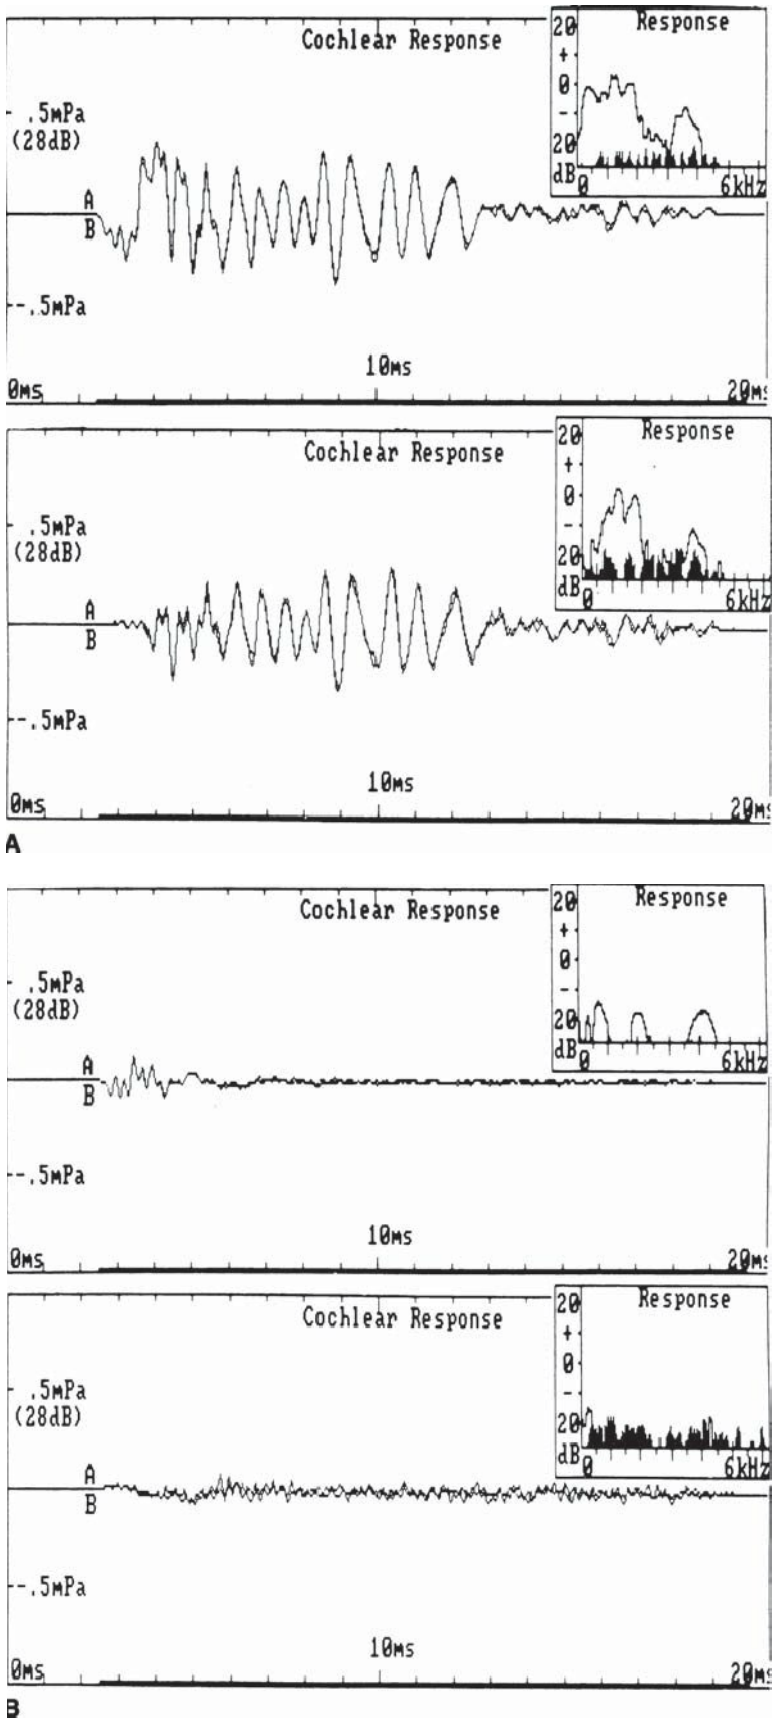

Figure 141.22 Cochlear echoes, also called *stimulated cochlear emissions*, from a normal ear **(A)** and a deaf ear **(B).** (From Kemp DT, Ryan S, Bray P. Otoacoustic emission analysis and interpretation for clinical purpose. *Adv Audio* 1990;12:77–92, with permission.)

information about the cochlea through splitting of the responses into different frequency bands. TEOAEs are highly sensitive to cochlear pathology in frequency-specific manner. Frequencies at which hearing thresholds exceed 20 to 30 dB hearing loss (HL) are typically absent in the TEOAE response (21,22). Because of their sensitivity to cochlear dysfunction, TEOAEs have found widespread application in newborn hearing screening programs (23).

Distortion-product OAEs also are used widely in clinical situations. The TEOAE and DPOAE techniques complement each other. DPOAEs offer a wider frequency range of observation with less sensitivity to minor and subclinical conditions in adults. When two primary tones, F1 and F2, are presented to the cochlea, several distortion products are produced. The most prominent of all these intermodulation distortion products is the cubic distortion tone, 2F1–F2. Measurement of DPOAEs at multiple stimulus levels can establish the OAE "growth rate." Healthy ears tend to exhibit a DPOAE growth rate of 1 dB of OAE per 1 dB of stimulus or less. Ears with some impairment show steeper growth. Single DPOAE results can be misleading, and results must be averaged across a range of frequencies. The DPOAE is easily recordable in patients with a normal middle ear system (24,25).

AUDITORY CENTRAL NERVOUS SYSTEM

The ascending and descending auditory pathways are described briefly herein in relation to auditory evoked potentials. Schematics of the afferent and efferent pathways are shown in Figures 141.13 and 141.23, respectively. These diagrams oversimplify the system but provide a rough introduction to the auditory CNS and its complexity. All eighth-nerve afferent fibers stop at the level of the cochlear nucleus. Five major cell types are found within the cochlear nucleus, each with distinct morphologic and physiologic features, such as response to stimulus onset, stimulus offset, and frequency modulation. From the cochlear nucleus, most fibers cross the brainstem to the contralateral superior olivary complex; a much smaller number of fibers run to the ipsilateral superior olivary complex.

The superior olivary complex is considered the first center in the ascending auditory system, where inputs from both ears converge. Auditory nuclei above the superior olivary complex can be excitatory or inhibitory with inputs from each ear. Stimulation of the contralateral ear typically is excitatory to cell bodies of the auditory CNS, whereas stimulation of the ipsilateral ear is inhibitory. As shown in Figure 141.13, the medial superior olivary complex is the origin of the crossed efferent fibers that terminate on outer hair cells, whereas the lateral superior olivary complex is the origin for the uncrossed efferent fibers that terminate on inner hair cells. Although many functions have been attributed to the efferent auditory system, especially protecting the cochlea from loud sounds, the functions of the system are unknown; those that have been proposed are easily debated (26,27).

The inferior colliculus is a complex nucleus with at least 18 major cell types and at least five areas of specialization. It is involved in probably all forms of auditory behavior, including differential sensitivity for frequency and intensity, loudness, and binaural hearing. The inferior colliculus is clearly more than a relay center. The medial geniculate body of the thalamus sends projections to the auditory cortex, but its specific functions are unknown.

The auditory cortex is located in the sylvian fissure of the temporal lobe; many secondary auditory areas are clustered around the primary area. In each area, the cells are tonotopically organized in a columnar manner, each column having a special attribute. The cells in one column can have different tuning at a similar characteristic frequency, whereas another column can be associated with intensity encoding, another with providing inhibitory responses to stimulation of one ear and excitatory responses of the other ear, and so on. As is common for thalamic connections with the cortex, nuclei within the medial geniculate body that send fibers to the auditory cortex also receive fibers from the same area of the cortex. Bilateral lesions of the temporal lobe have been shown to produce wide-ranging effects (cortical deafness, in which several auditory behaviors are severely affected, including speech discrimination, localization of sound, temporal processing of information, and the detection of faint, short-duration signals) (28). Another important feature of the auditory system is its tonotopic nature. From the basilar membrane to the auditory cortex, the system is organized spatially with respect to frequency. Each place on the basilar membrane responds best to a specific frequency—high-frequency sounds are localized to the base, and low-frequency sounds, to the apex. The tonotopic organization of the cochlea is preserved at the cochlear nucleus. Figure 141.24 shows that as an electrode penetrates the cochlear nucleus, fibers with different characteristic frequencies are contacted, and the characteristic frequencies form an orderly progression. Similar data exist at all nuclei of the auditory CNS, including the auditory cortex.

The most obvious clinical application of basic information on the auditory CNS involves interpretation of evoked potentials. The auditory brainstem response (ABR) is one component of auditory evoked potentials. The existence of the ABR was first reported by Sohmer and Feinmesser in 1967 (29). The ABR is recorded from electrodes attached to various positions on the head. The ABR consists of a series of seven waves occurring within about 10 milliseconds after stimulus onset. The convention in the United States is to label wave peaks with Roman numerals. It is generally accepted that the ABR is generated by the auditory nerve and subsequent fiber tracts and nuclei within the auditory brainstem pathways. It is widely believed that each wave is generated as follows: wave I and II are the eighth nerve, III is cochlear nucleus, IV is superior olive/lateral leminiscus, and V is lateral leminiscus/inferior colliculus.

The ABR is generated by a click stimulus because it yields the clearest response. The ABR is used clinically both

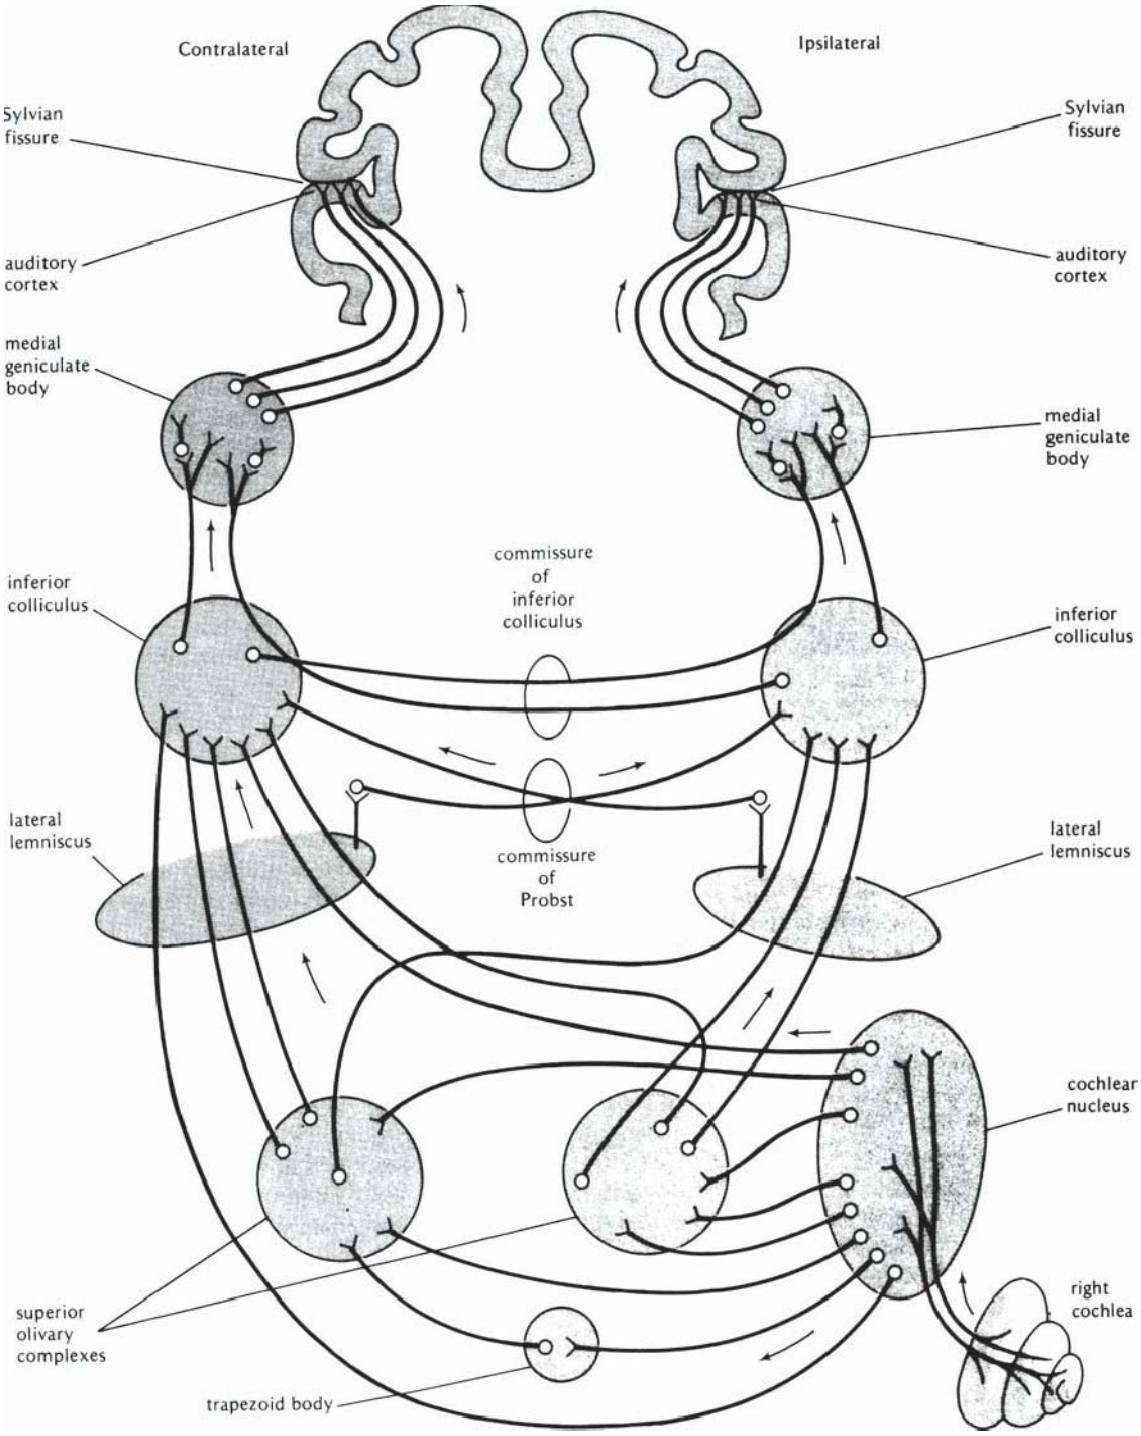

Figure 141.23 Highly schematic diagram of the ascending (afferent) pathways of the central auditory system from the right cochlea to the auditory cortex. No attempt is made to show the subdivisions and connections within the various regions, cerebellar connections, or connections with the reticular formation. (From Yost WA, Neilsen *DW. Fundamentals of hearing*, 2nd ed. New York: Holt, Rinehart & Winston, 1985:121.)

in the estimation of auditory sensitivity and in otoneurologic assessment. In this way, it can be used to detect lesions along the auditory nerve and brainstem pathways. The study can be performed regardless of state of wakefulness, and the result is unaffected by most medications. As a result, children are often tested while under sedation or during sleep.

The field of clinical objective audiometry has recently gained an additional technique in the auditory evoked response battery. The *auditory steady-state response* (ASSR) promises to be a valuable study in the workup of auditory dysfunction. Unlike ABRs, which are obtained through the use of transient stimuli, ASSRs are evoked by using sustained

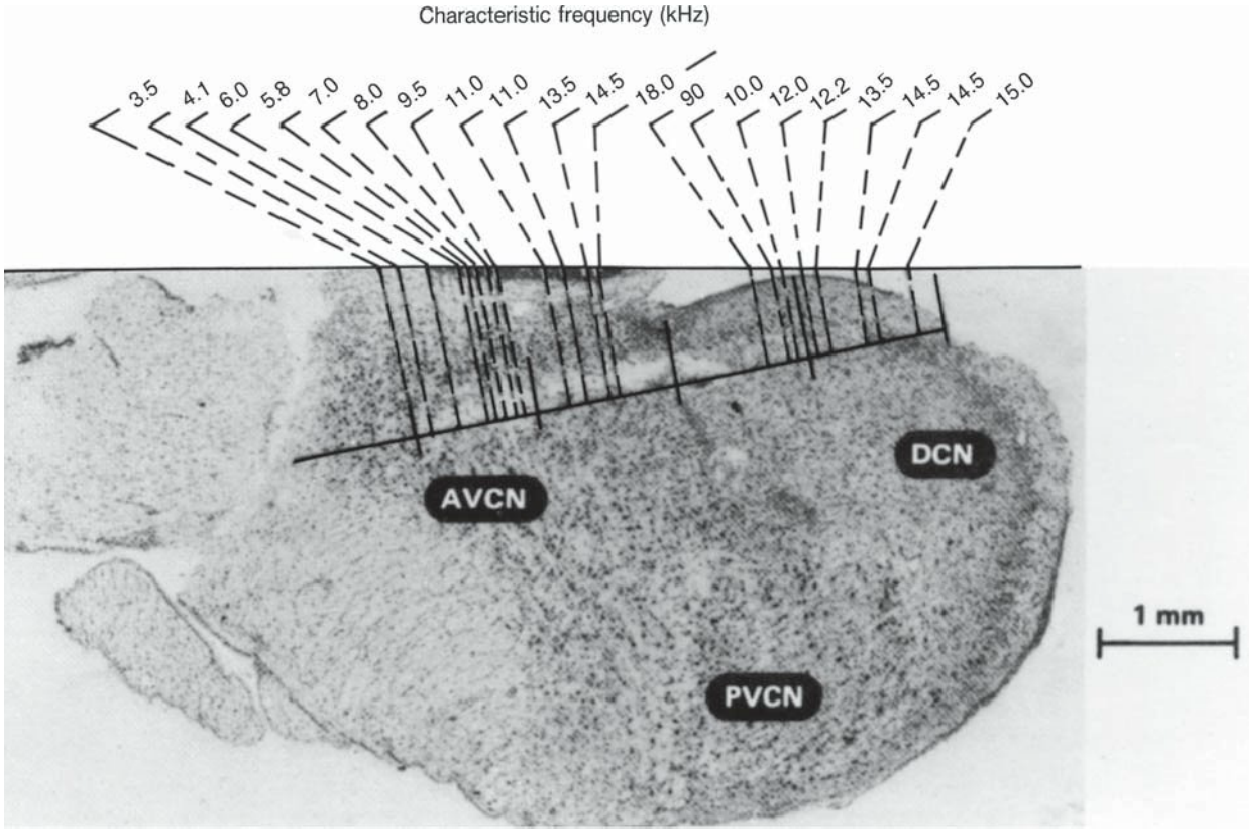

Figure 141.24 Cross section of cochlear nucleus shows the track made by electrode penetration. The characteristic frequencies of neurons recorded from various points within the anteroventral cochlear nucleus (*AVCN*) and dural cochlear nucleus (*DCN*) show that the spatial separation of frequency is maintained within those two divisions of the cochlear nucleus. PVCN, posteroventral cochlear nucleus. This tonotopic organization is maintained throughout the central auditory system. (Redrawn from Rose JE, Galambos R, Hughes JR. Microelectrode studies of the cochlear nuclei of the cat. *Bull Johns Hopkins Hosp* 1959;104:211, with permission.)

continuous tones. The tones are frequency specific because the continuous tones do not have spectral distortion problems as do brief tone bursts or click (30,31). Of note, ASSR also can be performed regardless of the state of wakefulness.

There are several advantages of ASSR over ABR. First, ASSR is a better technique for evaluating hearing aid performance because hearing aids and cochlear implants process continuous stimuli with less signal distortion than transient stimuli. Furthermore, ASSR can provide threshold information in a frequency-specific manner at intensity levels of 120 dB or greater (32,33). This allows differentiation of severe and profound hearing loss, which cannot be accomplished with ABR. This characteristic of ASSR may allow it to be used in assessing pediatric patients for cochlear implant candidacy (34). Last, ASSR has been shown to be more time efficient by determining more thresholds in a shorter time compared with ABR (35–37). Future research and clinical use are likely to solidify the status of ASSR in the audiologic armamentarium.

The neuroanatomic features of the system are complicated. Processing of neural information probably involves both parallel and serial processing. The former is anatomically described by a single fiber with ramifications to many target areas. Serial processing involves a fiber going to one target, which in turn goes to another target, and so forth. In the auditory CNS, both serial and parallel processing are involved. Because the auditory CNS is a highly redundant, complicated, and extremely powerful system, interpretation of evoked-potential data, and of other CNS neural data, is not straightforward.

HIGHLIGHTS

- The acoustic properties of the head and external ear are important, particularly because they provide cues for localizing sources of sound.
- The middle ear acts as a transformer between air and the fluid-filled cochlea and provides a sound pressure gain of 25 to 30 dB. The combined effect of the acoustic properties of the head, external ear, and middle ear, and the input impedance of the cochlea determine the frequency range of human hearing.

- The cochlea is a coiled bony tube approximately 35 mm long and divided into three compartments—the scala tympani, scala vestibuli, and scala media. The scalae tympani and vestibuli contain perilymph and are connected through the helicotrema at the apex of the cochlea. The scala media contains endolymph and has a positive DC resting potential of approximately 80 mV, which arises from Na^+ -K^+-ATPase pumps in the stria vascularis.
- The auditory transducer is the organ of Corti, which contains sensory cells (three rows of outer hair cells and one row of inner hair cells). Deflection of stereocilia (hairs) of the sensory cells by a mechanical traveling wave starts transduction.
- A traveling wave, from the base toward the apex of the cochlea, arises in response to piston-like movement of the stapes. The traveling wave has a sharply tuned peak at the base for high-frequency sound that progresses toward the apex as frequency decreases.
- Deflection of stereocilia by the traveling wave opens and closes ion channels; the result is current flow (potassium ion) into the sensory cell. The potassium flux arises from the +80 mV endocochlear potential added to the negative intracellular potential of inner and outer hair cells. The resulting depolarization causes an enzyme cascade that releases chemical transmitters and activates afferent nerve fibers.
- Approximately 90% to 95% of the radial nerve fibers (type I) innervate inner hair cells. Approximately 5% to 10% (type II, outer spiral fibers) are connected to outer hair cells. Each inner hair cell is innervated by 15 to 20 type I neurons. Each type II neuron branches to innervate approximately 10 outer hair cells. Approximately 1,800 efferent fibers project to the sensory cells from the ipsilateral and contralateral superior olivary complexes.
- The most basic measure of auditory nerve function is the tuning curve of a single auditory nerve fiber. Tuning curves of single fibers of the nerve are strikingly similar to tuning curves of the mechanical traveling wave. Injury to sensory cells and stereocilia alters the features of tuning curves, including sensitivity and sharp tuning.
- The middle ear system is passive and linear in response to signals as great as 130 dB SPL, but the inner ear is an active system with its own amplifier and is nonlinear. These properties allow the inner ear to respond to a wide range of intensities and provide the basis for suppression phenomena.
- Although the efferent auditory system is well developed, the functional significance is not well understood. It may have a role in the cochlear transduction and in protecting the cochlea from overexposure to intense sound.

142 Assessment of Peripheral and Central Auditory Function

James W. Hall III *Patrick J. Antonelli*

New techniques and strategies for assessment of the auditory function in adults have been introduced in recent years. Pure-tone audiometry, immittance measurement (tympanometry and acoustic reflexes), and calculation of word recognition scores continue to be important for hearing assessment, and the traditional audiogram is useful in summarizing the results of basic audiologic assessment. Clinical audiology, however, now also includes other behavioral and electrophysiologic test procedures. For example, electrocochleography (ECochG) can contribute to the diagnosis of Ménière disease. Auditory brainstem response (ABR) offers a readily accessible, and relatively inexpensive, means for estimating hearing sensitivity in infants and young children and for the identification of retrocochlear auditory dysfunction. Otoacoustic emissions (OAEs), because of unique sensitivity and specificity to cochlear dysfunction, have become an integral component of the clinical audiologic test protocol. And, within recent years, the auditory steady state response (ASSR) has emerged as a valuable addition to the pediatric audiologic test battery. A variety of speech and nonspeech behavioral measures and several cortical auditory evoked responses are available for clinical assessment of central auditory nervous system dysfunction and associated auditory processing disorders (APDs).

This chapter summarizes current techniques and strategies for hearing assessment among adults. The emphasis is on use of a test battery that maximizes diagnostic accuracy and efficiency and minimizes test time and cost. A glossary of common audiologic terms and abbreviations is provided at the end of the chapter.

BASIC AUDIOLOGIC TEST BATTERY

Pure-Tone Audiometry

Pure-tone audiometry is the most common measurement of hearing sensitivity. Stimuli are pure tones (sinusoids) at octave frequencies typically from 250 Hz up to 8,000 Hz and, often, two interoctave frequencies (3,000 Hz and 6,000 Hz). Interoctave hearing loss is a characteristic of commonly encountered problems, such as noise-induced cochlear dysfunction. High-frequency audiometry for stimulus frequencies greater than 8,000 Hz (up to 20,000 Hz) is technically feasible and clinically useful to certain populations, such as patients at risk for ototoxicity. Test results in many clinics are graphed on an audiogram. Two versions of audiograms are illustrated in Figure 142.1. All audiograms include at the minimum a graph for plotting hearing threshold levels as a function of the frequency of pure-tone signals, although the exact format and symbols vary.

The unit of stimulus intensity is the decibel (dB), a logarithmic unit. The intensity of any sound is defined by the ratio of its sound pressure or sound intensity to a reference sound pressure or sound intensity. The reference sound pressure is the amount of pressure against the eardrum, caused by air molecules when a sound is present, that vibrates the eardrum and can just be detected by a normal human ear. Briefly, the relation for sound intensity is described as $dB = 10 \log_{10}$ (sound intensity/reference intensity) or for sound pressure as $dB = 20 \log_{10}$ (sound pressure/reference pressure). The reference sound pressure is defined as decibels sound pressure level (dBSPL) and is derived from one of two physical quantities: (a) 0.0002 dyne/cm^2 or (b) 20 micropascals root mean square (μPa) $= 2 \times 10^{-5}$ Pa.

Clinically, the intensity of sound is described in decibels hearing level (dB HL), a biologic reference level, rather than in sound pressure level. On an audiogram (Fig. 142.1), the decibel scale has as its reference 0 dB, which is described as audiometric 0. This is the standard for the intensity level that corresponds to the mean normal hearing threshold level, the minimal detectable intensity for each test frequency for young adults with normal hearing. Another common unit for expressing sound intensity is decibels

Masking is indicated by filled symbols. Categories of hearing loss of shown on the right ear graph, whereas typical findings for a conductive hearing loss are shown in the left ear graph. **B:** The traditional audiogram form utilizes symbols (see audiogram legend) for each of 13 signal presentation types. It does not permit graphic display of immittance or speech measurement findings.

sensation level (dB SL), which is intensity of the stimulus in decibels above an individual's hearing threshold. For example, a word recognition test can be administered at an intensity level of 40 dB SL (40 dB above the person's pure-tone average [PTA]).

In audiologic assessment of cooperative children and adults, hearing thresholds for tonal or speech signals are measured separately for each ear with earphones (air-conduction stimulation). Insert earphones (ER-3A) are now the transducer of choice for routine audiologic assessment. They offer distinct advantages over traditional supraaural earphones, including increased comfort, reduced likelihood of ear canal collapse, greater interaural attenuation, and greater acceptance by young children. In addition, insert earphones contribute importantly to the control of infection in a clinical setting, as the insert portion is disposable. Pure-tone audiometry can be performed with stimuli presented with a bone-conduction oscillator or vibrator placed on the mastoid bone. During pure-tone audiometry, all equipment must meet the specifications of the American National Standards Institute (ANSI). Periodic equipment calibration and validation are necessary. Testing is conducted according to clinical adaptations of psychoacoustic methods (1). Patients are instructed to listen carefully for the tones and to respond, usually by pushing a button that activates a response light on the audiometer or by raising a hand, every time they believe they hear a tone. To minimize interference by ambient background acoustic noise, pure-tone audiometry always is performed with the patient in a double-walled, sound-treated room that meets ANSI specifications.

The clinically normal region on an audiogram is 0 to 20 dB HL, although for children hearing threshold levels exceeding 15 dB should be considered abnormal. Thresholds in the 20 to 40 dB HL region constitute mild hearing loss, 40 to 60 dB HL thresholds define moderate loss, and threshold levels greater than 60 dB HL are considered severe hearing loss (2). As a reference, the intensity level of whispered speech close to the ear is less than 25 dB HL. Conversational speech is in the 40 to 50 dB HL region, and a shouted voice within 1 foot (30 cm) of the ear is at a level of about 80 dB HL. The most important frequencies for understanding speech are 500 through 4,000 Hz, although higher frequencies can contribute to discrimination between certain speech sounds. Hearing sensitivity within the speech frequency region often is summarized by means of calculation of the PTA (PTA; hearing thresholds for 500, 1,000, and 2,000 Hz divided by three and reported in decibels). A four-frequency PTA including 3,000 Hz is required by the American Academy of Otolaryngology–Head and Neck Surgery.

Audiometric results are valid only when the patient's responses are caused by stimulation of the test ear. If a sound greater than 40 dB HL is presented to one ear through air conduction with supraaural earphones and cushions (resting on the outer ear), the acoustic energy can cross over from one side of the head to the other and stimulate the ear not being tested. The main mechanism of crossover is presumed to be bone-conduction stimulation caused by vibration of the earphone cushion against the skull at high stimulus intensity levels. The amount of sound intensity needed before crossover occurs is a reflection of interaural attenuation, that is, the sound insulation between the two ears provided by the head. Interaural attenuation is usually about 50 dB for lower test frequencies and 60 dB for higher test frequencies, such as those contributing to the ABR. Interaural attenuation is considerably higher for insert earphones (2). With bone-conduction stimulation, interaural attenuation is less than 10 dB. In clinical circumstances, the examiner needs to assume conservatively that interaural attenuation for bone-conducted signals is 0 dB. In other words, even a very faint sound presented to the mastoid bone of one ear by a bone-conduction vibrator can be transmitted through the skull to either or both inner ears. Perception of this bone-conducted signal depends on the patient's sensorineural hearing sensitivity in each ear.

Masking is the audiometric technique used to eliminate participation of the ear not being tested whenever air- and bone-conduction stimulation exceeds interaural attenuation. An appropriate noise (narrow-band noise for pure-tone signals and speech noise for speech signals) is presented to the ear not being tested when the stimulus is presented to the test ear. With adequate masking, any signal crossing over to the ear not being tested is masked by the noise. The level of masking noise presented to the ear not being tested must exceed the threshold of hearing for that ear. Excess levels of masking noise must be avoided because the noise can cross back over to the ear being tested. Selection of appropriate masking can be difficult, especially when there is bilateral hearing loss (2). Indeed, patients with severe bilateral conductive hearing loss may present the "masking dilemma," that is, when enough masking to the nontest ear actually crosses over to the test ear and interferes with accurate estimation of hearing threshold. An otolaryngologist interpreting audiologic results must verify that appropriate masking was used if testing was not performed by an audiologist.

Knowledge of the type of hearing loss, determined by means of comparison of the hearing thresholds for air- and bone-conduction signals, is useful in classifying a hearing loss as sensorineural (no air–bone gap), conductive (normal bone conduction and a loss by air conduction), or mixed (loss by bone conduction with a superimposed air–bone conduction gap).

Configuration refers to hearing loss as a function of the test frequency. With a sloping configuration, hearing is better for low frequencies and then becomes poorer for higher frequencies. The most common pattern associated with sensorineural hearing loss is a deficit in thresholds for higher test frequencies. The configuration can be gently sloping from low to high frequencies, be precipitously decreasing above a high frequency cutoff, such as 2,000 Hz,

or be characterized by a notching deficit within a certain frequency region, such as 4,000 Hz. A rising configuration is typified by relatively poor hearing for low-frequency stimuli and better hearing for the high frequencies. A rising configuration can be caused by varied types of middle ear abnormalities. An exception to the typical association of conductive hearing loss with rising configuration is Ménière disease (see Chapter 156). Ménière disease is one cochlear abnormality that may produce a rising configuration. A flat audiometric configuration often is recorded from patients with mixed hearing loss, that is, both sensorineural and conductive components are present. Other configurations, such as the midfrequency "cookie bite" pattern, are encountered in clinical practice. Test–retest variability in clinical pure-tone threshold estimation is typically ±5 dB.

Guidelines for Evaluation of Hearing Handicap

The results of pure-tone audiometry are adequately summarized in an audiogram and with the terms just defined, such as PTA and the degree, configuration, and type of hearing loss. It also is possible to quantify hearing loss in percentage units according to published and accepted guidelines (3). This approach sometimes is necessary in medicolegal cases or when a patient seeks compensation for hearing loss. According to the guidelines of the American Academy of Otolaryngology Committee on Hearing and Equilibrium and the American Council of Otolaryngology Committee on the Medical Aspects of Noise (3), permanent hearing impairment is defined as follows: "A change for the worse in either structure or function, outside the range of normal, is permanent impairment…. Permanent impairment is due to any anatomic or functional abnormality that produces hearing loss." This is differentiated from permanent hearing handicap, which is defined as follows: "The disadvantage imposed by an impairment sufficient to affect a person's efficiency in the activities of daily living is a permanent handicap" (3). The guidelines also detail the approach for converting hearing handicap for one or both ears into a percentage. The first step is to determine the degree of sensorineural hearing loss for four test frequencies (500, 1,000, 2,000, and 3,000 Hz) from the audiogram (Table 142.1). The next step is to follow the guidelines for computation of percentage hearing loss (3):

> If the monaural percent figure is the same for both ears, that figure expresses the percent hearing handicap. If the percent monaural hearing impairments are not the same, apply the formula:
>
> $$\left(5 \times \%\left[\text{better ear}\right]\right) + \left(1 \times \%\left[\text{poorer ear}\right]\right) / 6 = \%\ \text{hearing handicap}$$

The interoctave test frequency—3,000 Hz—in the calculation of percentage of hearing handicap is very important. It is good clinical practice to routinely obtain hearing thresholds from each ear for the 3,000 Hz frequency. This frequency is included in the formula for hearing loss (3) because much of the spectral information vital for speech understanding is within the 2,000 to 3,000 Hz region. Percentage of binaural hearing handicap is easily calculated with a detailed tabular matrix that relates the four-frequency degree of sensorineural hearing loss for the better versus poorer ear (4).

TABLE 142.1 GUIDELINES FOR CALCULATING PERCENTAGE OF MONAURAL HEARING IMPAIRMENT[a]

DSHL[b]	Percentage	DSHL	Percentage
100	0.0	240	52.5
105	1.9	245	54.4
110	3.8	250	56.2

[b]From the audiogram, find the decibel sum of the hearing threshold levels (DSHL) of 500, 1,000, 2,000, and 3,000 Hz.

Speech Audiometry

The purpose of speech audiometry is to determine how well a person hears and understands speech signals. Speech audiometry procedures usually are performed to measure hearing sensitivity (thresholds in decibels) for words or to estimate word recognition, such as speech discrimination, ability. Spondee reception threshold, also called speech threshold, is the softest intensity level at which a patient can correctly repeat words approximately 50% of the time. Spondee words, two syllable words with equal stress on

each syllable, such as hot dog, baseball, and eardrum, are presented to the patient monaurally through earphones. The technique is comparable with the method for determining pure-tone thresholds described earlier.

Because PTA reflects hearing threshold levels in the speech frequency region and speech threshold is measured with a speech signal, one can expect close agreement between the PTA and the speech threshold. If the difference between PTA and speech threshold exceeds ±7 dB, there is reason to suspect that one or both of the measures are invalid. An unusually good speech threshold relative to PTA, such as speech threshold of 5 dB and PTA of 45 dB, immediately alerts the examiner to the possibility of nonorganic hearing loss, such as malingering. With cooperative adult patients, particularly if pure-tone hearing thresholds are within the normal region from 500 to 4,000 Hz, there is probably little or no clinical benefit in measuring speech thresholds. Test time can be saved with no loss of diagnostic information by excluding speech threshold measurement from the test battery for such patients.

Speech recognition for phonetically balanced words is a common clinical approach for estimating a person's ability to hear and understand speech (2). A list of 25 or 50 single-syllable words typically are presented to the patient through earphones at one or more fixed intensity levels. The percentage of words correctly repeated by the patient is calculated by the examiner. One ear is tested at a time. Within the list of words, specific speech sounds (phonemes) occur approximately as often as they would in everyday conversation, that is, they are phonetically balanced. These words traditionally were spoken into a microphone by the examiner while the level was monitored with a volume unit meter. The words were routed to the patient through an audiometer after selection of the test ear and desired intensity level. This is an outdated and poor clinical practice because it lacks standardization and consistency and increases the variability of test outcome. For adult patients, it almost always is possible and always is preferable to use professionally produced, commercially available speech materials presented with a tape recorder or compact disk player and an audiometer (2). Live voice probably continues to be used by many practitioners, especially in the assessment of children, because of minor efficiency gains.

Speech perception in the presence of noise is also assessed clinically. One of the most popular and well-researched procedures is the hearing in noise test, abbreviated HINT (5). Representative sentences of a standard length and phonetic complexity are presented with a low level of background noise, which is more reflective of speech understanding in real-world environments. HINT is a key measure of auditory performance used to screen hearing impaired individuals for cochlear implant candidates. The HINT is now available in over a dozen languages.

Acoustic (Aural) Immittance (Impedance) Measurement

Introduction

Aural immittance (impedance) measurement is an important part of the basic audiometric test battery. Immittance is a term derived from the terms for two related techniques for assessing middle ear function—impedance and admittance. These techniques have been used clinically since 1970 (6). The external ear canal is sealed with a soft rubber probe tip. The probe tip is connected to a device that produces a tone delivered toward the eardrum. Middle ear impedance or admittance is calculated from the intensity and other physical properties, such as phase, of the tone in the ear canal. A middle ear (tympanic membrane and ossicular system) with low impedance (higher admittance) more readily accepts the acoustic energy of the probe tone. A middle ear with abnormally high impedance (lower admittance) caused by, for example, fluid in the middle ear space tends to reject energy flow. Thus impedance (admittance) characteristics of the middle ear system can be inferred objectively with this technique and related to well-known patterns of findings for various pathologic conditions of the middle ear.

Tympanometry

Tympanometry is the dynamic recording of middle ear impedance as air pressure in the ear canal is systematically increased or decreased. The technique is a sensitive measure of the integrity of the tympanic membrane and of middle ear function (Fig. 142.2). Compliance (the reciprocal of stiffness) of the middle ear, the dominant component of immittance, is the vertical dimension of a tympanogram. Tympanometry is popular clinically because it requires little technical skill and only several seconds to perform. It is an electrophysiologic, as opposed to behavioral, method that does not depend on cooperation of the patient, and it is a highly sensitive index of middle ear function. Tympanometric patterns, in combination with audiographic patterns, allow differentiation and classification of middle ear disorders.

The most clinically widespread approach to describing tympanograms was described first by Jerger in 1970 (6). There are three general types of tympanogram—A, B, and C. A normal, or type A, tympanogram has a distinct peak in compliance within 0 to 100 mm water (dPa) in the ear canal (Fig. 142.2). To be classified as normal, the location of the compliance peak on the pressure dimension and the height of the peak must be within normal range, indicated in Figure 142.2 by the stippled area. On a type B tympanogram, there is no peak in compliance, but there is a flat pattern with little or even no apparent change in compliance as a function of pressure in the ear canal. This pattern is most often associated with the presence of fluid within the middle ear space (otitis media), although other middle ear disorders also can produce a type B tympanogram. Although a type B tympanogram can appear to be recorded from

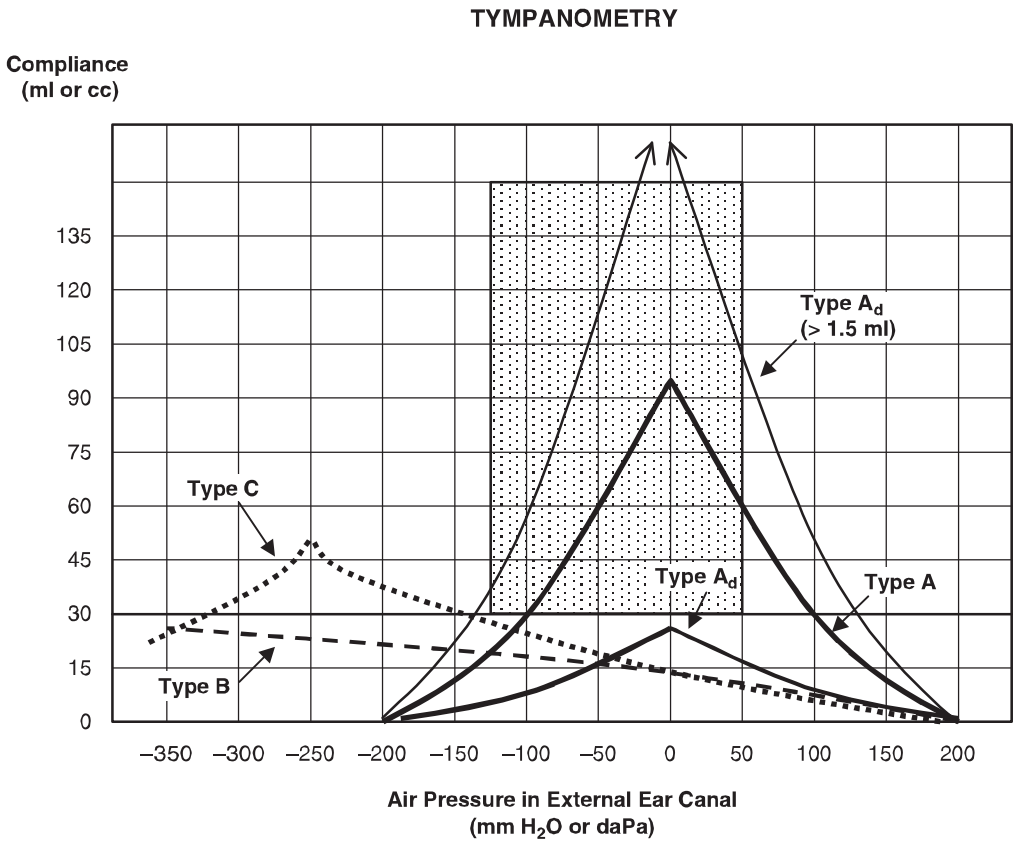

Figure 142.2 Classification system for tympanograms.

ears with perforated tympanic membranes, technically, this finding is invalid because the change in ear canal pressure needed for tympanometry is not achieved owing to the perforation. Type C tympanograms have a distinct peak in compliance as do type A recordings, but the peak is within the negative pressure region beyond approximately 100 mm water (dPa). This pattern usually occurs among patients with eustachian-tube dysfunction and inadequate ventilation of the middle ear space. It often precedes acquisition of a type B tympanogram in the development of otitis media.

A variation of a type A tympanogram is type A_s (Fig. 142. 2). The *s* stands for shallow. Peak compliance is less than the lower normal limit of compliance. That is, middle ear impedance is abnormally high. The type A_s pattern is common among patients with fixation of the ossicular chain, including some patients with the diagnosis of otosclerosis. In contrast, with an usually steep and high-compliance tympanogram (type A_d for deep), the peak can exceed the upper compliance limits of the equipment. A type A_d tympanogram occurs among patients with disruption of the ossicular chain, which leaves the middle ear extremely mobile and overly compliant, that is, there is little impedance. In the absence of serious hearing loss, this tympanographic pattern usually is associated with minor tympanic membrane abnormality, such as atrophy. At the beginning of a tympanometric examination, high positive or negative pressure is introduced into the ear canal. This essentially decouples the middle ear system from the measurement. If the impedance device records an abnormally large equivalent volume of air (2 cm or more in an adult, or twice the volume recorded for the other ear) between the probe tip and presumably the eardrum at this stage in the procedure, the integrity of the eardrum is questioned. That is, the immittance device is recording not only ear canal volume but also volume of the middle ear space. This test finding is consistent with perforation of the tympanic membrane or the presence of an open (patent) middle ear ventilation tube.

Acoustic Stapedial Reflex Measurement

The stapedial muscle within the middle ear is the smallest muscle in the body. Measurement of contractions of the stapedial muscle in response to high sound intensity levels (usually 80 dB or greater) is the basis of the acoustic reflex. Acoustic reflex measurement is clinically useful for estimating hearing sensitivity and for differentiating sites of auditory disorders, including the middle ear, inner ear, eighth cranial nerve, and auditory brainstem (2,6). The afferent portion of the acoustic reflex arc is the eighth cranial nerve. Complex brainstem pathways lead from the cochlear nucleus on the stimulated side to the region of the motor nucleus of the seventh cranial (facial) nerve on both sides (ipsilateral and contralateral to the stimulus) of the brainstem. The efferent portion of the arc is the seventh cranial

nerve, which innervates the stapedius muscle. The muscle contracts, causing increased stiffness (decreased compliance) of the middle ear system. The small change in compliance that follows stapedius muscle contraction within 10 ms is detected with the probe and immittance device, much as compliance changes are detected during tympanometry.

Acoustic reflex measurement is useful clinically because it quickly provides objective information on the status of the auditory system from middle ear to brainstem. Distinctive acoustic reflex patterns for ipsilateral and contralateral stimulation and measurement conditions characterize middle ear, cochlear, eighth nerve, brainstem, and even facial nerve dysfunction (lower portion of Fig. 142.1A). Comparison of acoustic reflex threshold levels—the lowest stimulus intensity level that activates the reflex—for tonal versus noise signals allows estimation of the degree of cochlear hearing loss (2). This technique is especially valuable in the care of children and difficult-to-test patients. Note, however, that even modest changes in the middle ear mechanism, often manifest by mild conductive hearing loss (e.g., otosclerosis), may lead to the loss of acoustic reflex responses. Conversely, the presence of intact reflexes in combination with a significant conductive hearing loss should be viewed as inconsistent with true pathology of the middle ear sound conduction mechanism. This could result from spurious test results or from inner ear pathology, such as canal dehiscence.

AUDITORY EVOKED RESPONSES

Auditory Brainstem Response

Auditory evoked responses are electrophysiologic recordings of responses to sounds. With proper test protocols, the responses can be recorded clinically from activation of all levels of the auditory system, from cochlea to cortex (7). Among these responses, the ABR, which neurologists often call the brainstem auditory evoked response, is used most often clinically. An ABR recording is shown schematically in Figure. 142.3. The ABR is generated with transient acoustic stimuli (clicks or tone bursts) and detected with surface electrodes (disks) placed on the forehead and near the ears (earlobe or within the external ear canal). The ABR represents minimal electrophysiologic activity (less than 1 microvolt) within electroencephalographic activity that is 100 times larger in amplitude. With a commercially available computer-based device, it is possible to present rapidly (20 to 30 per second) thousands of sound stimuli and, by means of signal averaging, to detect reliable ABR waveforms in a matter of minutes.

Extensive research has shown that the ABR wave components arise from the eighth cranial nerve and auditory regions in the caudal and rostral brainstem (Fig. 142.3). Wave I unquestionably represents the synchronously stimulated compound action potentials (APs) from the distal (cochlear) end of the eighth cranial nerve. Wave II may arise from the eighth nerve but near the brainstem (the proximal end). Waves I and II are generated by structures ipsilateral to the stimulated ear. All later ABR waves have multiple generators within the auditory brainstem. Wave III, which usually is prominent, is generated within the caudal pons with likely contributions from the cochlear nuclei, trapezoid body, and superior olivary complex (7). The most prominent and rostral component of the ABR—wave V—is thought to arise in the region of the lateral lemniscus as it approaches the inferior colliculus, probably contralateral to the ear stimulated.

The ABR is not a test of hearing. It reflects synchronous firing of a subset of onset neurons within the auditory system. In ABR waveform analysis, the first objective is to assure that the response is reliably recorded. At the minimum, two replicated waveforms are averaged. If the response cannot be replicated, the test protocol is modified, and technical problems are considered and systematically ruled out. When the existence of a response that can be replicated is confirmed, reproducible absolute latencies for each wave component and relative (interwave) latencies between components are calculated in milliseconds. These latency data for each ear are assessed for symmetry (wave V within 0.4 ms between ears) and compared to appropriate normative data (7).

Common ABR waveform patterns are illustrated in Figure 142.4. A well-formed and clear wave I at a delayed latency value for the maximum stimulus intensity level is characteristic of conductive or mixed hearing loss. When wave I is small and poorly formed but interwave latency values are within normal limits (the wave I through V latency value less than 4.60 ms), high-frequency sensory (cochlear) hearing loss is suspected. Delayed interwave latency values are the signature of retrocochlear auditory dysfunction. Abnormal delays between the early wave components (I through III) are consistent with posterior fossa lesions that involve the eighth cranial nerve or lower brainstem, whereas prolonged latency of waves III through V suggests intraaxial auditory brainstem dysfunction.

A primary goal in any neurodiagnostic evaluation of ABR is to record a clear and reliable wave I component. Wave I is the benchmark for peripheral auditory function. Subsequent interwave latencies offer indices of retrocochlear (eighth cranial nerve and brainstem) function that are relatively unaffected by conductive or sensory hearing loss. The likelihood that wave I is recorded is enhanced through use of ear canal or tympanic membrane electrode designs and through alterations in the test protocol, such as a slower stimulus rate, rarefaction stimulus polarity, and maximum stimulus intensity level (7).

Reports on ABR dating back to the late 1970s have confirmed that waveforms evoked by high-intensity signals yield neurodiagnostic information about cochlear and retrocochlear auditory function. The data can be used in the identification of retrocochlear disorders, such as acoustic

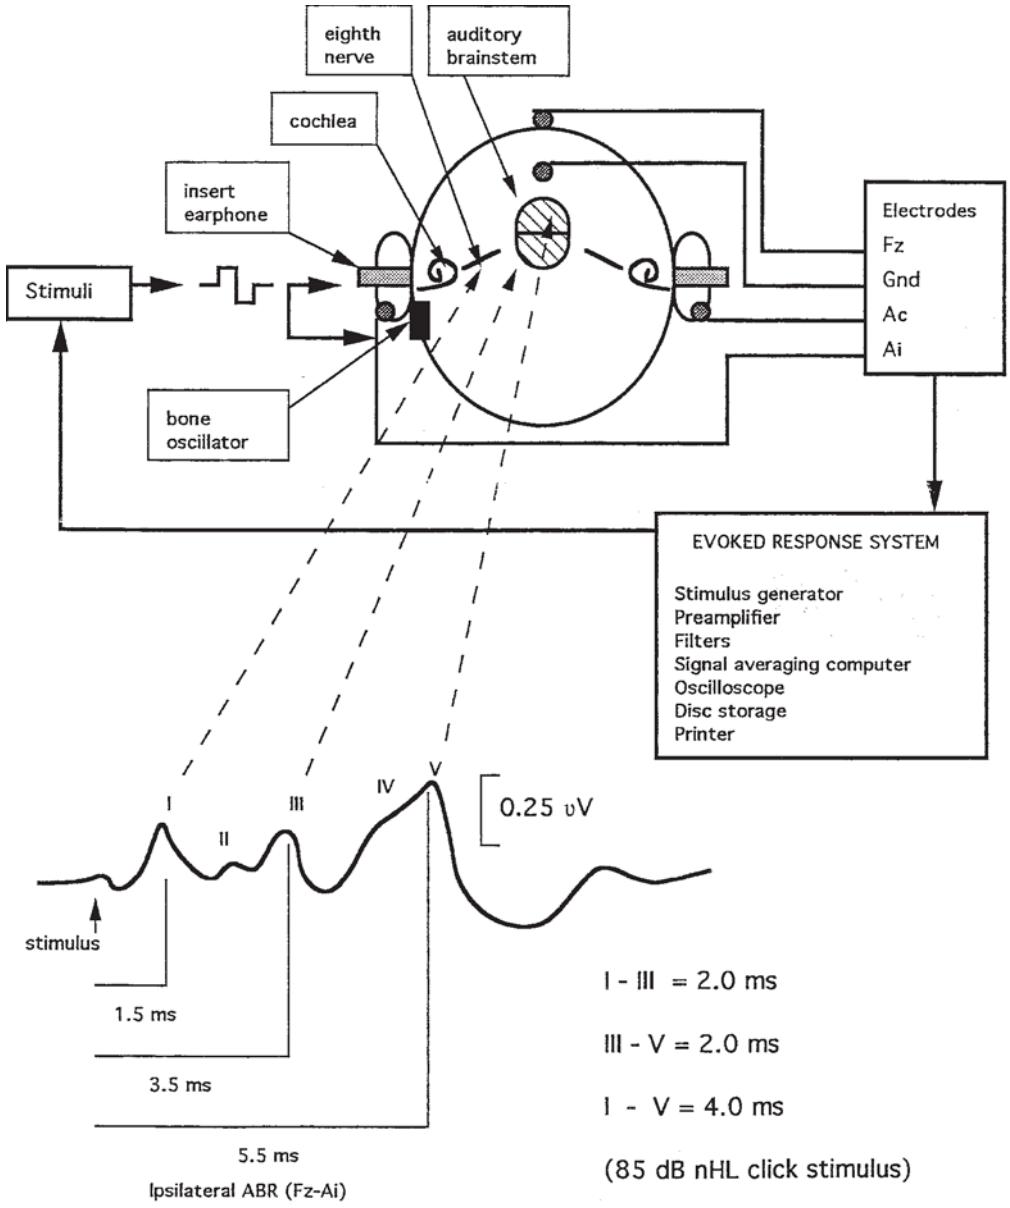

Figure 142.3 Schematic shows the instrumentation for recording the ABR and important relations between auditory anatomic features and waveform components. A simple strategy for analysis of ABR waveform in neurodiagnosis also is shown.

neuroma, with an accuracy that exceeds 95%, at least for medium to large tumors. With the development of sophisticated neuroradiologic techniques, such as magnetic resonance imaging (MRI) with enhancement, and earlier diagnosis of smaller tumors, the sensitivity of ABR has dropped (8). Inexpensive fast spin echo MRI is technically feasible and available clinically, making ABR less commonly used as a screen for retrocochlear tumors.

False-negative ABR outcomes can occur in patients at risk of retrocochlear auditory dysfunction, particularly in individuals with intracanicular vestibular schwannomas (9). The poor results are evidence of the relatively poorer sensitivity of ABR than that of MRI to mass lesions. However, false-positive outcomes of MRI also have been reported among patients with normal ABR results and no surgical evidence of tumor (10). It must be kept in mind that ABR is a measure of function, whereas computed tomography and conventional MRI are measures of structure (see Chapter 147). Assessment of ABR continues to be a readily available, relatively inexpensive, and reasonably sensitive procedure for initial diagnostic evaluation of eighth-nerve and auditory brainstem status in the care of patients with retrocochlear signs and symptoms. ABR is particularly useful in patients for whom concerns are limited to larger tumors, the elderly, the medically infirm, and individuals who have contraindications to MRI (e.g., a pacemaker). As described in Chapter 131, assessment of ABR can also be valuable in electrophysiologic monitoring of the eighth cranial nerve and auditory brainstem function during neurotologic operations such as vestibular nerve section and posterior fossa tumor removal.

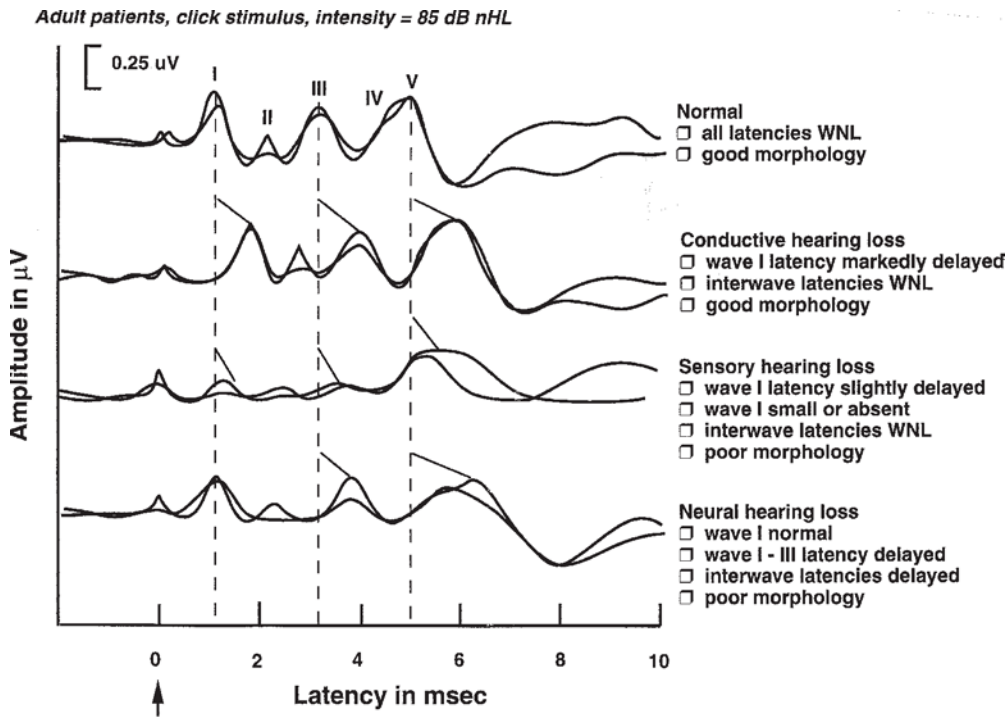

Figure 142.4 ABR patterns associated with various types of auditory dysfunction. Information about dysfunction can be inferred from the latency of specific waves and overall structure of the waveforms.

The application of ABR in the estimation of hearing sensitivity in infants and young children is now essential (7). Accurate and early hearing aid fitting is, of course, critical for infants with serious hearing loss. With the emergence of universal newborn hearing screening, children at risk for hearing loss can be routinely identified at birth. Research on the benefits of early intervention for hearing loss in infants (11) argues strongly for the diagnosis of hearing loss and the beginning of hearing aid use before a child is 6 months old. Appropriate hearing aid fitting, however, requires information on hearing sensitivity at specific frequencies within the range of hearing that is critical for understanding speech. Unfortunately, it is not possible to obtain behavioral estimates of hearing sensitivity (an audiogram) at such a young age. By performing ABR recordings with frequency-specific signals (tone bursts), hearing thresholds can be estimated electrophysiologically and infant hearing aid fitting can be accomplished within months after birth. Electrophysiologic estimation of hearing sensitivity with ABR does have one serious clinical constraint. The maximum intensity level is only about 80 dB for very brief (transient) click and tone burst signals used to elicit the ABR. Therefore, the ABR cannot be used to estimate hearing sensitivity in the severe to profound range of impairment. As with any test, false positives may occur. A small percentage of children with relatively normal hearing may have abnormal or absent ABR waveforms. ABR testing should be corroborated with other tests of auditory function, including behavioral responses.

A relatively recent clinical electrophysiologic measure, the ASSR, has proven useful for these infants (7). The ASSR is elicited with pure-tone signals (steady state signals), rather than transient signals (clicks or tone bursts). The pure tone signals are altered with rapid modulation of the amplitude and, sometimes, frequency. The pure tone signal activates the cochlea at the specific frequencies (e.g., 1,000 or 500 Hz) and provides the type of information on hearing that is available with the audiogram. In addition, energy at the modulation rate (e.g., 80 per second) is generated in the auditory system and can be detected automatically with sophisticated algorithms for signal detection. The major clinical advantage of ASSR is the ability to estimate hearing sensitivity at discrete frequencies for children with hearing loss exceeding 80 dB HL. Thus, the ABR and ASSR can be used in combination to define any degree of hearing loss in children at any age, including infants soon after birth. Analysis of ASSR findings can be particularly helpful in the earlier and more confident identification of infants who are likely candidates for cochlear implantation.

Electrocochleography

For more than 30 years, ECochG has been used to assess peripheral auditory function. The examination is performed most often for intraoperative monitoring of cochlear and eighth-nerve status and in the diagnosis of Ménière disease (7). Optimal ECochG waveforms are recorded with a small needle electrode placed through the tympanic membrane and on the promontory, although electrode placement on the tympanic membrane or, to a lesser extent, in the ear canal can be clinically useful. Stimulus and acquisition criteria for ECochG have been well defined for decades. The three major components of the ECochG are the cochlear microphonic,

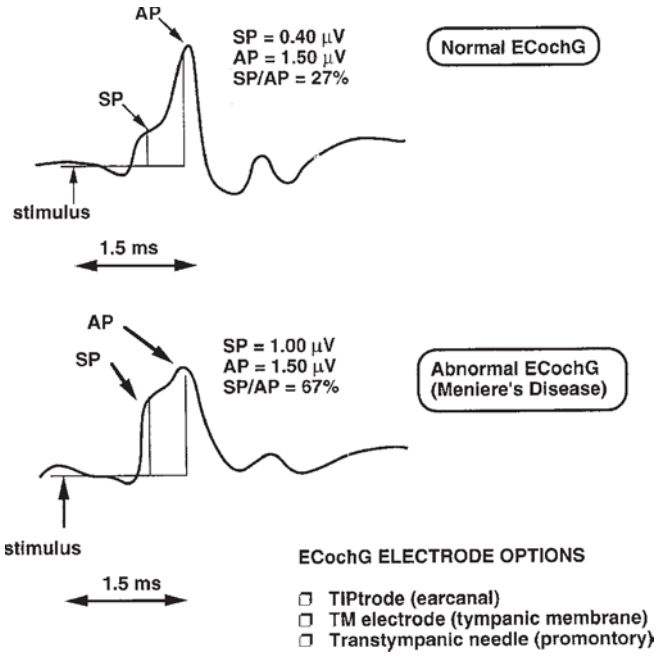

Figure 142.5 ECochG waveforms show normal relation of SP and AP and abnormally enlarged SP/AP relation for a patient with Ménière disease. Absolute and relative amplitude values for the SP and AP components and the criteria for definition of a normal response vary greatly for different electrode sites (ear canal vs. tympanic membrane vs. promontory).

summating potential (SP), and AP. The cochlear microphonic (CM) and SP reflect cochlear bioelectric activity. The AP is generated by synchronous firing of distal afferent eighth-nerve fibers and is equivalent to ABR wave I (Fig. 142.5).

The typical ECochG analysis technique in neurotology requires determination of the amplitude of the SP and the AP from a common baseline. The ratio of the SP to the AP (SP/AP) is calculated and reported as a percentage. Normal ranges and cutoffs for SP/AP ratio have been reported for each electrode type. Abnormal SP/AP ratio values are defined as more than 50% for the ear canal electrode type, more than 40% for a tympanic membrane electrode, and more than 30% for a transtympanic needle electrode (7).

Among patients with Ménière disease, the characteristic ECochG finding is abnormal enlargement of the relation between the component amplitudes of the SP and the AP. With the tympanic membrane electrode technique, the sensitivity of ECochG in the diagnosis of endolymphatic hydrops is 57%; the specificity was 94% in a series of 100 patients (12). Only 3 of 30 patients had false-positive results. Thus an abnormally enlarged SP/AP ratio is highly suggestive of endolymphatic hydrops, according to these data. In the study (10), the likelihood of an abnormal ECochG SP/AP ratio was statistically higher as hearing loss increased and when hearing loss fluctuated. Similar elevations in the SP/AP ratio have, however, been reported in perilymph fistula (13–15), autoimmune inner ear disease (16,17), and superior semicircular canal dehiscence (18).

ECochG also plays a critical role in the accurate diagnosis of auditory neuropathy spectrum disorder, or ANSD (7). This complex assortment of auditory disorders is characterized by the absence of an ABR despite integrity of the outer hair cells (as determined by ECochG and/or OAEs). Sites of dysfunction in ANSD include the inner hair cells, the synapse between the inner hair cells and afferent auditory nerve fibers, or auditory nerve fibers (e.g., spiral ganglion). Close analysis of the pattern of ECochG findings, specifically the presence or absence of the cochlear microphonic CM, SP, and AP, permits differentiation between presynaptic dysfunction (affecting inner hair cells) and postsynaptic dysfunction (affecting auditory nerve fibers). In combination with MRI studies of the auditory nerve, ECochG provides diagnostic information important in making decisions about management of ANSD. ECochG outcome is particularly useful in determining whether cochlear implantation is an appropriate treatment option (7).

Cortical Auditory Evoked Responses

More than a dozen subtypes of auditory evoked responses can be recorded beyond the brainstem, from auditory regions of the thalamus, hippocampus, internal capsule, and cortex. Prominent among them in clinical audiology are the auditory middle latency response (AMLR), the auditory late response (ALR), and the P300 response (7). Cortical auditory evoked responses were reported as early as the 1930s. In fact, all of the above-noted responses were well described before the ABR was discovered.

Cortical auditory evoked responses are characterized by longer latencies (100 to 300 ms) than ECochG waveforms and ABR because they arise from more rostral regions of the auditory central nervous system (CNS) and depend on multisynaptic pathways. Amplitudes of the cortical responses are considerably larger (2 to 20 times) than those of the earlier responses because they reflect activity evoked from a greater number of neurons. Measurements are distinctly different for the cortical versus cochlear or brainstem responses. For example, stimulus rate must be slower and physiologic filter settings lower. As a rule, stimulus intensities are moderate, rather than high. Cortical evoked responses are best elicited with longer-duration, and therefore frequency-specific, tonal stimuli, rather than the click stimuli optimal for ECochG and ABR. The analysis time must extend beyond the expected latency of the response (more than 300 ms) for cortical responses. Recording electrode sites also are different for cortical responses. There is more emphasis on scalp sites over the hemispheres and less concern about electrode sites near the ears.

The AMLR consists of a prominent positive voltage (labeled Pa) component in the 25 to 30 ms region. When recorded with electrodes located over the temporal–parietal region, the AMLR is generated by pathways leading to the primary cortex and from this region of the temporal lobe. The ALR occurs later in time, with major peaks (N1 and P2) appearing within the time frame of 100 to 200 ms. A variety of types of signals can be used to elicit the ALR, including speech (e.g., phonemes "da"and "ga.") The AMLR and

ALR are now undergoing considerable investigation for the electrophysiologic assessment of children and adults, and for the documentation of effectiveness of intervention (e.g., auditory training, hearing aids, and cochlear implants) for communication impairment (19).

The P300 response is recorded with what is typically called the oddball paradigm. Two types of stimuli are used. One—the frequent stimulus—is presented frequently in a predictable manner. The other—the rare or deviant stimulus—is presented infrequently and pseudorandomly. The rare stimuli account for less than 20% of the total stimuli presented. The patient is instructed to ignore the frequent stimuli and to attend to the rare stimuli. The waveform for the frequent stimulus is essentially an ALR consisting of a positive peak of 5 to 10 mV within the 150 to 200 ms region. In contrast, the waveform averaged from the attended rare stimuli is characterized normally by a large positive peak in the 300 ms region, hence the term P300 response. Presumed generators of the P300 response include regions of the medial temporal lobe (hippocampus) that are important in auditory attention.

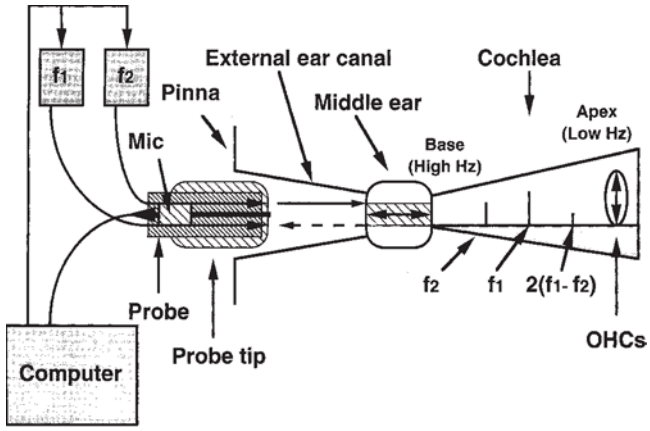

Figure 142.6 Equipment and procedure for measurement of distortion product otoacoustic emissions (DPOAEs). The two stimulus frequencies (f_1, f_2) are presented to the ear with a soft probe (*inward-pointing arrows*). The DPOAEs (at the frequency $2f_1$–f_2) produced by the outer hair cells are propagated outward through the middle ear to the external ear canal. Amplitude of DPOAE in dBSPL is plotted as a function of the frequency of the stimuli (the f_2 stimulus).

OTOACOUSTIC EMISSIONS

OAEs are low-intensity sounds produced by the cochlea either spontaneously, or more commonly, in response to an acoustic stimulus. A moderate-intensity click or an appropriate combination of two tones can evoke outer hair cell movement or motility (2,20). Outer hair cell motility affects basilar membrane biomechanics; the result is a form of intracochlear energy amplification and cochlear tuning for precise frequency resolution. Outer hair cell motility generates mechanical energy within the cochlea that is propagated outward through the middle ear system and the tympanic membrane to the ear canal. Vibration of the tympanic membrane produces an acoustic signal (the OAE), which can be measured with a sensitive microphone.

There are two broad classes of OAE—spontaneous and evoked. Spontaneous otoacoustic emissions (SOAEs) occur among only approximately 60% of persons with normal hearing. They are measured in the external ear canal when there is no external sound stimulation. A marked sex effect has been confirmed for SOAE. Women have SOAE at twice the rate of men. Evoked OAEs, elicited by moderate levels (50 to 80 dBSPL) of acoustic stimulation in the external ear canal, are generally classified according to the characteristics of the stimuli used to elicit them or the characteristics of the cochlear events that generate them. Stimulus-frequency OAEs, which are technically difficult to record, are the least studied of the evoked OAE.

Distortion-product otoacoustic emissions (DPOAEs) are produced when two pure-tone stimuli at frequencies f_1 and f_2 are presented to the ear simultaneously (Fig. 142.6). The most robust DPOAE occurs at the frequency determined by the equation $2f_1 - f_2$, whereas the actual cochlear frequency region assessed with DPOAE is between these two frequencies, and probably close to the f_2 stimulus for recommended test protocols (2,12). With all instruments commercially available for recording DPOAE, amplitude detected in the ear canal and described in dBSPL is plotted as a function of the frequencies of the stimuli in a DPOAEgram. Transiently evoked otoacoustic emissions (TEOAEs) are elicited with brief acoustic stimuli such as clicks or tonebursts. Although there are distinct differences in the methods for recording DPOAE and TEOAE, and the exact cochlear mechanisms responsible for generation are different, each type of evoked OAE is being incorporated into routine auditory assessment of children and adults (2,20).

When outer hair cells are structurally damaged or at least nonfunctional, OAEs cannot be evoked with acoustic stimuli. Among patients with mild cochlear dysfunction, OAEs can be recorded but amplitudes are below normal limits for some or all stimulus frequencies. Some patients with abnormal OAEs that indicate cochlear dysfunction have normal pure-tone audiograms, and OAEs provide information about auditory function at far more frequencies (up to 20 per octave) than does an audiogram. An example of these advantages is a patient with tinnitus but normal audiologic findings (20). Abnormal OAEs are expected in the frequency region represented by the tinnitus. Up to 30% of a population of outer hair cells can be damaged without substantially affecting a simple audiogram (21). In such cases, abnormal OAE findings are invariably recorded. Conversely, OAEs may be recorded in individuals with severely impaired auditory function, either as a result of mass lesion on the auditory nerve (22) or auditory neuropathy (23). OAEs are generally not detected in patients with middle ear pathology. However, OAEs can also be recorded in patients with tympanostomy tubes. Normal OAEs in such cases confirm that the tube is

patent and, in addition, that outer hair cells are intact. The noninvasive nature of OAE recording, coupled with accuracy and objectivity in assessing cochlear, especially outer hair cell, function suggests diverse potential clinical applications that range from auditory screening to sensorineural diagnosis (2,20). A listing of clinical applications and their rationale is provided in Table 142.2.

ASSESSMENT OF AUDITORY PROCESSING DISORDERS

Background

Myklebust (24) in 1954 wrote, "hearing is a receptive sense … and essential for normal language behavior." … "the diagnostician of auditory problems in children has traditionally emphasized peripheral damage. It is desirable that he also include considerations of central damage" (24). He also explained that "central deafness (central APD) is a deficiency in transmitting auditory impulses to the higher brain centers while receptive aphasia (language disorder) is a deficiency in the interpretation of these impulses after they have been delivered" (24). During this era, Bocca et al. (25) reported that surgically confirmed central auditory system abnormalities can be detected with sufficiently sensitive audiologic procedures.

These pioneering observations and studies have since been validated by many clinical investigations. There are now a variety of behavioral and electrophysiologic techniques for the assessment of peripheral and central auditory system function, including APDs involving the peripheral or central auditory system. The term APD is used to describe a deficit in the perception or complete analysis of auditory information due to central auditory nervous system dysfunction, usually at the level of the cerebral cortex (2,26). Central auditory processing takes place before language processing or comprehension. The results of extensive auditory neuroscience research during the past 20 years, including findings for objective assessment of CNS function like auditory evoked responses and functional MRI, have provided compelling evidence of APDs. Taken together, the substantial peer-reviewed literature on APDs confirms that "we hear with our brain."

Risk Factors for Central Auditory Nervous System Dysfunction

The Joint Committee on Infant Hearing (27) has delineated a number of indicators associated with sensorineural and conductive hearing loss among neonates and infants. Some of these indicators, such as *in utero* infection, bacterial infection, asphyxia, hyperbilirubinemia, and head trauma, as well as other neurologic insults in infancy (intraventricular hemorrhage and hydrocephalus) can be associated with central as well as peripheral auditory nervous system dysfunction. An important indicator identified by the joint committee and of interest to primary care professionals is "parent/caregiver concern regarding hearing, speech, language, and/or developmental delay" (27). Additional indications for evaluation of children for APD are teachers' concerns about hearing, recurrent middle ear disease, language impairment, attention deficit disorder with or without hyperactivity, reading delay, and learning disabilities. Central auditory nervous system dysfunction can coexist with any of these disorders. Among adults, risk factors for central auditory nervous system dysfunction include, but are not limited to, advanced age and history or clinical evidence of stroke, head injury including traumatic brain injury, brain neoplasms, Alzheimer disease, and other disorders affecting the CNS (26). It is a good clinical policy always to consider the possibility of central auditory dysfunction when a patient describes hearing problems that do not conform with audiographic findings.

APD Test Battery

The central auditory system consists of auditory regions within brainstem and midbrain, the thalamus, and the cerebral cortex, specifically the Heschl gyrus on the superior gyrus of the temporal lobe. The auditory evoked responses described earlier are useful in the assessment of the central auditory nervous system (2,7). Assessment for APD typically is conducted with a battery of behavioral tests that have proven sensitivity to central auditory dysfunction. In most cases, peripheral auditory function is normal. The overall goal is to measure reliable performance for each ear on a series of speech audiometric procedures, including a dichotic word test, such as dichotic digits, a dichotic sentence test, a speech-in-competition test (e.g., HINT or synthetic sentence identification with ipsilateral competing message, abbreviated SSI-ICM), and reliable performance with binaural stimulation on one or more nonspeech measures, such as pitch pattern sequence and duration pattern

tests. Auditory evoked responses are recorded if specifically requested by the referring practitioner or if there are any concerns about the reliability or interpretation of behavioral test performance. Findings of evaluations for APD are compared with age-corrected normative data. Minimal criteria for confirmation of APD are scores less than the age-corrected normal region (more than 2.5 standard deviation below the mean) for one or both ears for at least two different procedures performed on a child with normal results of peripheral auditory tests (26).

In constructing an APD test battery, it is wise to rely on procedures not apt to be influenced by linguistic, cognitive, or attention disorders. Interpretation of APD test results is most straightforward when deficits are unilateral. The findings confirm that the patient has understood the task and that the outcome is not caused by a linguistic, cognitive, or attention disorder. A pronounced unilateral abnormality, specifically a marked left ear deficit, is one of the most common patterns of APD test battery findings. Another rather definite APD test battery pattern is reduced performance apparent only on difficult portions of a test. This finding implies an auditory as opposed to linguistic, cognitive, or strictly attentional explanation for the child's poor performance. Other important features of a clinically feasible APD test battery are (a) resistance to the influence of even slight peripheral auditory dysfunction, (b) availability of adequate age-matched normative data, and (c) use of professionally produced test materials recorded on tape or a compact disk. Earlier concerns about the usefulness of APD assessment with rudimentary procedures lacking these criteria were justifiable. Now, however, there are clinically feasible and commercially available procedures for testing children and adults (2). In addition, there is recent evidence in children with APDs of auditory nervous system development and functional improvement following the completion of computer-based and conventional auditory training programs (19,26).

INDICATIONS FOR DIAGNOSTIC AUDIOLOGIC ASSESSMENT

Children

Hearing loss, regardless of causation, affects the speech and language development of infants and young children. Communication deficits can occur within the first 6 months of life. Hearing loss among preschool and school-age children interferes with educational development. Identification of hearing loss at birth and prompt and appropriate intervention before the age of 6 months are essential if a child is to reach his or her communicative and educational potential (11). Testing a child's hearing at regular intervals during the first 5 years of life is the responsibility of pediatricians and primary care physicians (27,28). Otolaryngologists and audiologists must coordinate efforts in properly and promptly assessing and managing hearing loss among children.

Adults

The first suspicion of hearing loss among adults occurs while a medical history is being obtained. The patient cites hearing loss as the chief symptom, or close questioning reveals that the patient has difficulty in hearing, especially difficulty in understanding speech. Sometimes, this problem is apparent or is most noticeable only under specific conditions, such as when the patient is speaking on the telephone or conversing in noisy environments or conversing with certain persons, such as children or women, whose voices tend to be fainter and higher pitched than those of men. The medical history can provide other information that suggests risk of hearing loss, such as exposure to damaging levels of recreational or work-related noise or administration of ototoxic medications. Specific symptoms, such as tinnitus or vertigo, or physical findings of otologic abnormalities or of other pathologic conditions associated with auditory system involvement, also indicate the need for audiologic assessment.

STAFF TRAINING AND AUTOMATED TESTING

In some countries, such as the United States, audiometry is typically performed by clinically licensed audiologist with a graduate degree (e.g., Doctor of Audiology) from an accredited academic institution. Audiometric technicians, commonly nurses or other members of an otolaryngologist's clinic staff, have been employed to maximize availability of testing coverage and to minimize cost. Although testing by such individuals may be excellent, handling difficult situations, such as masking and interaural attenuation, may prove problematic. Similarly, self-administered, computer-automated audiometers (e.g., Otogram, Tympany, Stafford, TX) have seen tremendous growth in popularity in recent years. Early studies have shown good reliability between conventional, audiologist-administered and self-administered, computer-automated audiometry, but clinical experience with these newer modalities is limited (29,30). Results obtained with less extensively trained technicians and with automated audiometers may serve well as screening studies. Validation by more experienced and well-trained audiologists and corroboration with tuning forks should be considered before making any treatment decisions that imparts any appreciable risk to the patient. A clinician who bases treatment decisions based on audiometric assessments performed by technicians and automated audiometers implicitly takes responsibility for their diagnostic accuracy.

GLOSSARY

ABLB Alternate binaural loudness balance. A traditional diagnostic auditory procedure for detecting loudness recruitment used in differentiating cochlear from retrocochlear auditory dysfunction in unilateral hearing

loss. The task is to balance the sensation of loudness for the better versus poorer hearing ear. Loudness recruitment is a cochlear auditory sign.

ABR (BAER) Auditory brainstem response (brainstem auditory evoked response). Electrical activity, evoked (stimulated) by sounds of very brief duration, that arises from the eighth cranial nerve and auditory portions of the brainstem. Usually recorded from the surface of the scalp and external ear with disk-type electrodes and processed with a fast signal averaging computer. Wave components are labeled with Roman numerals and described according to latency in milliseconds after the stimulus and amplitude in microvolts from one peak to the following trough.

AC Air conduction Audiometric signals presented through earphones to the ear canal.

Admittance An acoustic immittance measure corresponding to the ease of energy flow through the middle ear system

air–bone gap The difference in pure-tone thresholds for air-conducted versus bone-conducted signals. With calibrated audiometers, the normal ear and the sensorineurally impaired ear show no air–bone gap; conductive hearing losses are characterized by an air–bone gap.

ASSR Auditory steady state response An electrophysiologic measure similar to the ABR, but elicited with pure tone signals (vs. transient signals for ABR) that are modulated rapidly in amplitude and frequency. Electrophysiologic activity in the brain is generated by the signal modulation, and detected automatically with a sophisticated processing algorithm.

Audiologist A hearing care professional educated and trained clinically to measure the function of the auditory system and to provide nonmedical care of persons with auditory and communicative losses. Minimal educational requirements and professional credentials for audiologists are a master's degree or Doctor of Audiology (Au.D.) and state licensure.

Auditory neuropathy spectrum disorder (ANSD) A complex collection of auditory disorders that can involve various sites of dysfunction, including the inner hair cells, auditory neurotransmitters, and auditory nerve fibers. ANSD may be an early finding in patients with genetic auditory disorders, neurodegenerative diseases, and other neurological pathology.

Auditory processing disorder (APD) Dysfunction in the auditory system, including central auditory pathways and centers, that impairs effective and efficient processing of auditory information. APD may exist in persons with normal hearing sensitivity.

BC Bone conduction Audiometric signals presented to the skull, such as mastoid bone or forehead, by means of an oscillator.

BCL Békésy comfortable loudness. A Békésy audiometry procedure conducted at a comfortable loudness level as opposed to threshold level.

Békésy audiometry An audiometric procedure performed with a Békésy audiometer for differentiating cochlear and retrocochlear auditory dysfunction. Békésy audiometry is based on comparison of responses to pulsed and continuous tones varied across a wide frequency range. Four patterns of Békésy responses were classified by Jerger.

BOA Behavioral observation audiometry. A pediatric behavioral audiometry procedure in which motor responses to sounds such as eye opening and head turning are detected by a trained observer.

Configuration The shape or pattern of an audiogram. Shows how hearing loss varies as a function of the audiometric test frequency. The three main configurations are rising (low-frequency loss), sloping (high-frequency loss), and flat.

Crossover Property by which sound stimulus presented to one ear (test ear) travels around the head (by means of air conduction) or across the head (by means of bone conduction) to stimulate the other ear (nontest ear). See interaural attenuation and masking dilemma.

dB HL Decibels hearing level A decibel scale referenced to accepted standards for normal hearing (0 dB is average normal hearing for each audiometric test frequency).

dB nHL Decibels normal hearing level A decibel scale used in ABR measurement referenced to average behavioral threshold for the click stimulus of a small group of normal-hearing subjects.

dB SL Decibels sensation level Sound intensity described in reference to an individual patient's behavioral threshold for an audiometric frequency or another measure of hearing threshold, such as the speech-reception threshold.

dBSPL Decibels sound pressure level A decibel scale referenced to a physical standard for intensity, such as 0.0002 dyne/cm^2.

Dichotic Simultaneous presentation of a different sound to each ear.

DPOAEs Distortion product otoacoustic emissions Otoacoustic emissions evoked by two closely spaced pure tone frequencies that measure outer hair cell function and nonlinear activity within the cochlea

DPgram, DPOAEgram A graph of distortion product otoacoustic emission amplitude in the ear canal (dBSPL) as a function of the frequencies of the stimulus tones (Hz).

ECochG Electrocochleography Recording of evoked responses originating from the cochlea (the summating potential (SP), the cochlear microphonic (CM), and the eighth cranial nerve (the action potential, AP).

ENG Electronystagmography A test of vestibular function in which nystagmus is recorded with electrodes placed near the eyes during stimulation of the vestibular system.

ENoG Electroneurography Recording of myogenic activity of the facial muscles, usually in the nasolabial fold,

in response to electrical stimulation of the facial nerve as it exits the stylomastoid foramen.

Hearing in Noise Test (HINT) A clinical test of speech perception of sentences in noise. The sentence-to-noise difference (ratio) is manipulated during administration of the HINT.

Immittance The word immittance is a combination of two related terms: impedance and admittance. Each term is defined in the glossary.

Impedance An acoustic immittance measure corresponding to the resistance to energy flow through the middle ear system

Interaural attenuation Insulation to the crossover of sound (acoustic or mechanical energy) from one ear to the other provided by the head. Varies depending on whether the signal is presented by air conduction (interaural attenuation more than 40 dB) or bone conduction (interaural attenuation less than 10 dB). Insert earphones offer maximum interaural attenuation.

Malingering Feigning or exaggerating a hearing loss. Also called presbycusis, functional hearing loss, or nonorganic hearing loss.

Masking (masker) A controlled background noise presented usually to the ear not being tested in an audiometric procedure to prevent a response from that ear caused by crossover when interaural attenuation is exceeded.

Masking dilemma A problem encountered in audiometric assessment of patients with severe conductive hearing loss. The level of masking noise necessary to overcome the conductive component and adequately mask the ear not being tested exceeds interaural attenuation levels. The masking noise can cross over to the ear being tested and mask the signal, such as a pure tone or speech. In the masking dilemma, enough masking is too much masking. The masking dilemma can be reduced by the use of insert earphones. The sensory acuity level test also is helpful for measuring ear-specific bone conduction hearing thresholds for patients who present the masking dilemma.

MCL Most comfortable level The intensity level of a sound perceived as comfortable.

MLD Masking level difference An audiometric procedure used to compare a threshold response with masking noise presented in phase as opposed to out of phase with a pure-tone or speech signal. Release from masking is a normal phenomenon reflecting auditory brainstem integrity.

OAE Otoacoustic emissions Sounds generated by energy produced by the outer hair cells in the cochlea and detected with a microphone placed in the external ear canal.

PB Phonetically balanced Word lists developed in the late 1940s that contain all the phonetic elements of general American English speech that occur with the approximate frequency of occurrence in conversational speech.

PI Performance intensity A measure of speech recognition or understanding as a function of the intensity level of the speech signal. See rollover.

PTA Pure-tone average The arithmetic average of hearing threshold levels for 500, 1,000, and 2,000 Hz, or the speech frequency region of the audiogram. The PTA should agree within ±7 dB with the speech-reception threshold.

Rollover A decrease in speech recognition performance, in percentage correct, at high signal intensity levels as opposed to lower levels. Rollover is an audiometric sign of retrocochlear auditory dysfunction.

SAL Sensory acuity level An audiometric procedure developed by Jerger for assessing bone-conduction hearing among patients with serious conductive hearing loss. Air-conduction thresholds are determined without masking and with masking presented by bone conduction to the forehead. The size of the masked shift in hearing thresholds corresponds to the degree of the conductive hearing loss component.

SAT (SDT) Speech awareness threshold (speech detection threshold) The lowest intensity level at which a person can detect the presence of a speech signal. The SAT approximates the best hearing level in the 250 to 8,000 Hz audiometric frequency region.

SISI Short increment intensity index A clinical procedure developed by Jerger for assessing the ability to detect a 1 dB increase in intensity. A high SISI score is consistent with cochlear auditory dysfunction.

S/N Signal-to-noise ratio The signal-to-noise ratio is the difference between the intensity level of a sound or electrical event and background acoustic or electrophysiologic energy.

SRT Speech-reception level The lowest intensity level at which a person can accurately identify a speech signal, such as two-syllable spondee words. See PTA.

SSI Synthetic sentence identification A measure of central auditory function that involves identification of syntactically incomplete sentences (a closed set of 10 sentences) presented simultaneously with a competing message (an ongoing story about Davy Crockett).

SSW Staggered spondaic word test A measure of central auditory function developed by Katz in which spondee words are presented dichotically.

Tone decay test A clinical measure of auditory adaptation in which a tone is presented continuously to an ear with a hearing loss until it becomes inaudible. There are numerous versions of tone decay tests. Excessive tone decay is a sign of retrocochlear auditory dysfunction.

TROCA Tangible reinforcement operant conditioning audiometry A pediatric behavioral audiometry technique used to reinforce a response to auditory signals with food. TROCA is used mainly in the care of children with mental retardation or developmental delay.

UCL (LDL) Uncomfortable level (loudness discomfort level) The intensity level of a sound perceived as too loud.

VRA Visual reinforcement audiometry A pediatric behavioral audiometry procedure used to reinforce localization responses to acoustic signals with a visual event, such as an animal playing.

HIGHLIGHTS

- Pure-tone audiometry is the most common measure of hearing sensitivity.
- Masking is the audiometric technique used to eliminate participation of the ear not being tested whenever air- and bone-conduction stimulation exceeds interaural attenuation.
- Speech audiometry procedures usually are performed to measure hearing sensitivity (thresholds in decibels) for words or to estimate word recognition, such as speech discrimination, ability.
- Immittance is a term derived from the terms for two related techniques of assessing middle ear function (impedance and admittance), techniques that have been used clinically since 1970.
- Tympanometry is the dynamic recording of middle ear impedance as air pressure in the ear canal is systematically increased or decreased.
- Acoustic reflex measurement is useful clinically because it can quickly provide objective information about the status of the auditory system from middle ear to brainstem.
- Extensive research has shown that the ABR wave components arise from the eighth cranial nerve and auditory regions in the caudal and rostral brainstem.
- Optimal ECochG waveforms are recorded with a small needle electrode placed through the tympanic membrane onto the promontory, although placement on the tympanic membrane and to a lesser extent the ear canal also is clinically useful.
- OAEs are low-intensity sounds produced by the cochlea in response to an acoustic stimulus. OAEs are a popular technique for hearing screening of infants and older children, and for objective diagnostic confirmation of outer hair cell integrity
- Indicators of sensorineural or conductive hearing loss among neonates and infants include intrauterine infection, bacterial infection, asphyxia, hyperbilirubinemia, and head trauma, as well as neurologic insults during infancy.
- No single measure of auditory function is adequate for comprehensive hearing assessment.
- Hearing loss, regardless of causation, affects the speech and language development of infants and young children.

Vestibular Function and Anatomy

143

J. Christopher Holt *Shawn D. Newlands*

Nearly all animals have ways of monitoring their own movements and orienting themselves with respect to various sensory cues in their environment. In vertebrates, such behaviors depend heavily on a functioning vestibular system, a critical sensory system that begins in the inner ear as a collection of peripheral detectors for motion and gravity and ends among a number of higher neural centers within the central nervous system (CNS). These higher centers process and integrate incoming motion information from the periphery to inform our perception of our position in space and relative to other objects, to coordinate our movements, and to formulate appropriate reflexes (1). The vestibular system is physically linked to the peripheral auditory system through their cohabitation in the inner ear, and like the auditory system, ultimately converts mechanical forces (i.e., rotation, translation, and/or gravitational forces rather than sound energy) into a neural code that is interpreted centrally. The ability of the vestibular system to detect movements of the head and body resides in the vestibular hair cell whose sensitivity to mechanical stimuli is coupled to a series of electrochemical processes that ultimately change the firing rate of vestibular afferent neurons. Despite the obvious necessity for the vestibular system, we often fail to appreciate its role unless it becomes deficient or defective, at which point, one becomes acutely aware of its importance. In the pages that follow, we discuss the gross anatomy of the peripheral vestibular system, the anatomy and physiology of vestibular hair cells and afferent neurons, the biophysics of sensory transduction, and the organization and functional connectivity of vestibular inputs to the CNS. This chapter serves only as an introduction to the vestibular system; for a more thorough treatment, readers are encouraged to consult dedicated texts.

GROSS ANATOMY OF THE VESTIBULAR SYSTEM

The vestibular labyrinth of vertebrates is an anatomically complex structure consisting of a series of fluid-filled tubes and sacks containing distinct sensory end organs for the detection of both angular and linear acceleration of the head and body (Fig. 143.1). In mammals, the membranous vestibular labyrinth is threaded through a bony labyrinth formed by the dense, hard bone of the otic capsule, within the petrous portion of each temporal bone. A sodium-rich, CSF-like fluid called perilymph bathes the space between the bony and membranous labyrinth, whereas the lumen of the membranous labyrinth is filled with endolymph, a potassium-rich fluid that closely resembles the normal intracellular milieu. Both the perilymphatic and endolymphatic spaces of the vestibular labyrinth are contiguous with the respective spaces of the cochlea. As such, both fluid compartments circulate between the cochlea and the vestibular labyrinth, and thus the homeostatic mechanisms for hearing discussed in Chapter 141 are crucial for vestibular function as well.

The term vestibular labyrinth generally refers to the paired right and left labyrinths together, which are essentially mirror images of each other (see Fig. 143.2A). Each side is comprised of three orthogonally arranged semicircular canals (horizontal or lateral, anterior or superior, and posterior) and two sac-like structures called the utricle and saccule. The utricle and saccule are collectively referred to as the otolith organs. Innervation for the canals, saccule, and utricle all travel in the vestibular nerve portion of cranial nerve VIII. The anterior canal, horizontal canal, utricle, and anterior one-third of the saccule receive their innervation by way of the superior division of the vestibular nerve,

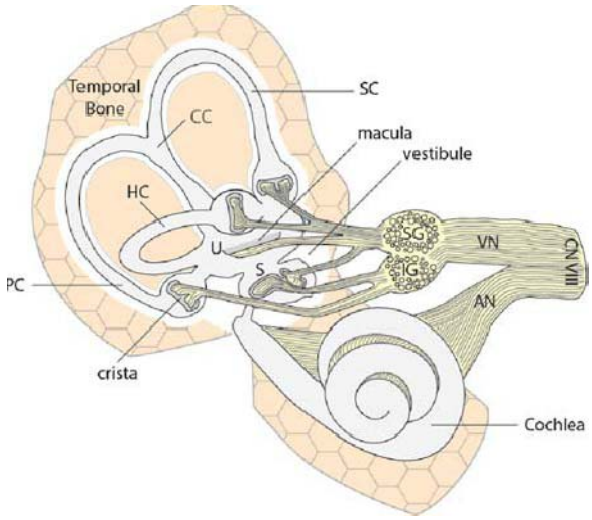

Figure 143.1 The vestibular labyrinth and its innervation. AN, auditory nerve; CC, common crus; CN VIII, cranial nerve 8; HC, horizontal canal; IG, inferior ganglion; PC, posterior vertical semicircular canal; S, saccule; SC, superior or anterior vertical semicircular canal; SG, superior ganglion; U, utricle; VN, vestibular nerve. Shaded areas at each of the nerve endings represent the sensory neuroepithelium.

whereas the inferior division innervates the posterior two-thirds of the saccule and posterior canal (Fig. 143.1). Upon reaching each end organ, the innervation terminates within the sensory portions of the membranous labyrinth. The sensory neuroepithelium of the semicircular canals and otolithic organs are called the crista and macula, respectively (Fig. 143.1).

One end of each semicircular canal is expanded to form what is called the ampulla. The ampulla is presumably enlarged to accommodate the sensory neuroepithelium and associated accessory structures. The ampulla of either the horizontal or superior semicircular canal is located at the anterior end of each canal, whereas the ampulla of the posterior semicircular canal is located more laterally. The nonampullated ends of the posterior and superior semicircular canals join to form the common crus that subsequently enters the vestibule posteromedially. The nonampullated end of the lateral semicircular canal enters the vestibule posterolaterally.

The semicircular canals detect angular acceleration and thus are well suited for monitoring rotations of the head. A canal's greatest sensitivity to angular acceleration occurs when the head rotation is made within the plane of that canal. The anatomical organization of the three semicircular canals within the temporal bone is illustrated in Figure 143.2. Horizontal canals are pitched approximately 30 degrees above the horizontal axial plane while the head is upright. The vertical canals (i.e., anterior and posterior) are situated roughly at right angles to the horizontal canals and to each other. Thus, when one looks down at the top of the head, the plane of the anterior canal is oriented at approximately 45 degrees off the midsagittal axis and 45 degrees anterior to the interaural line. The plane of the posterior canal is also 45 degrees off the midsagittal line but aligned roughly 45 degrees behind the interaural line. Thus, the anterior canal on the left is essentially parallel to the posterior canal on the right. The right anterior canal

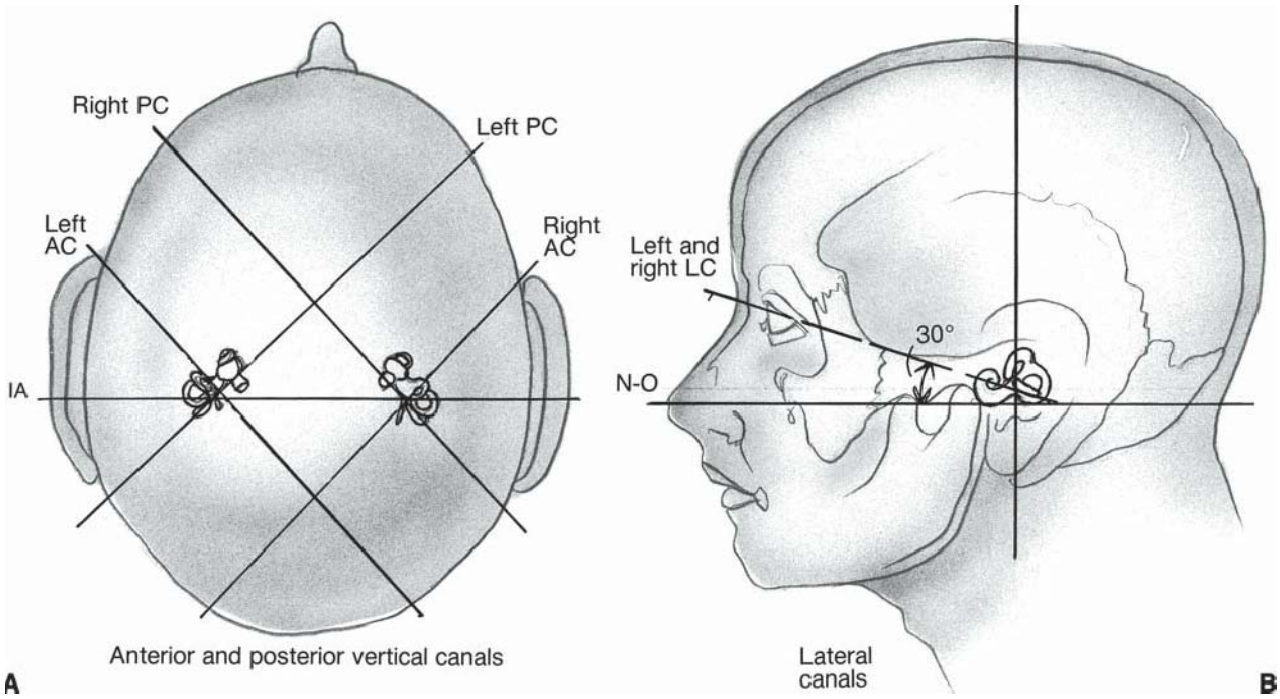

Figure 143.2 **A:** Orientation of the vertical canals in the human head. **B:** Plane of the lateral (horizontal) semicircular canals. AC, anterior or superior vertical semicircular canal; IA, interaural; LC, lateral or horizontal semicircular canal; N-O, nasal–occipital axis; PC, posterior vertical semicircular canal.

and the left posterior canal are similarly aligned. The plane parallel to the left anterior canal and right posterior canal passing through the center of the head is perpendicular to the horizontal canal plane and is referred to as the LARP plane. Conversely, the plane perpendicular to both the horizontal canal plane and the LARP plane, but parallel to the right anterior and left posterior plane is referred to as the RALP plane. Because of this canal pairing system (i.e., HC-HC, LA-RP, and RA-LP), movement that excites one canal will inhibit the other, which forms the basis for a push–pull system. As we discuss later, both the excitation and inhibition converge centrally to improve the sensitivity of the system.

The otolith organs, represented in most mammals and humans by the utricle and saccule, are housed in the major chamber of the vestibular labyrinth called the vestibule. In contrast to the semicircular canals, the otolith organs detect linear acceleration in the plane of each organ. Though neither organ is perfectly planar, the utricular macula is approximately aligned parallel to the earth and is roughly aligned with the ipsilateral horizontal canal (Fig. 143.3). The saccular macula is perpendicular and at right angles to the utricle. Thus, the utricle is sensitive to motion in the horizontal plane, and the saccule is sensitive to movements in the sagittal plane. Collectively, the otolith organs are anatomically organized to detect and monitor linear accelerations along three axes that are perpendicular to each other: interaural, nasal–occipital, and rostral–caudal (Figs. 143.2 and 143.3).

CELLULAR ANATOMY OF THE VESTIBULAR END ORGAN

In order to understand the cellular basis of how various head movements are detected and encoded by the peripheral vestibular system, further examination of the end organ is warranted. An illustration of the sensory neuroepithelium typical of each vestibular end organ is shown in Figure 143.4A. A cross-section through either the crista or macula reveals four distinct cellular constituents: (a) hair cells, (b) supporting cells, (c) afferent nerve fibers and terminals, and (d) efferent nerve fibers and terminals. The roles that each constituent plays in vestibular physiology and function are highlighted below.

Vestibular Hair Cells

As with the auditory system, sensory transduction in the vestibular system is accomplished by a specialized neuroepithelial cell called the hair cell, so named because of the tuft of finger-like projections located along its apical pole (Fig. 143.4A). It is this apical tuft that confers mechanical sensitivity to both auditory and vestibular hair cells. On the basis of their morphology, physiology, and afferent innervation, vestibular hair cells are classified as either type I or type II (2). The type II hair cell is a prototypical, cylindrically shaped hair cell that receives its afferent innervation as a number of bouton terminals along its basolateral edges. In contrast, the type I hair cell is flask-shaped with a rounded base and constricted apical neck, and is innervated by a cup-like, calyx afferent terminal, which almost entirely encapsulates the type I hair cell. Hair cells communicate with their respective afferent neurons by releasing the excitatory neurotransmitter glutamate from specialized presynaptic structures called synaptic ribbons. Type II hair cells are found in the vestibular end organs of all vertebrates while type I hair cells and calyx afferent neurons are restricted to amniotes (i.e., reptiles, birds, and mammals). Likely emphasizing their respective functional roles, type I and type II hair cells and their respective afferent neurons often follow zonal boundaries and thus are not evenly distributed throughout the crista or macula.

Although most of the hair cell and all of its innervation occupy the perilymphatic space, the hair bundle itself is suspended in the endolymphatic compartment. Here, it projects into a gelatinous accessory structure called the cupula in canals or the otolithic membrane in the utricle and saccule. This particular anatomical arrangement is necessary for the proper function of the hair cell and its detection of head movements. The hair bundles of vestibular hair cells are composed of a single eccentrically placed kinocilium and multiple rows of stereocilia (Fig. 143.4). There are typically 20 to 100 stereocilia per hair cell. The kinocilium is the tallest member of the hair bundle and its position at the edge of the apical surface

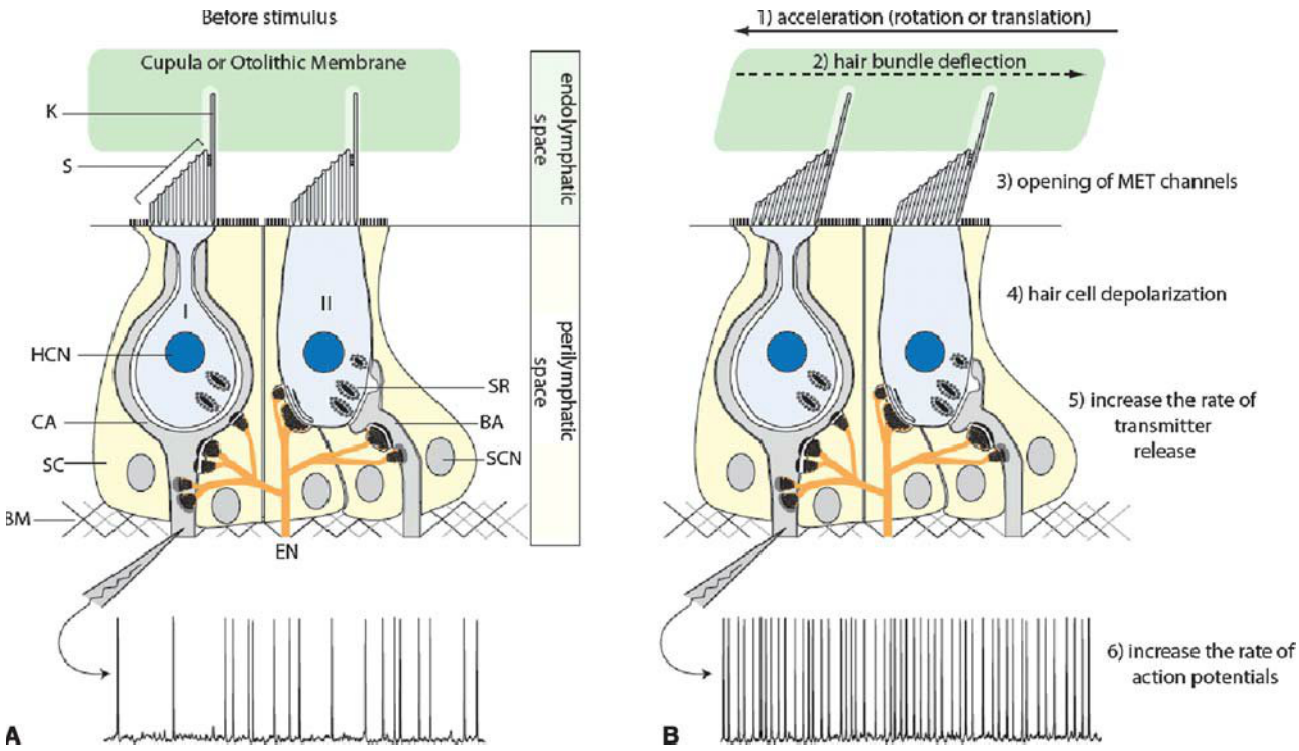

Figure 143.4 Anatomy and physiology of the sensory neuroepithelium. **A:** Cellular constituents of the sensory neuroepithelium. BA, bouton afferent; BM, basement membrane; CA, calyx afferent; EN, efferent neuron; HCN, hair cell nucleus; I, type I hair cell; II, type II hair cell; K, kinocilia; S, stereocilia; SC, supporting cell; SR, synaptic ribbon. Hair cells continuously release neurotransmitter that depolarizes afferent terminals to generate action potentials. Recording from a calyx afferent reveals the baseline discharge (**bottom**). **B:** Coupling acceleration to hair cell stimulation and afferent discharge. Rotation or translation to the left results in an inertial shift of the cupula or otoconial mass to the right. This shift deflects the hair bundle toward the kinocilium, which opens MET channels in the stereocilia to further depolarize the hair cell. Hair cells subsequently release more glutamate on to afferent terminals resulting in an increase in action potential discharge. Note the increase in the rate of action potentials (**bottom**).

indicates the orientation of the hair cell. An orderly array of adjacent stereocilia is organized in a descending staircase formation when moving away from the kinocilium. As can be seen in Figure 143.5, this particular geometrical arrangement confers a so-called morphological polarization vector (PV) or axis, which can be identified by drawing a line from the smallest stereocilia through the kinocilium. It turns out that the functional axis of the hair cell is aligned with the morphological axis. It is along this axis that a hair cell is most sensitive to displacement of the bundle. This is made possible by the expression of mechanoelectrical transduction (MET) channels along the tips of the stereocilia that open during hair bundle deflection (3). The mechanosensitivity of MET channels is provided by filamentous tip links that connect MET channels in a lower stereocilium with the membrane of its taller, adjacent neighboring sterocilium. Relative motion of the stereocilia, upon deflecting the hair bundle toward the kinocilium, exerts tension on the tip links thereby prompting the opening of MET channels. What results is an influx of potassium ions from the endolymphatic compartment into the stereocilia that subsequently depolarizes the hair cell. Conversely, deflection of stereocilia away from the kinocilium decreases tip link tension, closes MET channels, and subsequently hyperpolarizes the hair cell. Displacement of the stereocilia perpendicular to the polarization axis, however, causes little to no response in the hair cell. In any one sensory end organ, neighboring hair cells tend to have PVs that are aligned. This is certainly true of canal hair cells whose hair bundles all face the same direction. Hair bundle orientation in otolithic maculae, however, varies considerably particularly along the striola, a line where hair bundle orientation reverses direction nearly 180 degrees (see Fig. 143.6).

Like most neurons, hair cells are able to maintain a negative resting membrane potential, which is necessary for conveying mechanical events at the bundle to vestibular afferent neurons that synapse along their basolateral edges. In the absence of a vestibular stimulus (i.e., no bundle deflection), enough MET channels are thought to remain open to sufficiently depolarize vestibular hair cells. This baseline depolarization permits the continuous release of glutamate from synaptic ribbons located along the basal pole of the hair cell. Once released, glutamate then activates postsynaptic glutamate receptors to depolarize adjacent afferent nerve terminals. Afferent

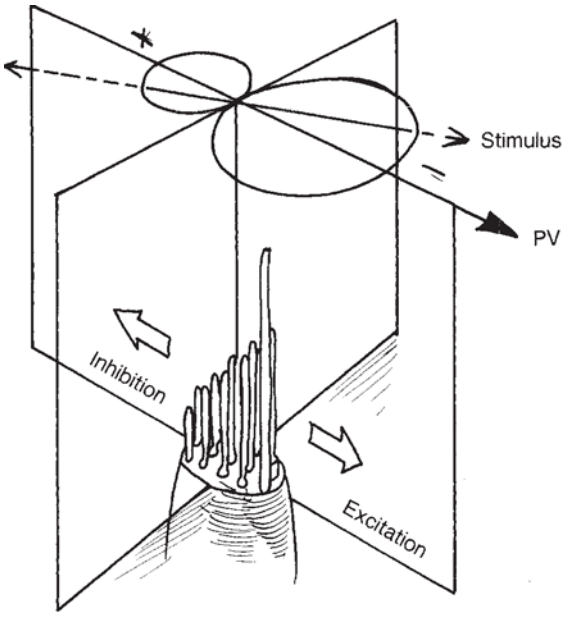

Figure 143.5 Directional sensitivity of the hair cell approximating a cosine function of stimulus direction. The output varies as the cosine of the angle between the direction of maximum sensitivity and the applied displacement varies. PV, polarization vector. (Modified from Loewenstein WR. Handbook of sensory physiology, Vol. 1. In: *Principles of receptor physiology.* New York, NY: Springer-Verlag, 1971:415, with permission.)

depolarization results in the generation of action potentials in the afferent neuron that are then transmitted to the brain (Fig. 143.4A). This type of release process is important because it allows for bidirectional modulation of hair cell transmitter release as well as the downstream rate of afferent action potentials. Deflection of the hair cell bundle toward the kinocilium depolarizes the hair cell, enhances glutamate release, and increases the rate of afferent action potentials, whereas deflection of the hair cell bundle away from the kinocilium hyperpolarizes the hair cell, reduces transmitter release, and decreases the rate of action potentials. In this way, one hair cell can detect both acceleration and deceleration along the axis of their morphological PV.

Direction of *arrows* indicates direction of the hair bundle deflection that excites hair cells in that region of the macula. *Dashed line* represents the striola where hair bundle orientation flips by 180 degrees. (Modified from Barber HO, Stockwell CW. *Manual of electronystmography*, 2nd ed. St. Louis, MO: Mosby, 1980:31; Fig. 2-21.)

Supporting Cells

In addition to hair cells, the neuroepithelium also contains other epithelial cells called supporting cells, aptly named as they provide both structural and homeostatic "support" to the sensory epithelium. The nucleus and much of the supporting cell's cytoplasm can be found between the base of hair cells and the underlying basement membrane (Fig. 143.4A). From there, they extend upward where they envelop both hair cells and afferent neurons. Along their apical margins, supporting cells combine with hair cells to form a tight barrier between the perilymphatic and endolymphatic compartments. Functions of supporting cells include glutamate uptake, potassium transport, and the synthesis and secretion of extracellular macromolecules that makeup the cupula and otolithic membrane. Another group of supporting cells called dark cells can be found at the margins of the transitional epithelium surrounding the neuroepithelium. They are critical in the production and maintenance of the ionic composition of the endolymph (4).

Vestibular Afferent Neurons

Based on of the morphology of their peripheral terminations, vestibular afferent neurons are classified as one of three distinct types: bouton, calyx, or dimorphic. As indicated earlier, calyx afferent neurons with their calyceal endings terminate exclusively on type I hair cells where they can innervate anywhere from one to five hair cells. Bouton afferent neurons end as small button-like terminals along the basolateral membrane of only type II hair cells. Dimorphic afferent neurons are a hybrid bearing both calyx endings on type I hair cells and bouton endings on type II hair cells. In mammals, dimorphic afferent neurons represent the largest proportion of afferent fibers in the vestibular nerve. Conveniently, immunohistochemical studies have also shown that antibodies against the calcium-binding protein calretinin and the intermediate filament protein peripherin can be used to identify these three afferent classes. Calretinin is only seen in calyx afferent neurons, whereas peripherin is seen only in bouton afferent neurons. Both markers, however, are not expressed in dimorphic afferent neurons.

There are other anatomical distinctions among these different afferent types. Calyx afferent neurons have characteristically thick axons, whereas bouton afferent neurons

are much thinner. Dimorphic afferent neurons, however, run the gamut of thick to thin with respect to fiber diameter. Here, it is more convenient to relate the thickness of vestibular afferent neurons with their different zonal innervation patterns. The neuroepithelium of the semicircular canals (i.e., crista) can be divided concentrically into a central, intermediate, and peripheral zone with type I hair cells predominating in the central zone and type II hair cells being more common in the intermediate and peripheral zones (5,6). As such, calyx afferent endings are restricted to the central zone, whereas bouton afferent neurons terminate in the peripheral zone. Dimorphic afferent neurons innervate all three zones where their relative axonal diameter is graded from thick to thin as you move from the central to peripheral zones. A comparable organization is seen in the utricle where calyx afferent neurons terminate in the striolar region, dimorphic afferent terminals are seen throughout the macula, and bouton afferent neurons terminate peripherally. It is thought that similar regionalization occurs in the saccule as well.

One might suspect that given their different anatomical attributes, vestibular afferent neurons would likely exhibit variations in their physiology. In fact, differences in conduction velocity, discharge regularity, and sensitivity to vestibular and galvanic stimulation can also be used to identify a vestibular afferent's morphological class (i.e., calyx, dimorphic, and bouton). Calyx afferent neurons innervating the central crista zone or striolar region of otolithic organs are irregularly discharging, quite sensitive to galvanic stimulation, and yet have a low sensitivity to vestibular stimulation. Dimorphic afferent neurons vary depending on what zone they innervate. For example, dimorphic afferent neurons terminating more centrally (or within the striola) are irregularly discharging and sensitive to both galvanic and vestibular stimulation. In contrast, dimorphic and bouton afferent neurons terminating peripherally (either in the macula or crista) are regularly discharging and much less sensitive to both galvanic and natural stimulation (7). While vestibular stimuli actively engage the hair bundle's transduction apparatus, galvanic (i.e., electrical) stimulation is thought to directly interact with the afferent's spike encoder, the site of action potential generation. In this way, galvanic stimulation presumably bypasses the hair cell and provides an assessment of the afferent's response properties. Therefore, differences in hair cell input (e.g., type I vs. type II) might account for afferent neurons having similar galvanic sensitivities, but different responses to vestibular stimuli. Such is likely the case for comparisons between calyx and central dimorphic afferent neurons.

These different afferent types may be of more interest than just physiological curiosity. The high sensitivity of irregular afferent neurons makes them ideal to detect small perturbations but they are expected to display nonlinear response dynamics given that they readily silence when the head moves in the inhibitory direction. These afferent neurons may be best suited for quick, nonlinear reflexes such as vestibulospinal responses used to prevent a fall. In contrast, the linear characteristics of the thinner, more regular afferent neurons are likely more appropriate for linear vestibular reflexes, like the vestibuloocular reflex, that must work over a wide range of frequencies and peak velocities (8).

Both semicircular canal and otolith afferent neurons are cosine tuned, which means that they have one best characteristic response vector. For utricular afferent neurons, these vectors can lie anywhere in the horizontal plane and are dependent on the orientation vector of the hair cells that they innervate. The responses of afferent neurons are proportional to the cosine of the angle between the direction of stimulation and the orientation vector of the afferent neurons. Similarly, the rotational vector of maximum stimulation for semicircular canal afferent neurons is in the plane of rotation of the canal. The response of the afferent neuron decreases as a function of the cosine of the angle between the plane of rotation and the canal plane. The cosine tuning of the afferent neuron is consistent with the fact that transmitter release by hair cells is proportional to the cosine of the angle between the displacement of the hair cell bundle and the direction of stimulation (Fig. 143.5). The coding of the vestibular system is such that the direction of stimulation is determined by which afferent neurons are stimulated and the intensity of the movement is related to the intensity of the response of the stimulated afferent neuron.

Vestibular Efferent Neurons

The vestibular neuroepithelium is also innervated by vestibular efferent neurons. These predominantly cholinergic neurons originate bilaterally in the brainstem in areas adjacent to the abducens nucleus and genu of the facial nerve. They exit the brainstem and enter the vestibular periphery by way of cranial nerve VIII. Upon reaching the vestibular end organs, efferent neurons can terminate along the base of type II hair cells, on bouton afferent terminals that synapse on type II hair cells, or on the outer face and parent axon of calyx afferent neurons (Fig. 143.4A). Observations of a direct efferent innervation of type I hair cells are rare as the type I hair cell is mostly shielded by the calyx ending. Electrical stimulation of efferent neurons has been shown to hyperpolarize or depolarize hair cells as well as directly excite vestibular afferent neurons (9). The functions of the vestibular efferent system in mammals are not well understood but likely include modulating the excitability and sensitivity of both vestibular hair cells and afferent neurons to incoming vestibular stimuli.

BASIC PHYSICS OF MECHANOTRANSDUCTION

To reiterate, with respect to head motion, the utricle and saccule detect and transduce linear accelerations (i.e., translation or gravity), whereas the semicircular canals

have the task of detecting and transducing angular accelerations (i.e., rotations). Now that we understand the basic principles by which vestibular hair cells operate and communicate with vestibular afferent neurons, how do we physically couple the mechanosensitivity of hair cells to the different kinds of head movements? This feat is accomplished by tethering the hair bundle to some inertial mass that is appropriately displaced during head movements. For semicircular canals, hair bundles insert into the cupula, whereas for the utricle and saccule, hair bundles are attached to the otolithic membrane. Figure 143.4A illustrates how the neuroepithelium behaves in the moments before a vestibular stimulus arrives (i.e., no acceleration). Under these circumstances, continuous release of glutamate from the hair cell helps to maintain the baseline firing of afferent action potentials. Figure 143.4B shows the sequential responses of the neuroepithelium when it is suddenly accelerated to the left. Given their inertial properties, the cupula or otolithic membrane shifts in the opposite direction to head rotation, in this case to the right. This shift deflects the hair bundles toward the kinocilium that then opens MET channels to depolarize hair cells to release more glutamate, thereby increasing the discharge rate of the afferent nerve.

To describe displacements of the cupula and otolithic membrane during head movements, it is helpful to use Newton's second law, which relates the acceleration ($\vec{a}$, a vector having both direction and amplitude) of any object of mass (m) to the force ($\vec{F}$, also a vector) needed to accelerate the said object. For the saccule and utricle, calcium carbonate crystals, or otoconia, sitting atop the otolithic membrane, provide the inertial mass. For describing linear acceleration of the otoconial mass, Newton's second law can be written as $\vec{F} = m\vec{a}$. However, the otoconial mass is also affected by gravity ($\vec{g}$, yet another vector). Thus, the total force acting on the otolithic membrane is $\vec{F} = m(\vec{a} + \vec{g})$, which shows that otoconial mass will not differentiate linear acceleration from gravity (i.e., translation vs. tilt). For describing how angular acceleration stimulates the semicircular canal, Newton's second law would be written as $\vec{T} = J \times \vec{a}$, where $\vec{a}$ is angular acceleration and $\vec{T}$ is amount of torque produced by that acceleration. J, the moment of inertia (i.e., mass equivalent), is provided by the endolymph within the membranous labyrinth. Torque is not affected by linear acceleration, which is consistent with role of the semicircular canals in detecting only head rotations.

MECHANOTRANSDUCTION IN THE SEMICIRCULAR CANALS

Recall that the semicircular canals are toroidal or doughnut-shaped (Figs. 143.1 and 143.7). As the membranous labyrinth threads its way through the temporal bone, it is anchored to the bony labyrinth in several spots. Each ampulla, in addition to containing the sensory

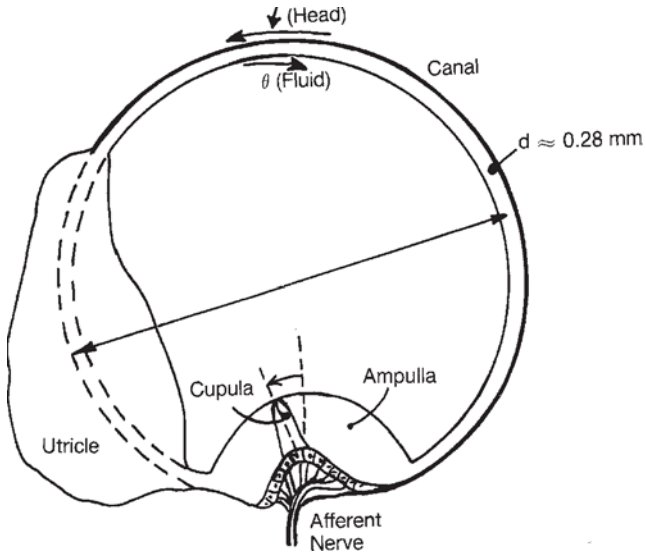

Figure 143.7 Semicircular canal. (Modified from Milsum J. *Biological control systems analysis.* New York, NY: McGraw-Hill, 1966, with permission.)

neuroepithelium, houses the cupula that practically spans the entire lumenal space beyond the apical edges of the crista to form a septum or diaphragm. Hair cells are coupled to this diaphragm by projecting their hair bundles into the cupula. As a result of this design, any rotation in the plane of the canal moves the bony and membranous labyrinth along with the head, whereby the inertia of the endolymph in the membranous canal causes deflection of the cupula in the opposite direction. As the cupula is deflected, the stereocilia bend either toward or away from the kinocilium, ultimately leading to an increase or decrease, respectively, in the firing rate of canal afferent neurons. The system is maximally sensitive to rotations made within the plane of the canal. This is because the kinocilia and resulting morphological orientation axes of hair cells are parallel to the long axis of the canal. In case of the lateral semicircular canal, hair cells are excited when endolymphatic flow deflects the cupula toward the vestibule. Hair cell excitation in the posterior and superior semicircular canals requires endolymphatic flow to deflect the cupula away from the vestibule.

Over 50 years ago, Steinhausen developed a theoretical model of the semicircular canal called the *torsion pendulum model*. By estimating the mass and viscous damping properties of the endolymph, the resetting force of the cupula, and by measuring the geometric properties of the semicircular canal, one can relate cupular deflection to rotation of the head. The model predicts that deflection of the cupula is proportional to head velocity so long as the frequency of head velocity falls between 0.1 and 10 Hz. Beyond the boundaries of this frequency range, however, the sensitivity of the semicircular canal to velocity decreases as cupular deflection under these conditions is not as great. At 0 Hz, which corresponds to constant-velocity rotation, the

torsion-pendulum model predicts there will be no response. The model's prediction agrees with the perception of a person who is turned at a constant velocity around a vertical axis. Subjects can detect the initial acceleration, but in the absence of other sensory cues such as vision, they can no longer sense further rotation after 30 to 60 seconds. At this time, if subjects are suddenly brought to a full stop, they will have the distinct sensation of turning in the opposite direction. This is because of the inertia of the endolymph, which continues to rotate and now deflects the cupula in a direction opposite to that seen with the initial rotation. Reflexive eye movements measured during these steps of velocity mirror the sensation felt by the subjects and are the basis for several clinical vestibular assessments including the Bárány test and tests of the vestibuloocular reflex.

MECHANOTRANSDUCTION IN THE OTOLITH ORGANS

As with the semicircular canals, the apical bundles of hair cells in the macula of otolith organs (i.e., utricle and saccule) are also tethered overhead to a gelatinous superstructure. Instead of cupular deflections driven by the inertial mass of the endolymph during angular accelerations, the inertial mass in otolithic organs is provided by a mound of calcium carbonate crystals known as otoconia that sits atop the otolithic membrane. Located immediately underneath are the sensory hair cells whose apical bundles are in direct contact with the otolithic membrane. Such mechanical linkage allows hair cells in the otolithic organs to detect linear motion of the head and body. Here, displacement of the otolithic mass occurs due to translational motion or changes in orientation with respect to gravity, both of which involve linear acceleration.

Unlike the semicircular canals, where the PVs of each of the hair cells in the crista are directionally aligned, the PVs of hair cells in otolithic maculae are oriented in different directions, making each hair cell maximally sensitive to acceleration in that particular direction (Fig. 143.6). A simplified otolithic organ is illustrated in Figure 143.8. Small arrows above each hair cell indicate the functional axis of that particular hair cell where the direction of maximal excitation would occur. The long arrow at the top indicates the acceleration of the otolith mass. Hair cells whose functional axes are aligned with the acceleration of the mass are excited maximally, whereas hair cells that have perpendicular PVs are not stimulated. It is from this arrangement of hair cells that the brain can estimate the magnitude and direction of linear acceleration. If all PVs were identically aligned as in the canal, it would be impossible to determine the magnitude and direction of an acceleration vector in the plane of any otolithic macula. At least two different orientations are needed to resolve the vector in two dimensions just as at least three separate orientations are needed to resolve the magnitude and direction of an acceleration vector in three dimensions.

Each otolithic organ has sensory hair cells arranged in a wide variety of orientations with respect to their PVs (Fig. 143.6). This is particularly evident within the striolar region where the orientation of hair cells on either side of the striola is roughly 180 degrees out of phase. In otolithic maculae, the striola is an approximately 100 µm zone that runs the length of the macula. The striola divides the utricular or saccular macula into medial or dorsal and lateral or ventral extrastriolar zones, respectively. PVs are oriented toward the striola in the utricular macula and away from the striola in the saccular macula. This planar geometry essentially allows detection of linear accelerations in all directions of the plane. Because of this architecture, the asymmetries inherent in the sensitivity of a single hair cell can be canceled out within one otolithic organ itself. The right and left otolithic organs, like semicircular canals, have mirror symmetry around the sagittal plane. The exact neural connections of the otolith organs have not been as extensively studied as those of the pairs of semicircular canals. Thus, the exact circuitry for resolving

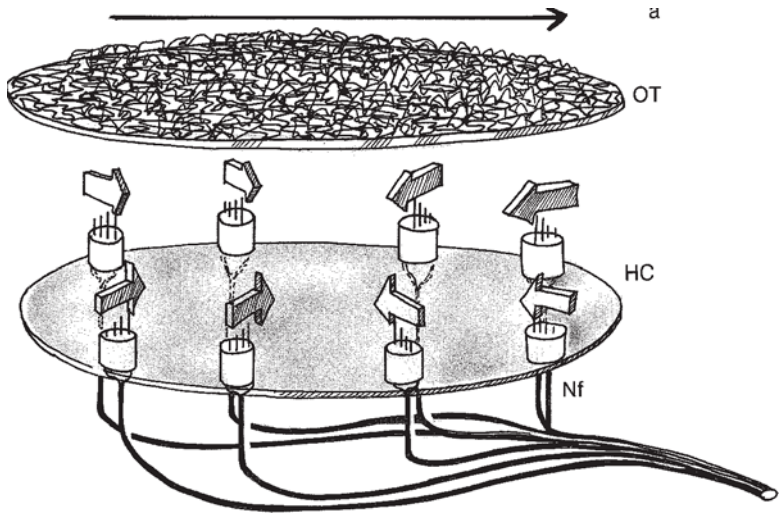

Figure 143.8 Simplified otolith organ. The otoconial mass (OT) is suspended above the sensory hair cells (HC) in an exploded view. Each hair cell is innervated by one afferent nerve fiber (Nf). These nerve fibers join together to form a branch of the vestibular nerve. Each hair cell has a *small arrow* above it that corresponds to the direction of its functional PV. This *arrow* is always pointing in the direction of the kinocilium. The *long arrow* above the otolithic mass is a linear acceleration vector. The response of hair cell depends on the cosine of the direction between its PV and linear acceleration (*a*).

linear acceleration in three-dimensional space has not been determined.

Figure 143.9 illustrates the basic principle by which two otolith organs operating in the same plane can be used to detect head tilt or translation of the head in the plane of the otolithic macula. With no acceleration in the plane of the macula, the rate of action potentials from afferent neurons innervating each otolith organ should be constant and equal. But once the head is tilted to the left, afferent discharge from the left otolithic organ will increase, while that of the right otolithic organ will decrease. This is due to the effect of gravity on the otoconial mass. Comparable responses will also be seen with translation of the head to the right where the otoconial mass will accelerate to the left. This acceleration again produces an increase of the firing rate of the left nerve and decrease in the firing rate of the right nerve. In both cases, maximum sensitivity is obtained by means of subtracting the firing rate of the right nerve from that of the left. This illustration (Fig. 143.9) shows that the asymmetry present in one hair cell innervating an otolith organ can be canceled by combining it with a signal from a hair cell that has the same polarization factor in the other side. It also shows that afferent activity from otolith organs alone cannot be used to distinguish between translation and tilt.

Einstein recognized that an ambiguity exists between linear acceleration and gravity. In aviation, this can be a real problem during the acceleration of takeoff, when pilots have trouble differentiating the acceleration of the airplane from the gravity vector. Because translational motion in one direction creates the same inertial force as gravity to tilt in the opposite direction (Fig. 143.9), this problem is known as tilt-translational ambiguity. Recent research has demonstrated that the CNS uses semicircular canal information (activated during tilt but not during translation) in combination with the otolith input to distinguish, for example, tilting the head upward versus accelerating forward as in a car, sled, or airplane (10). However, this mechanism works poorly at low frequency rotations, because the semicircular canals work poorly at low frequencies. In the circumstance where the rotational component of the motion is at low frequencies (less than 0.1 Hz), the brain uses visual or tactile information to help interpret the otolith signal. In the absence of nonotolith input, such as vision or rotation at frequencies above 0.1 Hz, the system defaults to interpreting linear acceleration as tilt (or gravity). Returning to the aviation example, fighter pilots taking off from an aircraft carrier deck at night will feel as if they are tilted backward during forward acceleration. Because of the ambiguity, the natural correction for this feeling is to steer the plane downward, which could result in disaster.

VESTIBULAR BRAINSTEM

Vestibular afferent neurons are bipolar neurons whose cell bodies reside in the inferior and superior vestibular (Scarpa) ganglion (Fig. 143.1). Following their terminations on hair cells, the peripheral (dendritic) processes of these neurons exit the sensory neuroepithelium and collect in the inferior and superior vestibular nerves. The inferior division includes neurons from the posterior canal and the posterior saccule, whereas the anterior division includes utricular, horizontal canal, and anterior canal afferent neurons as well as afferent neurons from the anterior portions of the saccular macula. Central axonal branches of primary afferent neurons ramify in the vestibular nuclei. Afferent terminals from the different end organs primarily innervate the various divisions of the vestibular nuclei, although vestibular afferent terminations are seen in the cerebellum and other brainstem nuclei as well. The precise terminations by end organ (semicircular canal or otolith) in the CNS are similar in many species (11). Not only does the brainstem region receive convergent input from different branches of the vestibular nerve, but individual neurons in the vestibular nuclei can also receive afferent input from one, two, or more end organs (canal ampullae or otolithic maculae). Thus, the vestibular nuclei have the task of integrating information from multiple ipsilateral receptors.

There are four major vestibular nuclei in the brainstem: the lateral (Deiters), superior, medial, and inferior (spinal or descending) nuclei. In addition, there are several minor vestibular nuclei that have been identified in several

different species by various investigators. The vestibular nuclei not only receive vestibular information but other information pertaining to spatial orientation as well. These inputs include optokinetic signals through the accessory optic system, neck proprioceptive signals, and Purkinje cell projections from the cerebellar cortex. After leaving the vestibular nuclei, vestibular signals are passed throughout the CNS along distinct neural pathways. The primary upstream targets of the vestibular nuclei include (a) the ocular motor nuclei via the medial longitudinal fasciculus and the ascending tract of Deiters, (b) the spinal cord via the medial and lateral vestibulospinal tracts, (c) the cerebellum via the cerebellar peduncles, and (d) the contralateral vestibular nuclei by way of the vestibular commissural system. Other neural pathways connect the vestibular nuclei with the thalamus, which are involved in our perception of our orientation in space, and the autonomic system, which has implications in motion sickness and blood pressure control.

One important function of the vestibular commissural system is reciprocal inhibition. For many neurons in the central vestibular nuclei, their discharge is modulated not only by excitatory input from the ipsilateral vestibular nerve, but also by crossed inhibitory input from the contralateral side (inhibition of an inhibitory input is similar to excitation). This commissural inhibition is often modulated in phase with the paired canal from the contralateral labyrinth. Thus, a secondary neuron in the right vestibular nucleus might be driven by ipsilateral horizontal canal afferent neurons that are excitatory and increase firing for ipsilateral rotation and by inhibitory neurons that are modulated in phase with contralateral (left) rotation. This reciprocal mechanism is the basis of the so-called push–pull connection that increases the sensitivity of the system through convergence in signals between the functionally paired semicircular canals (left horizontal–right horizontal, left anterior–right posterior, left posterior–right anterior) in either ear. In this way, the paired canals complement one another and may help cancel out the asymmetries inherent in hair cell transduction mechanisms and afferent firing patterns.

The best studied vestibular reflex is the vestibuloocular reflex. Vestibuloocular reflexes are of two types: compensatory reflexes that stabilize gaze during motion and orienting reflexes that align the eye with the gravitational vector. One of the challenges for the nervous system is to translate signals from the semicircular canal planes into coordinates appropriate for effector action. Those who study the vestibular system use an external frame of reference as shown in Figure 143.3: the interaural or *pitch* axis, the nasal–occipital or *roll* axis, and the rostral–caudal or *yaw* axis. The vestibulo-oculomotor system, however, is thought to use a coordinate system based on the orientation of the three pairs of semicircular canals. Experiments have shown that stimulation of afferent branches of the vestibular nerve that come exclusively from one semicircular canal produces reflexive eye movements that tend to rotate around the axis of greatest sensitivity for that canal. The three agonist–antagonist pairs of eye muscles themselves do not produce eye movements that completely correspond to these axes of orientation of the semicircular canals. Thus, there is a distribution of signals from the semicircular canals to produce compensatory eye movement of the desired magnitude and direction. Because the orientation of the three pairs of semicircular canals roughly aligns with three pairs of extraocular eye muscles, the transformation in the CNS to coordinate eye movements is relatively simple. In contrast, control of head position and trunk position is much more complicated, and overall is not as well understood.

The nervous system can adapt its response by comparing vestibular input to other sensory input. When the head moves, the vestibuloocular reflex stabilizes the image of an object in space on the retina by producing an eye movement compensatory to the head movement. For example, the motion of the head 10 degrees to the right produces eye movement 10 degrees to the left. Provisions have been made in the nervous system for this response to adapt when necessary, owing to factors such as disease or aging. One such example is people with myopia who wear eyeglasses. If the magnification of the lens is 1.2 times, rotation of the head 10 degrees to the right produces rotation of the world as viewed by the eye 12 degrees to the left and therefore demands a corresponding reflexive eye movement 12 degrees to the left. The nervous system makes this form of adaptive change to resolve a conflict between afferent inputs, in this case vestibular and visual inputs. In this example, the nervous system can correspondingly increase the amount of eye movement produced for a given head movement so that the error between head motion input and eye motion response is reduced to nearly zero. This gain of plasticity requires participation of the flocculus of the cerebellum.

CURRENT VESTIBULAR INQUIRY

Like most fields in basic sciences, the vestibular system is actively studied in a number of excellent laboratories. Among the many actively investigated areas are the pharmacology of the vestibular periphery, interactions between active head movements and the passive vestibular reflexes, the role of vestibular signals in spatial orientation, the function of the vestibular efferent system, physiologic and cellular mechanisms of adaptation and compensation after vestibular injury, and the adaptation of the vestibular system to microgravity. In addition, efforts are ongoing to develop prosthetic devices to aid patients with vestibular deficits. This research holds the promise of improving our understanding of this vital, well-conserved, and underappreciated "sixth" sensory system.

HIGHLIGHTS

- The vestibular system is an inertial guidance system in vertebrates. It is composed of two or more sensors of linear acceleration and three or more sensors of angular acceleration in each inner ear. The right and left inner ear structures are mirror images of each other.
- Vestibular motion sensors use inertial elements connected to sensory hair cells. Both linear and angular acceleration sensors in the inner ear use a three-step process to convert accelerations of the head into useful information for the nervous system. The elements in these three steps are inertia, sensory hair cells, and nerve fibers connected to the hair cells.
- Vestibular sensory hair cells are arranged in orderly arrays. The orientation of a hair cell is defined by the orientation of its kinocilia. This orientation is known as *morphologic polarization*. A corresponding physiologic attribute is called *functional polarization*, which means the hair cell is the most sensitive to displacement along its anatomically defined PV.
- Vestibular organs are arranged by pairs in functional planes. The right and left lateral semicircular canals lie in the same plane. The other four vertical canals lie in planes nearly perpendicular to the plane of the horizontal canal pair. The anterior vertical canal on one side is in nearly the same plane as the posterior vertical canal on the other, forming a functional pairing of the semicircular canals. The otolithic organs are similarly paired.
- Head movement produces compensatory reflexive eye movement. When the head moves, the vestibuloocular reflex tends to stabilize the image of an object in space on the retina by producing eye movement compensatory to the head movement.

144 Vestibular and Balance Laboratory Studies

Neil T. Shepard *Kristen L. Janky* *Jaynee A. Handelsman*

This chapter is one of the clinical companions to the preceding chapter on the vestibular function and anatomy. A clear understanding of those concepts and principles is vital to the appreciation of the information presented herein. The anatomy and physiology of the vestibular and balance systems form the basis against which interpretations of patients' presenting history, signs, symptoms and laboratory test results are developed. The nomenclature used in this chapter will follow that suggested for the International Classification of Vestibular Disorders (1). Therefore, the following are the definitions of the terms used to describe symptoms for patients reporting with vertigo, dizziness, or unsteadiness:

- Vertigo—sensation of self (internal) or environmental (external) movement when such movement is not occurring, for example, spinning, rocking, swaying, tilting, bobbing, sliding, or bouncing.
- Dizziness—sensation of disturbed or impaired spatial orientation without a sensation of self or environment movement.
- Unsteadiness—sensation of being unstable—independent of position without a directional preference.

In considering the evaluation of the patient with complaints of vertigo, unsteadiness, and dizziness or combinations of these descriptors, one must look beyond just the peripheral and central vestibular system with its oculomotor connections. The various pathways involved in postural control, only part of which have direct or indirect vestibular inputs, should be kept in mind during an evaluation. Additionally, significant variations in symptoms and test findings can be generated by migraine disorders (2) and/or anxiety disorders (3), yet these are diagnosed primarily by case history and require a specific line of questioning, not by the use of laboratory testing *per se*; however, the test helps to set up a profile.

Evaluation of the dizzy patient should be guided by the information required to make initial and subsequent management decisions. In the acute patient, the primary aim is to rule out significant cardiovascular and neurological disorders, quiet symptoms, and determine a working diagnosis. Extensive laboratory testing is generally unnecessary in the acute patient since the presenting symptoms and office examination will primarily guide initial management decisions (see chapter 165 by Joel Goebel on the clinical evaluation of the patient with vertigo in this text). In the chronic patient (defined as having symptoms that are intermittent or persistent for greater than 2 months), addressing the question of why natural central compensation has not taken place in a significant manner to reduce symptoms and establish a refined diagnosis and treatment program would be the goal. While aspects of the laboratory testing, especially caloric testing, can be of use in the acute patient, it is the exception that these would be used acutely. Therefore, for the purposes of this chapter, discussion is limited to the evaluation of the chronic patient.

For the chronic patient, a detailed neurotologic history together with a comprehensive direct vestibular office examination is as important as in the acute patient. In the chronic patient, a detailed pre-evaluation patient questionnaire combined with a focused history obtained at the start of laboratory testing can facilitate selection of appropriate laboratory tests and guide the examiner regarding what tests beyond a basic core series of evaluations are needed for any given patient. This use of a staged testing protocol effectively allows laboratory information to be collected prior to the clinician's direct office interview and examination so that all of the information can then be collectively analyzed in the context of the history and presenting symptoms (4).

Defining the role of the laboratory testing becomes an important aspect of the understanding of the benefit of the studies that are currently available.

- Determination of extent and site of lesion within the peripheral and central vestibular system
- Determination of the functional limitations in static and dynamic postural control (these may be related directly to gait abnormalities) and functional performance of the vestibuloocular reflex (VOR)
- Assessment of the status of the compensation process
- Along with symptom presentation, to aid in the prognosis and design of vestibular and balance rehabilitation

The collective use of the information is most often in the confirmation of the suspected site of lesion and diagnosis, both derived from the patient's history and direct office vestibular evaluation with audiometric evaluation. This does not imply a prioritized order to the testing versus the office visit, as with chronic dizzy patients it can be very useful to triage them to laboratory evaluations prior to the office visit.

A common misconception is that the studies will render a specific diagnosis or at a minimum drive the remainder of the investigation and help determine levels of disability. However, when the various tests listed below are reviewed and correlated with high-level activities of daily living, virtually no significant relationships exist for the chronic dizzy patient (5,6). Conversely, patient complaints cannot be used to predict the outcomes of these tests. In a limited manner, more functionally oriented evaluation tools such as computerized dynamic posturography (7) and dynamic visual acuity (DVA) testing (8) provide for correlation between test results, patient symptoms, and functional limitations (9,10). It is hypothesized that the reason for this dichotomy in test results versus functional disability and symptom complaints is the inability of the tests to adequately characterize the status of the central vestibular compensation process (9,11,12). Thus, vestibular laboratory testing is never a replacement for a detailed neurotologic history and physical examination, but needs to be interpreted in context of the history and physical examination.

LABORATORY STUDIES

The discussion to follow provides a brief description of the various laboratory studies that are available for the investigation of the patient with vertigo, dizziness, or unsteadiness. In each case, the purpose for the study, general information about administration of the test, and its general interpretations are provided. A detailed presentation of each of the studies is beyond the scope of this chapter and text. Interested readers are referred to other sources for further information (13–15). For organizational ease, the tests are divided into those in more routine use and those found only in dedicated tertiary balance centers.

Common Procedures

Electronystagmography/Videonystagmography

Electronystagmography (ENG) and videonystagmography (VNG) utilize complete computer-based systems for performing eye movement testing. During ENG testing, horizontal and vertical eye movements are recorded indirectly using electrodes via the corneoretinal potential (dipole). Electrodes are typically placed at each lateral canthus and above and below at least one eye with a common electrode on the forehead. During VNG testing, on the other hand, eye movements are recorded directly using infrared video cameras and digital video image technology. Specifically, for binocular recording, a reflected image of the eye is captured by cameras mounted above, in front of each eye or adjacent to the lateral canthi (Fig. 144.1) (16). For monocular recordings, a camera may be positioned directly in front of one eye (Fig. 144.1). Monocular recording has the disadvantage of failure to recognize and capture disconjugate eye movements. For both ENG and VNG, recording is typically limited to horizontal and vertical eye movements (three-dimensional systems are available adding the torsional movements but far from common use) and the data are recorded, digitally stored, and analyzed by the software in much the same way.

The ENG/VNG battery typically consists of a series of subtests designed to assess the function of the vestibular end organs, the central vestibuloocular pathways, and oculomotor processes, independent of vestibular input. ENG/VNG testing is useful for all patients of all ages with ongoing balance system disorders.

Oculomotor Evaluations

The availability of computerized ENG/VNG systems resulted in a transformation in the formal assessment of oculomotor function because of the ability to directly compare the timing and accuracy aspects of the eye movements with the target stimuli. The clinical utility of these tests is improved by exploiting their redundancy, such as when the results from multiple subtests point to the same site of lesion. Because oculomotor function changes with age, it is important to compare results with norms in order to minimize the number of false-positive results.

Gaze Stability Testing. The patient is typically asked to fixate on a stationary target that is positioned at eye level at a distance of 1 to 1.5 m, and the eyes are observed for the presence of nystagmus or other abnormal movements. Both horizontal and vertical eye movements are recorded. Eccentric gaze is also evaluated by moving the target from center to horizontally and vertically eccentric positions. Individuals without any peripheral or central involvement may demonstrate transient nystagmus when the eyes are at the extreme eccentric positions (referred to as end-point nystagmus, usually dies away within 5 seconds); persistent nystagmus that occurs when the targets are positioned appropriately is always considered to be abnormal.

Gaze-evoked nystagmus can originate from either the peripheral or the central vestibular system with differences in clinical presentation between the two. Nystagmus that is peripheral in origin will generally be direction fixed and

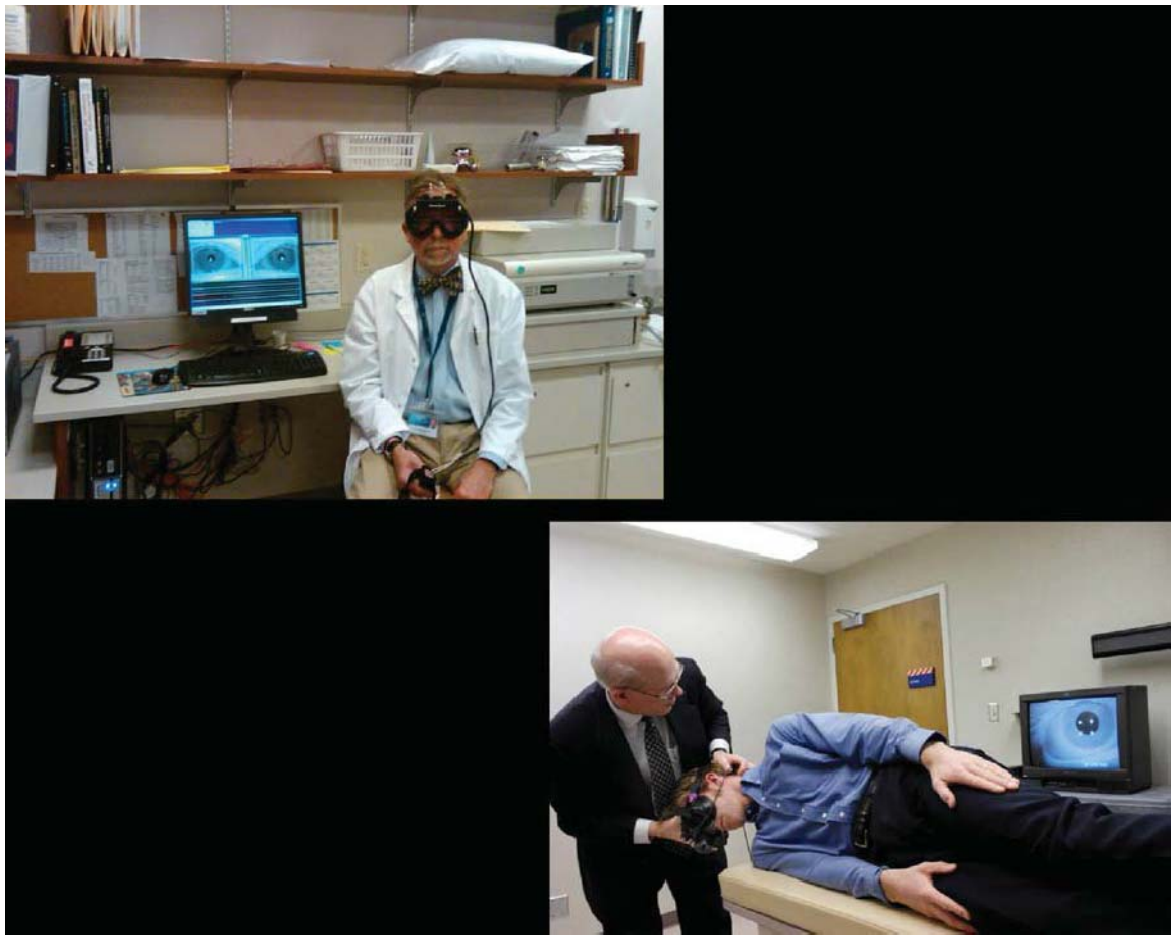

Figure 144.1 Shown are photographs that illustrate two eye movement recording techniques using VOG. The top picture shows a system with cameras mounted above reflecting see-through lenses and the display of the binocular recordings on the computer. The lower figure shows the use of monocular camera system affixed on the goggles directly in front of the right eye and the image seen on the monitor behind the subject.

enhance with fixation removed. Nystagmus is considered to be of central origin if it changes direction with change in gaze direction, if it evidences rebound, where the fast component of the nystagmus changes with the direction of the last eye movement, it enhances or does not change in intensity with fixation. In rare instances, eye movements can be consistent with both peripheral and central origin (e.g., Bruin nystagmus seen in Cerebellar-Pontine Angle mass lesions). A variety of other abnormalities may be evidenced during gaze testing such as congenital nystagmus and a variety of saccadic intrusions (special grouping of involuntary saccadic eye movements when visual fixation target is present), suggesting central vestibular system involvement (17).

Saccade Evaluation. As is the case in gaze testing, the patient is asked in saccade testing to follow a computer-controlled visual target. Random saccade testing is the paradigm that is most often included in the ENG/VNG battery. The patient's eye movements are compared by the computer to the target stimuli and the analysis typically yields measurements of saccade accuracy, latency, and velocity. Saccade accuracy generally refers to the amplitude of the eye movement relative to the target, latency refers to the delay between the onset of target movement and the initiation of eye movement, and velocity refers to the maximum sampled velocity of the saccade once it has been initiated.

The interpretation of saccade data must take into account patient variables such as age (although age-related normative data is not required), cognitive status, attention to task, visual acuity, sedation, sleep deprivation, comprehension level, and medications. Symmetrically inaccurate or slow saccades are often attributable to one or more of those variables. On the other hand, characteristic saccade abnormalities can suggest relatively specific sites of lesion and can provide for differentiating between brainstem and posterior cerebellar vermis involvement. For example, internuclear ophthalmoplegia (INO) results from a lesion in the medial longitudinal fasciculus (MLF) that causes a reduction of the neural signal to the ipsilateral medial rectus muscle (adduction) and preserved lateral-rectus-mediated movements (abduction). The resulting

saccades in INO demonstrate slow velocity of adducting eye movements and overshoot for abducting eye movements. Details of the suggested lesion sites based on various combinations of abnormalities of latency, velocity, and accuracy are beyond the scope of this chapter but are available elsewhere (17).

Smooth Pursuit Tracking. Testing of smooth pursuit ability is conducted by having a patient follow a computer-controlled visual target, typically moving in a sinusoidal pattern that varies in frequency over time. Patient eye movements are evaluated qualitatively by looking for smooth eye movements. As is true with saccade testing, patient variables can negatively impact performance and interfere with interpretation. Use of age-appropriate norms is essential, as pursuit performance tends to degrade with age. The main outcome parameter is gain, which is calculated by dividing eye velocity by target velocity. Of all the oculomotor subtests, pursuit tracking has been demonstrated to be the most sensitive to central vestibular system abnormalities; however, it does not provide the same site-of-lesion localization as the remaining oculomotor subtests (17). Abnormalities with pursuit are typically taken as an indication of possible vestibulocerebellar region involvement but lesions in a variety of other areas can produce abnormalities of pursuit especially when pursuit is disrupted for both eyes moving to the right or left. Asymmetrically impaired pursuit is a more specific finding and suggests a unilateral cerebellar hemispheric or asymmetrical posterior fossa lesion (13).

Optokinetic Nystagmus. In order to truly assess the optokinetic system, use of a full-field visual stimulus and a phenomenon called "optokinetic afternystagmus" is required (13). The production of true optokinetic nystagmus involves a combination of the neurological substrate involved with smooth pursuit tracking together with areas that respond to moving visual stimuli in a full-field format but do not respond to head movement, the so-called optokinetic areas. Further, when viewing a full-field (90% or more of the visual field filled with the repeated moving targets) stimulus, the initiation of the nystagmus is dominantly a result of smooth pursuit tracking with the OKN component added as the stimulus is continued requiring seconds to fully develop. The response then continues as a combination of both smooth pursuit tracking and optokinetics. Therefore, to evaluate OKN function in isolation from smooth pursuit, one must take advantage of a perseveration of nystagmus caused by stimulation of the optokinetic system when the person is suddenly put into the dark after a minimum of 30 seconds worth of stimulation (called optokinetic after nystagmus [OKAN]). As soon as the target has been extinguished for 1 second, the smooth pursuit system no longer has any influence and the OKAN is a direct result of the activity of the optokinetic system reflected through the area of the brainstem referred to as the velocity storage system. In order to produce the OKN stimulation through retinal input and signals transmitted via the accessory optic track, the stimulus needs to fill a minimum of 90% of the visual field and be capable of producing a circularvection effect (the illusion of circular motion when not moving).

Therefore, optokinetic nystagmus testing as a part of an ENG/VNG battery using a laser target or a traditional light bar is not a true optokinetic test but is a test dominated by smooth pursuit. Abnormal optokinetic nystagmus has a localizing value that is similar to smooth pursuit, although the sensitivity is poorer. For that reason, the cost–benefit ratio of inclusion of this test in the battery is poor.

Spontaneous Nystagmus

This test is performed with the patient sitting upright with the head straight. Eye movements are recorded while the patient is gazing straight ahead (not imagining a target) with visual fixation removed. Jerk nystagmus is the principal abnormality and is typically classified by the direction of the fast component of the nystagmus but measured by the velocity of the slow component. Clinically significant, direction-fixed nystagmus is interpreted to indicate pathology within the peripheral vestibular system if the oculomotor evaluation is normal and the nystagmus is significantly suppressed with visual fixation.

Hyperventilation Testing

The purpose of the hyperventilation test is to help diagnose, or unmask, disorders of the peripheral vestibular system and/or VIII cranial nerve (18–22). Secondly, the test can suggest possible anxiety disorder via premature symptoms without nystagmus (23). The hyperventilation test is completed by first removing fixation, either by Frenzel lenses or infrared goggles, and then having the patient take one breath per second for 30 to 90 seconds. Nystagmus induced by hyperventilation is considered significant if it persists greater than 5 seconds and if the peak slow-phase velocity is greater than 3 to 4 degrees per second, subtracting out any preexisting spontaneous nystagmus. If no nystagmus is provoked but the patient becomes symptomatic within the first 20 to 30 seconds, then anxiety issues are suspected.

Hyperventilation-induced nystagmus can beat ipsilesionally (with the fast-phase beating toward the side involved) or contralesionally (with the fast-phase beating away from the side involved). As a general rule of thumb, hyperventilation-induced nystagmus more often beats contralesionally in peripheral vestibular system lesions and ipsilesionally in VIII nerve or retrocochlear lesions: however, this relationship is not mutually exclusive.

Headshake

The headshake test also helps uncover asymmetries in peripheral and central vestibular system function and serves as an indication of dynamic central compensation. The headshake test is completed by removing fixation. The patient's head is shaken back and forth in the

horizontal plane at approximately 2 to 4 Hz for 10 to 15 seconds. Post headshake nystagmus is considered clinically significant if at least three to five consecutive beats of nystagmus are present directly following the headshake and if the nystagmus peak slow-phase velocity is greater than 3 to 4 degrees per second after subtracting out any preexisting spontaneous nystagmus (20,24–26). Both vertical and horizontal headshaking can also be completed. The headshake test has relatively low sensitivity (30% to 35%) but high specificity (90% to 95%) in peripheral vestibular disorders, with the incidence of postheadshake nystagmus increasing as the severity of caloric paresis increases. Postheadshake nystagmus has also been documented in as many as 50% of normal controls (27) and in horizontal canal benign paroxysmal position vertigo (BPPV) (28). Vertical nystagmus in response to either a horizontal or vertical headshake is frequently seen in central vestibuloocular disorders (29,30).

Testing for Benign Paroxysmal Position Vertigo

Doing the Hallpike and roll tests are a common part of the VNG; however, the most common form of BPPV, posterior canal, cannot be recognized with the printouts of a typical 2-dimensional recording system since the principle movement is torsional. Therefore, in reality, these tests are clinical office tests where the examiner must watch and report the eye movements with typical recordings unnecessary. However, if a video recording is available that can be of use in reviewing the total eye movements during the performance of the Hallpike or roll tests.

Static Positional Testing

The purpose of static positional testing is to examine the effect of gravity on positional changes of the head—otolithic influence. Positional nystagmus is present if the nystagmus is provoked by taking a provocative position that produces the jerk nystagmus that represents a change from spontaneous or not present spontaneously. This is the most commonly occurring finding in ENG/VNG testing. Eye movements are recorded while the patient assumes a number of positions that involve head turning and changing the position of the head relative to gravity. Static positional testing is generally completed in the sitting, supine, body right, body left, and precaloric positions and additionally, with the head turned right and left in the sitting, supine, and head hanging positions to examine the influence of cervical region on symptoms and eye movements. Positional nystagmus is classified as either direction fixed (e.g., right beating in all positions) or direction changing (e.g., right beating in some positions and left beating in others). Direction-changing nystagmus may be further categorized as geotropic (nystagmus beating toward the earth) or apogeotropic (nystagmus beating away from the earth). Generally, positional nystagmus is nonlocalizing, needing the interpretation to be done in the context of the oculomotor findings. Pure vertical nystagmus and nystagmus that changes direction in a fixed head position are of central origin and are the exceptions to the nonlocalizing aspect.

Caloric Irrigation Testing

Bithermal caloric testing is the only portion of the test battery that allows the examiner to evaluate individual ear function, and for that reason, it is valuable in assessing the relative responsiveness of the vestibular end organs. In caloric testing, a nonphysiologic stimulus (air or water) is utilized to induce stimulation or inhibition in the semicircular canals by creating a temperature gradient from the external auditory canal to the horizontal canal. The response is primarily the result of a pressure differential across the cupula caused by the temperature gradient coupled with placing the horizontal canal in the vertical plane, although other variables are also involved. Specifically, the head is positioned so that the horizontal canal is oriented parallel to the gravitational vector, with the nose of the patient upward and the head tilted 30 degrees upward from the horizontal plane. During a warm irrigation, the less-dense fluid attempts to rise upward. This produces a deviation of the cupula toward the utricle because of the pressure differential across the cupula, causing stimulation of the eighth nerve. The reverse action occurs for the more dense area of cooled fluid, causing inhibition. This results in the well-known mnemonic *COWS*, which refers to the direction of the fast component of the nystagmus: *C*old *O*pposite, *W*arm *S*ame (relative to the side of irrigation).

Typically, either water or air serves as the thermal stimulus. The stimulus temperature and duration are dependent upon stimulus type. Specifically, open-loop water irrigations are typically performed at 30°C and 44°C for cool and warm irrigations, respectively, whereas the appropriate air temperatures are 24°C and 50°C for cool and warm irrigations, respectively. Additionally, because air is a less efficient stimulus, the duration of the irrigation must be increased in order to obtain an optimal response. Recording time may also need to be increased when air calorics are used, particularly in the case of a tympanic membrane perforation. In many clinical settings, the typical stimulus duration for water irrigations is 30 to 40 seconds, while the typical stimulus duration for air is 60 to 90 seconds. Stimulus duration may be adjusted to accommodate patient needs, although in order to be able to make interear comparisons, it is essential that both ears are tested under identical conditions. Regardless of stimulus type, each ear is typically irrigated twice, alternating in such a way that the expected nystagmus direction is different for subsequent irrigations. The interstimulus interval should be sufficient to allow the response from the previous irrigation to have subsided completely.

Although the use of air is popular and has a practical advantage of being less messy, open-loop water provides a more consistent stimulus as it is impacted less by the shape or size of the external auditory meatus. With air, it is essential for the examiner to have a clear view of the tympanic

membrane throughout the irrigation in order to obtain an optimal response. While that is ideal with water irrigations as well, it is not necessary because the flow rate is sufficient to reach the tympanic membrane even in the face of a narrow or bent ear canal and the temperature of water maintains itself, whereas with air, as it contacts the walls the temperature changes at a significantly greater rate. The new American National Standards Institute guidelines for performing an ENG/VNG only provide information on open-loop water caloric irrigation in part because of the technical difficulties of air (31).

The caloric test is an assessment of the horizontal semicircular canal and, subsequently, the superior branch of the VIII cranial nerve. Sensitivity and specificity of the caloric test in response to air has been reported as 82% and 82%, respectively, and in response to water as 84% and 84%, respectively (32). Since there are no other objective tests considered as sensitive as the caloric irrigation test to determine horizontal canal involvement, the use of presenting symptoms becomes the comparator of choice for these studies.

Vestibular-Evoked Myogenic Potential

The purpose of the vestibular-evoked myogenic potential (VEMP) is to provide information regarding VIII nerve and otolith organ function and to potentially separate superior from inferior vestibular nerve and likewise utricular from saccular involvement (33,34). Like the caloric test, one benefit of the VEMP is that it provides ear-specific information. There are two types of VEMP responses: the cervical VEMP (cVEMP) and the ocular VEMP (oVEMP). The cVEMP is measured at the sternocleidomastoid muscle (SCM) and is a reflection of the ipsilateral vestibulocollic reflex, measuring the pathway from the saccule, down the inferior vestibular nerve to the brainstem, and then to motorneurons in the SCM, which result in a relaxation of the contracted SCM muscle (35). The oVEMP, on the other hand, is measured at the inferior oblique muscle (directly under the eye) and is a reflection of the VOR. The pathway for the oVEMP is less well understood than that for the cVEMP; however, recent evidence suggests that this response measures the pathway from the utricle, down the superior vestibular nerve to the brainstem, and then to motor neurons of the contralateral inferior oblique muscle, which result in excitation. The innate differences between the o- and cVEMP responses are that the cVEMP arises from the saccule and is an ipsilateral, inhibiting response while the oVEMP presumably arises from the utricle and is a contralateral, excitatory response. Both the o- and cVEMP are typically obtained in response to air conduction stimuli (clicks and/or tone burst) with the best waveforms occurring in response to 500 Hz tone bursts. VEMPs are reported in terms of threshold or suprathreshold amplitude, with subsequent interaural amplitude comparisons often reported. The outcome parameter reported (threshold vs. amplitude) is generally dependent on the pathology being assessed.

VEMPs have demonstrated their effectiveness for aiding diagnosis in a variety of conditions. Most notably, VEMPs are part of a standard battery when diagnosing superior canal dehiscence syndrome (SCDS) and other third window disorders. SCDS has been characterized by significantly lower o- and cVEMP thresholds and significantly larger o- and cVEMP amplitudes (36). The o- and cVEMP can also provide complementary information in determining site-of-lesion involvement in vestibular neuritis. In the event of superior vestibular neuritis, cVEMPs have been shown to be intact with absent oVEMPs and abnormal caloric responses (33,34). Conversely, inferior vestibular neuritis has been characterized by absent cVEMP and present oVEMP with normal caloric responses (34). Because the VEMP does not induce sensations of vertigo and provides ear-specific information, VEMP testing is an excellent assessment tool for the pediatric population.

Less Commonly Available Assessment Techniques

Secondary to the more limited use of the following tests, the respective discussions are less detailed than those above.

On-Axis Total Body Rotation—Rotational Chair

The purpose of the test is to expand the investigation of the peripheral vestibular system by applying natural head movements and using three outcome parameters to characterize the peripheral vestibular system together with its central projections as to (a) the timing relationship between eye movement and steady state (sinusoidal protocol) or transient (a step test) head movement, (b) the overall responsiveness of the system to the stimulus, and (c) the responsiveness when rotating to the right versus the left. In this manner, the test expands across frequency (beyond that of stimulation by caloric irrigations) the investigation of the function of the peripheral vestibular systems. This is the only test to investigate the extent of and verification of those with bilateral peripheral system hypofunction (37,38). The test is administered by having the patient seated in a chair that is driving in a sinusoidal or fixed velocity trajectory by a motor affixed to the chair. The axis of rotation is vertical and passes through the center of the patient's head (Fig. 144.2).

Off-Axis Total Body Rotation—Unilateral Centrifugation

The class of off-axis rotational tests has been developed for assessing the otolith organs (38). Unilateral centrifugation is one protocol of the off-axis total body rotation test performed with rotary chair equipment. With unilateral centrifugation, the chair is translated laterally, which projects the vertical axis of rotation through the peripheral vestibular organ on the right or the left (Fig. 144.3). The purpose of the test is to allow for evaluation of each utricular organ individually. Investigations to date show reliable detection

Figure 144.2 This is a photograph of a rotational chair system with the drive motor under the chair and the system enclosed in a light-tight enclosure (photo taken through the open door). The system has a means for maintaining the head secured to the chair and straps for maintaining the body still in the chair. A face camera (inferred) for visualizing the patient's face is seen on an extension coming off the right arm rest. Not shown is an inferred scene camera in the ceiling. The chair shown is able to perform lateral shifts on the drive motor to change the way the axis of rotation aligns with the head of the subject as shown in Figure 144.3.

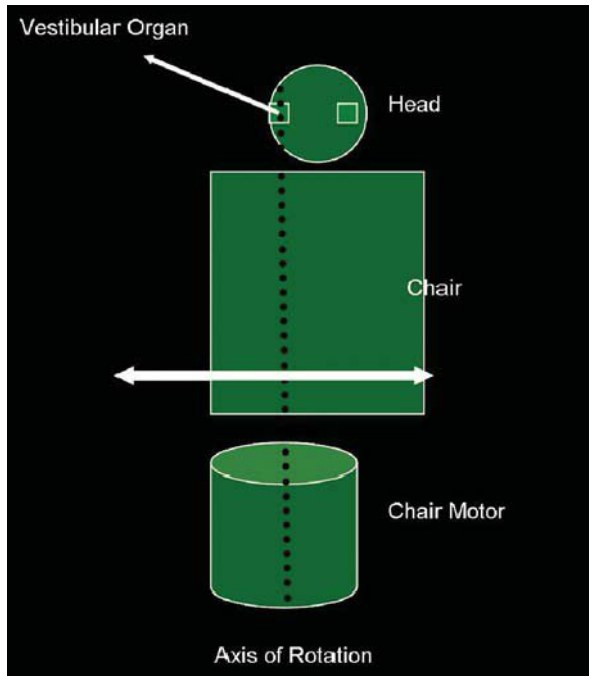

Figure 144.3 The cartoon illustrates the concept of shifting the axis of rotation to go through either the left or right (illustrated here through the right) vestibular end organ. In rotation under this condition, a specific horizontal force would be placed on the left utricular system that would cause a change in perception of vertical (tilting to the left), and when the subject is then asked to set a projected line to their perception of vertical they will set the line off to the right—a test called subjective visual vertical. During the stimulation, the eyes counter roll back to the right, and this is felt to be the basic cause for the shift in the line representing the subject's perception of vertical. The chair can then be shifted to the left and the same force placed on the right utricle and the tilt perception would be to the right and the vertical line is set to the left.

of those with surgically confirmed utricular lesions. The interested reader is referred to a recent study that provides a review of work to date contained in the introduction (39).

Head-Impulse Test

Starting as the head-thrust test for use in bedside evaluations (see chapter 165 on office evaluation by Joel Goebel), this test has expanded to be used with equipment and is referred to as the head-impulse test (HIT) (40). The test provides for a means of individually assessing the function of the VOR for the horizontal canals on the right and the left. It also provides for the assessment of the anterior and posterior canals individually. The assessment is in a different frequency range than that of the caloric test but there is a reasonable correlation between the caloric results and those of the clinical version (Head-Thrust Test) (41). Recently, with the addition of high-speed video recording devices and computer analysis, the sensitivity of the test for identification and monitoring of the function of the six individual canals has been improved (40). This improvement comes from being able to calculate the actual gain of the eye movement for a specific head movement. This technique avoids problems with central nervous compensatory activity that cause difficulty in the simple identification of a corrective saccade when the eye is taken off the target with a head movement secondary to a deficient VOR (42).

VEMP Threshold Response Curves

The cVEMP as discussed above provides for an assessment of the status of the saccule. The function of the saccule varies over frequency. When plotting VEMP threshold across frequency, the saccule demonstrates specific tuning characteristics. The most sensitive frequency is at 500 Hz (43) (Fig. 144.4). It has been suggested (44) that in an endolymphatic condition like that of Meniere syndrome the most sensitive frequency shifts upward. Therefore, the use of the threshold response curve is being proposed as an independent study that may be able to assist in the diagnosis of Meniere syndrome or the more general condition of endolymphatic hydrops. A pilot study using this method showed sensitivity and specificity for identification of Meniere syndrome to be 48% to 50% and 79% to 88%, respectively, suggesting that while a negative test is not useful, a test showing the upward shift may add to the argument of the disorder being present (45).

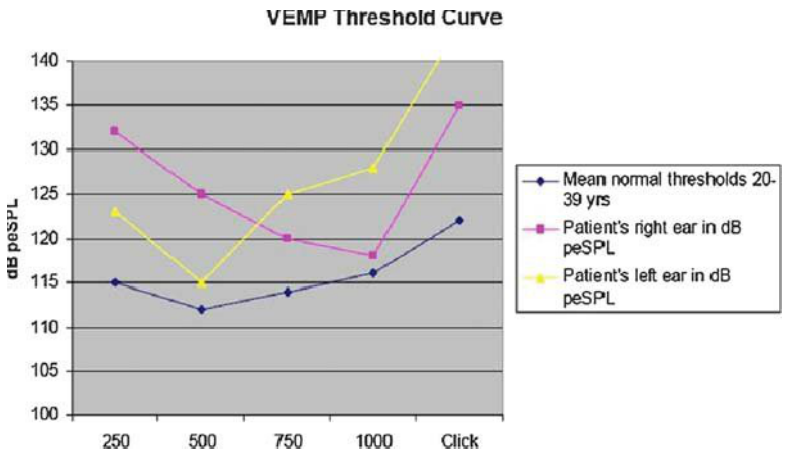

Figure 144.4 The graphic shows an example of the cVEMP threshold response curves for a patient with right Meniere syndrome. The plot gives cVEMP thresholds (in dB peak SPL) as a function of tone burst stimuli at 250 to 1 kHz and then with a click stimulus. The involved right side (plotted by *squares*) shows that the most sensitive frequency has shifted from the typical at 500 Hz (shown for the normative data by the *diamonds*), whereas the uninvolved left side (plotted in *triangles*) has a configuration that parallels the normal subjects.

Dynamic Visual Acuity and Gaze Stabilization Test

All of the investigative tools discussed to this point would be classified as extent and site-of-lesion studies. DVA and gaze stabilization test (GST) however, are considered studies that provide information about the functional use of the VOR. These tests could be normal even in the presence of VOR abnormalities (i.e., caloric hypofunction) indicating the lack of functional impact of the physiologic abnormality. Both studies assess clarity of vision during head motion. For DVA, the head speed is fixed and the size of the target to be recognized is systematically changed, whereas with the GST, the target size is fixed and head speed is varied. These studies are primarily used within treatment programs of vestibular and balance rehab to help monitor progress and determine deficits on which to focus. However, in symptomatic individuals, these studies have been shown to have sensitivity (64% to 71%) and specificity (88% to 93%) performance in identifying the involved peripheral system (46). The other purpose of these studies is to provide an objective quantification of a patient's complaint of oscillopsia. Recent work has been able to demonstrate that the DVA may be used as an effective indicator of falls risk (47).

Postural Control Assessment

For a given piece of laboratory equipment (Fig. 144.5), the purpose of the study will vary from strictly functional based to strictly site-of-lesion based contingent on the protocol used and the versatility of the equipment (48). Across most commercially available equipment, a similar protocol is used for functional evaluation of maintaining of upright stance under changing sensory input conditions—Sensory Organization Test (SOT) (Fig. 144.6). The outcome measure (independent of the details of the individual manufactures analysis) is body sway in anterior–posterior/medial–lateral space. The purpose of the SOT is to determine the individual's ability to utilize visual, proprioceptive/somatosensory, and vestibular cues for maintaining quiet stance. The test is performed by manipulating the visual and foot support surface cues in a systematic manner to reduce, or for vision eliminate, the cue, forcing reliance on other than the normal combination. The outcome of the test is related to the patient's functional ability to maintain stance as the sensory input cues are varied. This information can be used for development and monitoring of treatment programs.

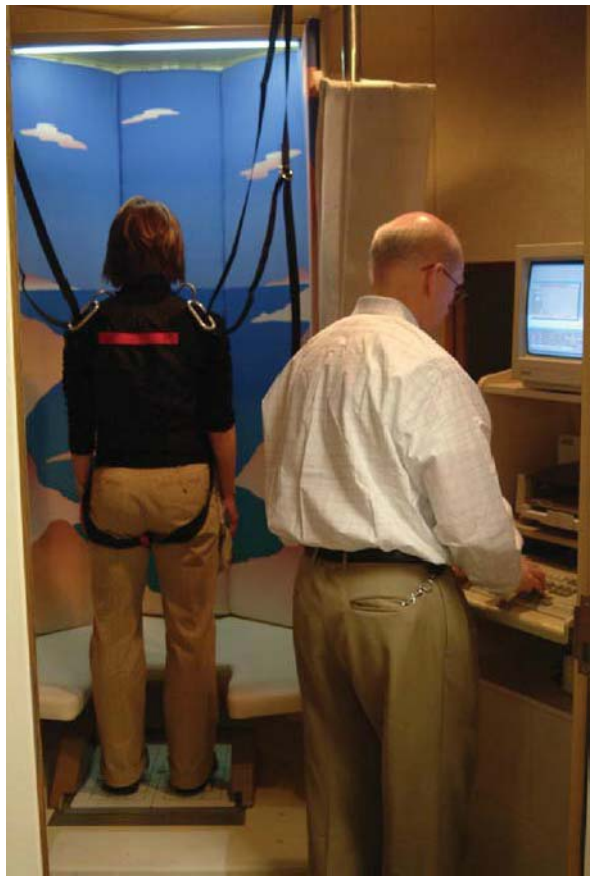

Figure 144.5 The photograph illustrates the positioning of a subject on one form of postural control platform secured from falling with the harness system. The subject is standing on a dual force plate that measures the change in the position of the force put against the right or left platform by the pressure of the foot against the floor (floor reaction force) for either the right or left foot. As the subject leans forward, the pressure under each foot shifts toward the toes. Movement of the platform on which the subject is standing and movement of the visual surround are used to perform the SOT discussed in the text, and the test conditions for the test are shown in Figure 144.6.

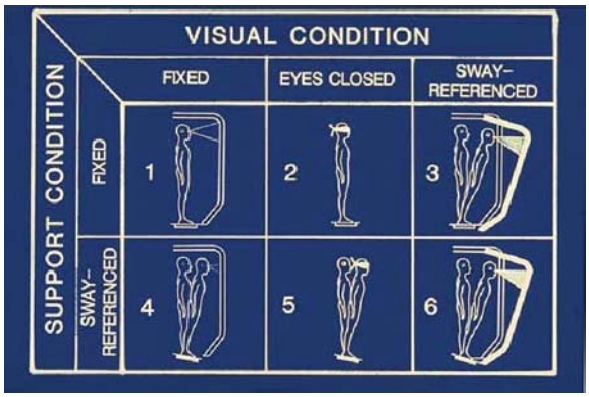

Figure 144.6 The schematic drawing shows the six conditions used in the SOT. The first three conditions provide for a stable, flat surface larger than the foot with plenty of friction to prevent slipping. Condition 1 is with eyes open, condition 2 has eyes closed, and condition 3 has eyes open but the visual surround is moving in response to the swaying of the subject on the platform so that visual information while accurate is of little or no use in knowing how the body is moving over the base of support (the feet). Conditions 4 to 6 use the same visual conditions as shown in 1 to 3 but now has the foot support surface (the force platform) moving in response to the subject's sway in the anterior/posterior plane.

The information is descriptive not diagnostic, therefore the SOT is not a site-of-lesion test (49).

Four other principle protocols are used in postural control assessment, all of which fall into the category of extent and site-of-lesion studies with the exception of #2. (a) Reaction to unexpected perturbation of the body's center of mass through tilt or linear translations, (b) protocol to determine an individual's ability to adapt to changes in surface orientation, (c) recording of distal lower limb muscles in response to sudden toes-up or down rotations around the ankle axis, and (d) quantifying an individual's sway response to changes in external auditory canal air pressure—focus on investigation of perilymphatic fistulas including canal dehiscences. Details of these tests are beyond the scope of this chapter, and the reader is referred to discussion by Shepard and Janky (50) for descriptions and list of references.

SPECIAL POPULATIONS

From the discussion above, it is clear that there are numerous tools available for the evaluation of the patient with complaints of dizziness, vertigo, and unsteadiness. There is overlap to a limited extent in the purpose such that not all studies are needed on every patient. The modest positive correlation between the various tests helps in trying to accommodate other than the otherwise normal patient with these complaints. Specifically, the child under the age 10 is better served by starting with rotational chair as an indication of possible peripheral vestibular system involvement. While most of the children above age 5 will cooperate with use of caloric irrigations, those 5 or under will not. For the child under age 2, it is unlikely the examiner would be able to obtain caloric irrigations; so again, the use of rotational chair can be very useful. If postural control is the primary focus in a young child (5 or under), there are a variety of tools available to review the developmental status of postural control ability compared to normative ranges (51). Additionally, for the EquiTest equipment, the normative range for the SOT goes from 3 to 80 years. There are also age normative data for 3 years and above the surface EMG recordings and for cVEMPs. The main principle in testing a child is to select the tests related to the primary child or parent complaint and figure that the next test you perform (even if it is the first one) will be the last one you will obtain. Also, it is rare that video oculography (VOG) can be used on a child under 5 because of the size of the masks, and it is not likely that the child will tolerate wearing the device; therefore, any of the VNG equipment or rotational chair device used needs to be able to easily shift between electrode and video recordings.

Other groups where VOG techniques would not work would be the adults with significant ptosis, the patients who are unable to maintain eyes open in a darkened environment, or patients with significant claustrophobia. For each, the use of electrode recording is the best technique.

It would be a very rare situation that a patient with dizziness, vertigo, or balance complaints could not be tested in some manner. This may require a change in a specific protocol such as with the patient who is blind. Since they cannot see a visual stimulus, the traditional saccade and pursuit tracking tests cannot be performed. Yet, the patient can use tactile information and imagined visual targets by following the thumb for pursuit and by looking from one thumb to another to see if an approximation of pursuit and saccade performance is present. Other examples are the patients with prior mastoid surgery (especially canal wall down mastoidectomy). In that situation, caloric irrigations can be performed, but it is not necessary to have the same duration or temperatures on the left and right. The responses from right and left cannot be compared in the typical manner, so the use of the irrigation is simply to see if both sides respond. Therefore, this test on the surgical side should be performed to the patient's comfort. Irrigation time should not be longer than the duration required for symptoms to begin, if that occurs prior to the typical 30 to 40 seconds. In a normal peripheral vestibular system, symptoms in a radical mastoidectomy patient may begin in as short as just a few seconds.

A last example of a common difficulty is with the patient with significant visual acuity problems (e.g., macular degeneration or the patient with retinitis pigmentosa) who has difficulty finding a target that has suddenly changed location as in saccade testing. Instead of using a random paradigm, a fixed position with predictable timing would produce a better estimate of saccade ability.

SUMMARY AND ILLUSTRATIVE CASE EXAMPLE

The discussion above gives a brief summary of the tools available for the laboratory evaluation of the patient with vertigo, dizziness, and/or unsteadiness of central or

peripheral vestibular origin. The key to the effective use of these tests is the integrated interpretation of the tests in the context of a detailed neurotologic history. In many cases, this requires a multidisciplinary approach but one in which the various specialists do not consult in isolation, but build their opinions integrated with those of the other subspecialists (audiology, neurology, psychiatry, general ENT or neurotology based on need, physical therapy). A case example is used to illustrate this concept.

A 43-year-old female presented with the primary complaint of constant internal vertigo and unsteadiness when lying, sitting, standing, and in motion. Symptoms were exacerbated with head/visual motion, visual complexity, and repeated noise exposure. The symptoms were reported to spontaneously increase in intensity without exposure to the visual or head movement stimuli. She reported hearing loss on the left with fluctuations. She was having an occasional fall without injury but not drop attacks. The patient was referred for a second opinion regarding her long-standing diagnosis of Meniere syndrome on the left.

The past medical history revealed long-standing history of migraine headaches. In 1999, she began with documented fluctuant and progressive loss of hearing on the left. Within a year, spontaneous events lasting 1 to 2 hours of external vertigo with unsteadiness, nausea, vomiting, and exacerbations in her auditory symptoms began to occur. The frequency was multiple times per month. She was diagnosed with left Meniere syndrome and started on dietary and diuretic treatment without adequate control. In 2004, an endolymphatic sac decompression procedure was performed with good control over the events of vertigo for 3 years. In 2007, the spontaneous events of external vertigo returned starting with an unusual spell where the vertigo was continuous for 4 days and then resolved. She began having recurrent events similar to those between 2000 and 2004. A distinct difference was that instead of returning to a normal baseline between the spells, she began between the spells to develop the internal vertigo and problems with unsteadiness with falls without injury provoked by visual patterns, visual motion, and visual complexity. In 2008, she underwent a left vestibular nerve section with absence of the spontaneous external vertigo and reduction in the visually provoked unsteadiness and internal vertigo but not absence. One year later, the spontaneous events of external vertigo returned. At this time, 50% of these spontaneous events were accompanied with focal headaches with migraine features and the other 50% of the events were associated with photophobia and osmophobia. Her visually provoked symptoms increased and she developed the constant nature of the internal (spinning in her head) vertigo with the always present unsteadiness. Her outside managing team was concerned that the nerve section on the left had been incomplete and offered her a left labyrinthectomy at which time the second opinion was requested.

At the time of her workup, she presented with a recent MRI of the brain without and with contrast and internal auditory canal protocol that was normal. Her audiogram is shown in Figure 144.7. Her direct office examination showed no abnormal nystagmus with or without visual fixation present. She was negative for Hallpike and roll tests. Her head thrust tests showed abnormal VOR function for all three semicircular canals on the left. Saccade

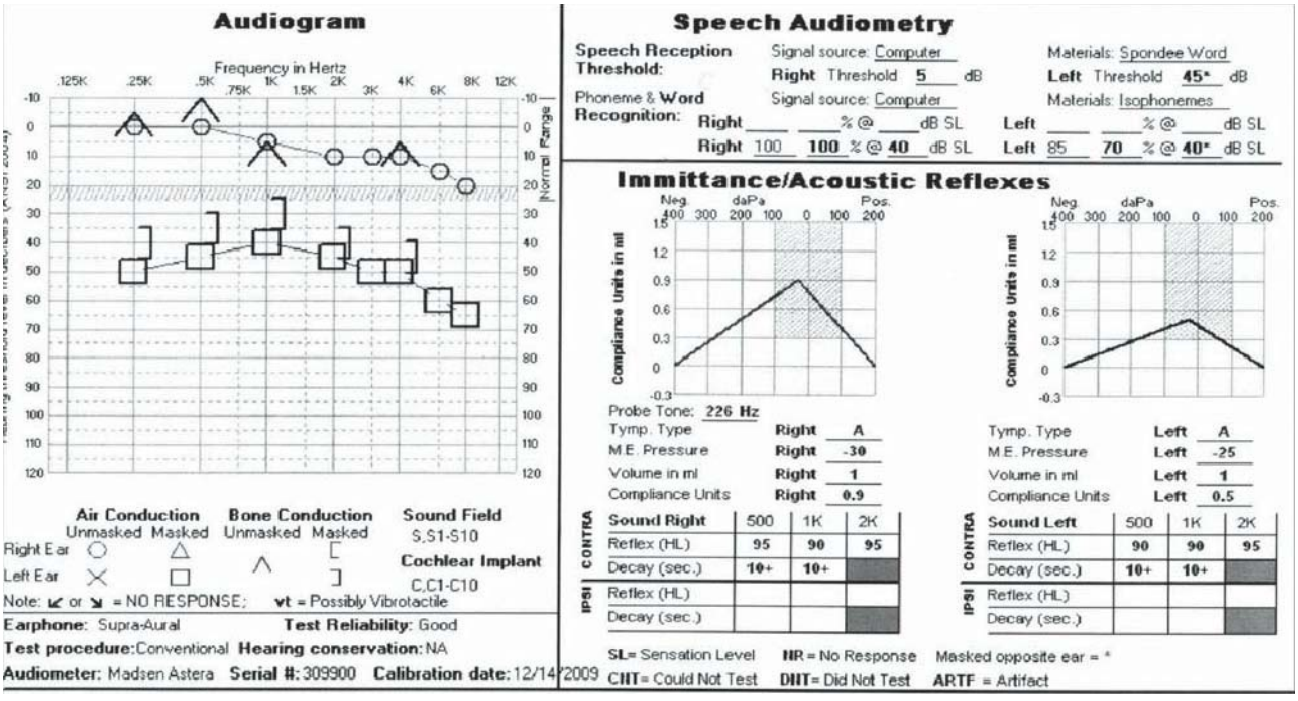

Figure 144.7 Shown is the audiogram for the case of the patient with left side Meniere syndrome, migraine-related dizziness, and chronic subjective dizziness.

function appeared normal and pursuit tracking was mildly disrupted with saccades. The VNG showed no response to warm or ice water (2°C to 3°C temperature) irrigations to the left and normal warm water irrigation to the right. Oculomotor studies were normal for saccade testing but showed that the saccadic disruption to pursuit tracking was beyond that expected or explainable for age. Rotational chair showed abnormalities consistent with peripheral unilateral involvement in a compensated state. cVEMPs were normal on the right and absent on the left. Unilateral centrifugation was normal on the right and utricular function was absent on the left. Postural control assessment showed abnormal sway with fall reactions when she was forced to rely on vestibular system cues alone and abnormal sway under all other conditions without fall reaction using a rhythmic sway—a pattern noted in patients with anxiety disorders. Finally, her Hospital Anxiety and Depression Scale test was highly positive for anxiety and depression. The summary integration of her test findings was that of a severe left peripheral vestibular hypofunction involving all semicircular canals, the saccule, and utricle on the left. The disruption in pursuit tracking was a property of her migraine headaches and not an indicator of other central system involvement given the normal MRI and neurological workup. The left hypofunction was in a partially compensated state. She was then evaluated by a neurotologist, a neurologist with subspecialty interests in dizziness and by a psychiatrist also with subspecialty interest and research activity in dizziness. The collective opinion was that while she had Meniere syndrome on the left in the past, it was now inactive and not related to her ongoing symptoms. Her 24/7 internal vertigo with unsteadiness and development of the visual sensitivities was related to anxiety disorder and the development of Chronic Subjective Dizziness Syndrome (52). Her spontaneous exacerbation in symptoms lasting hours was migraine-related dizziness. She was initiated on sequential trials of fluoxetine with a migraine prophylactic medication and then finally settled with venlafaxine and tricyclic antidepressant. Vestibular rehabilitation therapy, specifically habituation exercises for her sensitivity to head/visual motion and visual complexity with work on general balance, was used in conjunction with the medication, and no further treatment of any type was needed for her Meniere syndrome.

The case illustrates that as the presenting symptoms change over time there is need for reevaluation and likely change in diagnosis. The problem with this case was the insistence that even as the presenting symptoms and character of symptoms changed, everything was felt to be continuing as a result of Meniere syndrome. Second, the test findings were collectively supportive of a virtually compensated hypofunction other than the postural control findings that were dominantly related to her anxiety. The pursuit dysfunction with normal MRI and importantly a symptom presentation for headaches meeting international headache society criteria for migraine is what allowed that single finding to be attributed to migraine headaches and not an unknown central disorder.

The authors note that significant portions of the above text also appear in two other recent publications by the same authors (53,54).

HIGHLIGHTS

- Vestibular and balance laboratory studies can be used for determination of the extent site of lesion and for evaluating the functional aspects of the VOR and postural control.
- The purpose of the oculomotor tests is to determine if possible central vestibular system involvement should be suspected.
- Saccade testing along with gaze-stability evaluation can be used to suggest localization of lesions within the central vestibular system.
- Positional nystagmus is the most common abnormality on an ENG/VNG but in isolation is nonlocalizing.
- Caloric irrigations by air or water evaluate only the horizontal canals and allow for comparison of left versus right side responsiveness to an exogenous stimulus.
- Rotational chair provides a means for expanding the investigation of the peripheral vestibular system.
- c- and oVEMPs and unilateral centrifugation provide tools for the evaluation of the otolith organs.
- A combination of caloric irrigations, HIT, VEMPs, and unilateral centrifugation allow for investigation of all semicircular canals and both otolith organs on left and right.
- Postural control assessment via the SOT protocol is strictly a functional evaluation.
- The key to the effective use of the laboratory studies is the integrated interpretation of the study results in the context of the presenting history.

145 Neurophysiologic Intraoperative Monitoring

Brannon D. Mangus *Betty S. Tsai* *David S. Haynes*

The growth of otology, neurotology, and skull base surgery has allowed the surgical extirpation of intratemporal and retrocochlear pathology while preserving the seventh and eighth cranial nerves. Along with advanced microsurgical techniques, intraoperative neurophysiologic monitoring has played an integral role in the increase in expectations of cranial nerve preservation. The primary goal of intraoperative neurophysiologic monitoring is to aid in the preservation of nerve integrity and function and, in selected applications, allow for the prediction of postoperative functional impairment. Table 145.1 describes the ideal requirements for an intraoperative neurophysiologic monitor. The purpose of this chapter is to acquaint the reader with currently available techniques of neurophysiologic monitoring, primarily as they relate to the surgical management of temporal bone and posterior fossa pathology. This chapter also explores the indications, techniques, and potential controversies of intraoperative neurophysiologic monitoring with particular focus on facial and auditory nerve monitoring.

AUDITORY SYSTEM MONITORING

The primary goal of most otologic and neurotologic procedures is the eradication of disease while minimizing morbidity. When considering vestibular schwannomas and skull base tumors, many surgeons regard the preservation of hearing a secondary, yet significant, goal even in patients with functional hearing in the contralateral ear. Advances in diagnostic capabilities, specifically the routine use of contrast-enhanced MRI, have resulted in the earlier detection of smaller tumors. This detection, coupled with advances in microsurgical techniques and intraoperative neurophysiologic monitoring, has increasingly made preservation of hearing a reasonable goal in select situations. Furthermore, the likelihood of certain disease processes, such as neurofibromatosis type II, to produce bilateral lesions highlights the benefits of attempted hearing preservation.

The characterization of the human auditory evoked potentials in 1971 by Jewett and Williston allowed for the development of the first intraoperative monitoring system of the auditory nerve, first implemented in 1978 (1,2). Since then, intraoperative eighth nerve monitoring has been used during vestibular schwannoma resection, vestibular nerve section, facial nerve exploration, and other skull base procedures in which the auditory system can be placed at risk.

Of the procedures mentioned above, vestibular schwannoma resection carries the highest risk of postoperative hearing impairment (3). Many patients with a vestibular schwannoma already present with sensorineural hearing loss, which is believed to be secondary to cochlear dysfunction induced by internal auditory artery insufficiency or by cochlear nerve dysfunction resulting from pressure, atrophy, or tumor invasion. Although surgical techniques, such as the middle fossa approach and the suboccipital (retrosigmoid) approach, have been designed to minimize the likelihood of total hearing loss associated with the translabyrinthine approach, these measures preserve some degree of hearing in only 29% to 65% of patients depending on tumor size and location (4–8). During surgery, the auditory system may be injured via direct injury to the cochlea or membranous labyrinth, through labyrinthine artery injury with resultant cochlear ischemia, via cochlear nerve stretching, compression, transection, or thermal injury from drilling, cautery, or surgical dissection, or at the brainstem. Because of the variable coverage of the central glial segment of the nerve that often extends to the internal auditory canal (IAC), the auditory nerve may be more fragile than other cranial nerves, rendering it particularly susceptible to stretch or thermal injuries (9). During vestibular schwannoma resection, the goals of intraoperative auditory monitoring are twofold: to warn the surgeon when surgical manipulation may be causing auditory system injury and to predict postoperative hearing function.

TABLE 145.1 CHARACTERISTICS OF THE IDEAL NEUROPHYSIOLOGIC MONITOR

Functions in the operating room in the presence of other electrical devices, such as air drills and anesthesia machines, with minimal dysfunction or artifact.
Functions safely so that even if dysfunction does occur, no harm to the patient can occur.
Incorporates straightforward and reproducible setup and monitoring procedures to avoid delay in preparation for the procedure and to minimize errors in data analysis, operative time, and cost.
Accurately and continuously monitors the cranial nerve (end organ, peripheral system) at risk for intraoperative injury.
Exhibits sufficient sensitivity and specificity to detect intraoperative changes in the system being monitored for surgical alterations, without unnecessary false alarms.
Rapidly alerts the surgeon in sufficient time to alter surgical technique to minimize trauma to the system at risk.
In the case of intraoperative facial nerve monitoring, allows the surgeon to receive feedback through auditory, visual (electromyographic tracing, oscilloscope), or a combination of stimuli, so that the surgeon can monitor the facial nerve without the mandatory assistance of trained personnel, if desired.

AUDITORY SYSTEM MONITORING TECHNIQUES

A number of studies, but not all, have shown that auditory monitoring may improve outcomes in neurotologic surgery. Much controversy remains concerning which monitoring technique is best (10). The evoked potentials that are generated in response to auditory stimuli provide the foundation for neurophysiologic eighth nerve monitoring. There are three primary types of intraoperative auditory monitoring: brainstem auditory evoked potentials (BAEPs), also known as auditory brainstem response (ABR); electrocochleography (ECochG); and auditory nerve compound action potential (ANCAP), also known as direct eighth nerve monitoring (DENM) or cochlear nerve action potential (CNAP) monitoring. Each of the techniques has level-specific responses that provide useful information about auditory system integrity and function, as seen in Figure 145.1.

Although these techniques are described separately for purposes of discussion, when clinically applied to intraoperative monitoring of the auditory system, each may be used alone, or in combination with each other. They are classified as either far-field or near-field techniques based on the distance between the recording electrodes and the generators of the response (i.e., brainstem nuclei for ABR and cochlea for ECochG).

AUDITORY BRAINSTEM RESPONSE

The least invasive method of eighth nerve monitoring, ABR, is a commonly utilized far-field modality. Stimuli, often in the form of "clicks" or tone bursts, are presented to the ear through transducers or inset earphones, and responses from components of the auditory system are recorded from the scalp or external auditory canal with electroencephalogram amplifiers. When compared to near-field monitoring techniques (e.g., ECochG, CNAP), ABR has a low signal-to-noise ratio and, therefore, requires extensive, time-consuming averaging for useful interpretation.

The ABR tracing contains five peaks, moving from distal (cochlea) to proximal (brainstem) along the auditory pathway. The first two peaks (I and II) arise from activity along the distal and proximal ipsilateral cochlear nerve. The remainder of the ABR waves originate from the auditory brainstem. Wave III, which is prominent, corresponds to the cochlear nucleus; peak IV corresponds to the superior olivary nucleus; and peak V, the most prominent component of the ABR, corresponds to the lateral lemniscus and inferior colliculus, which also integrates inputs from the contralateral ear (11). Deviations from the baseline recording such as increasing latency intervals are analyzed relative to surgical manipulations. Changes in the ABR will

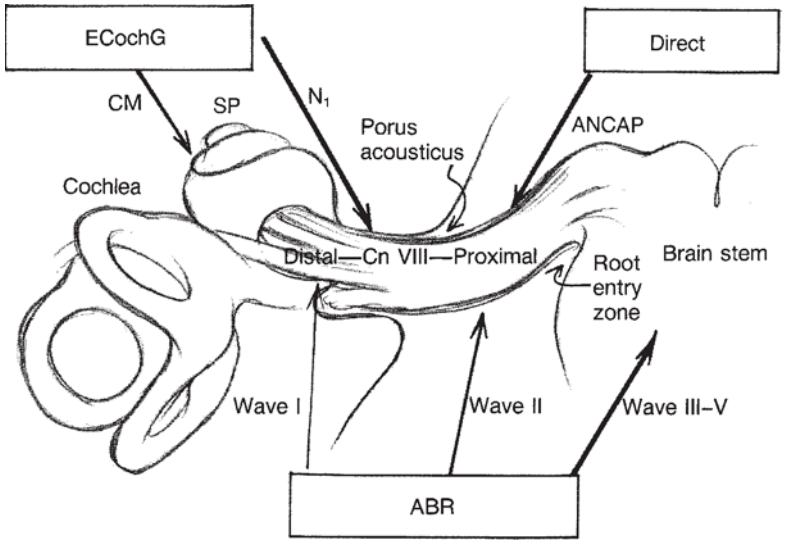

Figure 145.1 Schematic shows level-specific responses obtained with electrocochleographic, ABR, and direct ANCAP recordings.

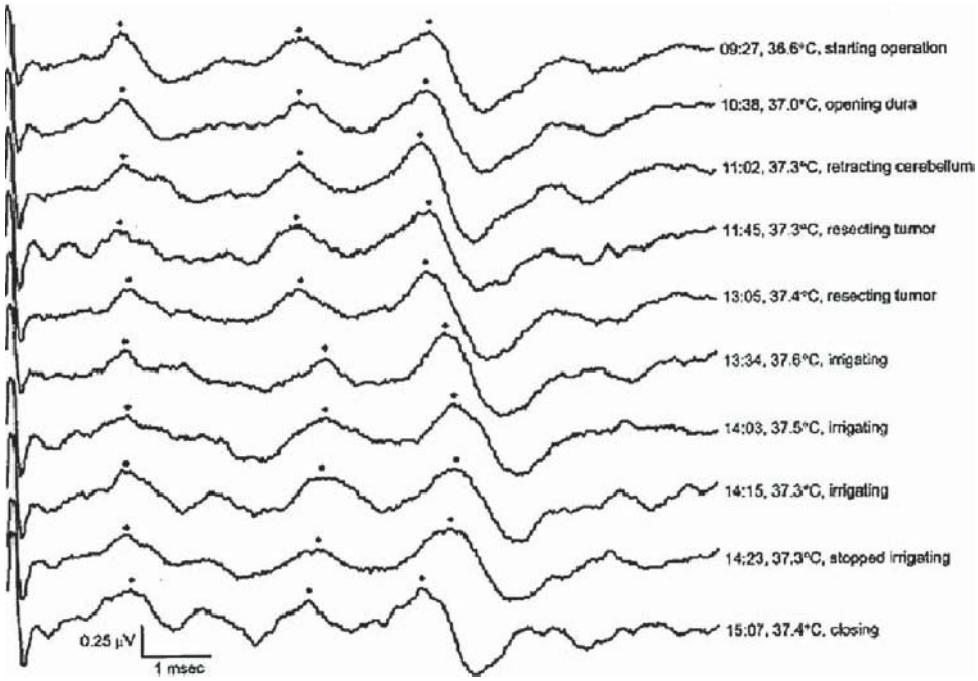

Figure 145.2 Intraoperative ABR to right ear stimulation during surgery for a meningioma in the right cerebellopontine angle. The ABRs were stable during cerebellar retraction and tumor resection. After the tumor had been removed, copious irrigation of the surgical field with cold fluids produced a transient prolongation of the I-to-III interpeak interval, reflecting slowed neural conduction within the eighth nerve resulting from local cooling. The peak latencies of waves I, III, and V are marked by the small diamonds, and the clock times, esophageal temperatures, and surgical procedures corresponding to each of the ABR waveforms are noted at the right. (Taken from Legatt AD. Mechanisms of intraoperative brainstem auditory evoked potential changes. *J Clin Neurophysiol* 2002;19:396–408, with permission from Lippincott Williams & Wilkins.)

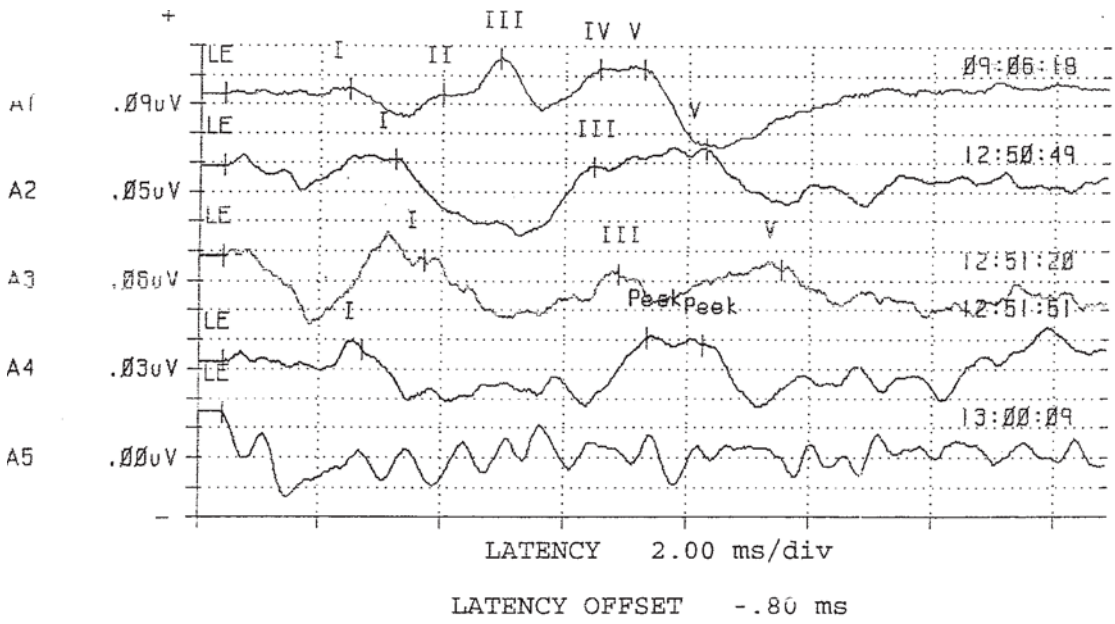
vary depending on the location of injury along the auditory pathway (see Fig. 145.2).

Different types of surgical manipulation can affect the intraoperative ABR in different ways. Drilling of the temporal bone can cause direct inner ear trauma or cochlear ischemia or infarction due to compromise of the internal auditory artery affecting all ABR components, including wave I. Mechanical or thermal injury to the eighth nerve will delay and potentially eliminate waves III and V, but leave wave I unaffected. Retraction of the cerebellum and brainstem stretches the eighth nerve resulting in an often reversible prolongation of the I-to-III peak interval. Similarly, vasospasm within the eighth nerve can cause potentially reversible ABR changes. Damage at or caudal to the superior olivary complex will delay or eliminate wave III, and damage to the brainstem auditory pathways at or below the level of the lateral lemniscus affect wave V in a similar fashion (9,12). Nontraumatic maneuvers such as opening the dura alters the conduction patterns of the ABR appearing as changes on the monitor; in these situations, an intraoperative baseline may need to be reestablished prior to further manipulation of the auditory system (12).

Changes to intraoperative ABR may also be caused by other physiologic mechanisms such as blood in the middle ear, certain volatile anesthetics, hypothermia, irrigation, and acoustic masking from drilling noise. During intraoperative ABR monitoring, examination of the pattern of changes, analysis of their correlation with surgical maneuvers, and investigation for possible technical reasons can help to determine the cause of the ABR changes and provide the appropriate information to the surgical team (9).

Extensive signal averaging required in ABR monitoring result in minutes lapsing between an offensive manipulation and the appearance of changes from the baseline recording. The surgeon must then retrospectively evaluate recent operative actions and provide a corrective action, if possible. This time lag is a significant limitation to this technique. However, fast ABR, which utilizes both an analog and digital filter with enhanced software, permits interpretable ABR readings in five seconds making it more suitable for intraoperative monitoring (13). Despite recent advancements, intraoperative ABR has yet to yield improved functional outcomes (14). Being a far-field technique, intraoperative ABR has increased susceptibility to disruption by various intraoperative procedures and surgical equipment because of its poor signal-to-noise ratio and poor temporal resolution (15).

An additional disadvantage of the ABR technique is that a useful preoperative ABR is required to serve as a baseline. This is often limited in the presence of known preoperative hearing loss. However, some patients with absent preoperative



LATENCIES (ms)

ABR waveforms can be monitored with other techniques (e.g., CNAP) with a significant percentage of these patients ultimately achieving hearing preservation (16).

Despite its limitations, intraoperative ABR during vestibular schwannoma resection may be associated with improved preservation of hearing (17,18). Strauss et al. showed in a prospective, randomized fashion that the implementation of corrective actions based on ABR changes could significantly improve the rate of functional hearing preservation (19). However, Jackson et al. showed that the use of intraoperative ABR did not change their ability to preserve hearing, with an overall rate of about 60% (20).

Several studies have attempted to evaluate the prognostic value of intraoperative ABR although their significance is unclear, but certain intraoperative ABR patterns are associated with postoperative hearing outcomes (20). Persistence of wave V at the conclusion of the procedure has been associated with serviceable hearing. Similarly, complete elimination or irreversible and progressive loss of wave V indicates a high likelihood of postoperative hearing loss (12,15).

However, preservation of wave V does not guarantee maintenance of postoperative hearing, as auditory function may decline postoperatively, despite its presence in the immediate postoperative period, possibly reflecting postoperative cochlear artery spasm (21). Also, the loss of intraoperative ABR recordings does not always imply that hearing is completely lost or unserviceable. Variable reversible loss of ABR tracings has been associated with varied hearing outcomes (15,22). Figure 145.3 shows a series of intraoperative ABR recordings on a 52-year-old male who had undergone resection of an intracanalicular vestibular schwannoma via a middle fossa approach. Tracing A1 shows a baseline intraoperative recording. During dissection of the tumor at the fundus of the IAC, there is a prolongation of wave I to III latency, seen in tracing A2. Although further tracings, A3 through A5, show progressive deterioration of the ABR recording, comparison between this patient's preoperative and postoperative audiogram showed preservation of serviceable hearing (see Figs. 145.4 and 145.5).

Intraoperative ABR monitoring has also been shown to decrease auditory morbidity during posterior fossa microvascular decompression for hemifacial spasm and trigeminal neuralgia (23–26). However, microvascular decompression for hemifacial spasm without intraoperative ABR monitoring has also been shown to provide similar postoperative auditory results (27).

ELECTROCOCHLEOGRAPHY

ECochG is a near-field technique that monitors the cochlea and the most distal portion of the auditory nerve. As such, the signal can be obtained more rapidly with fewer

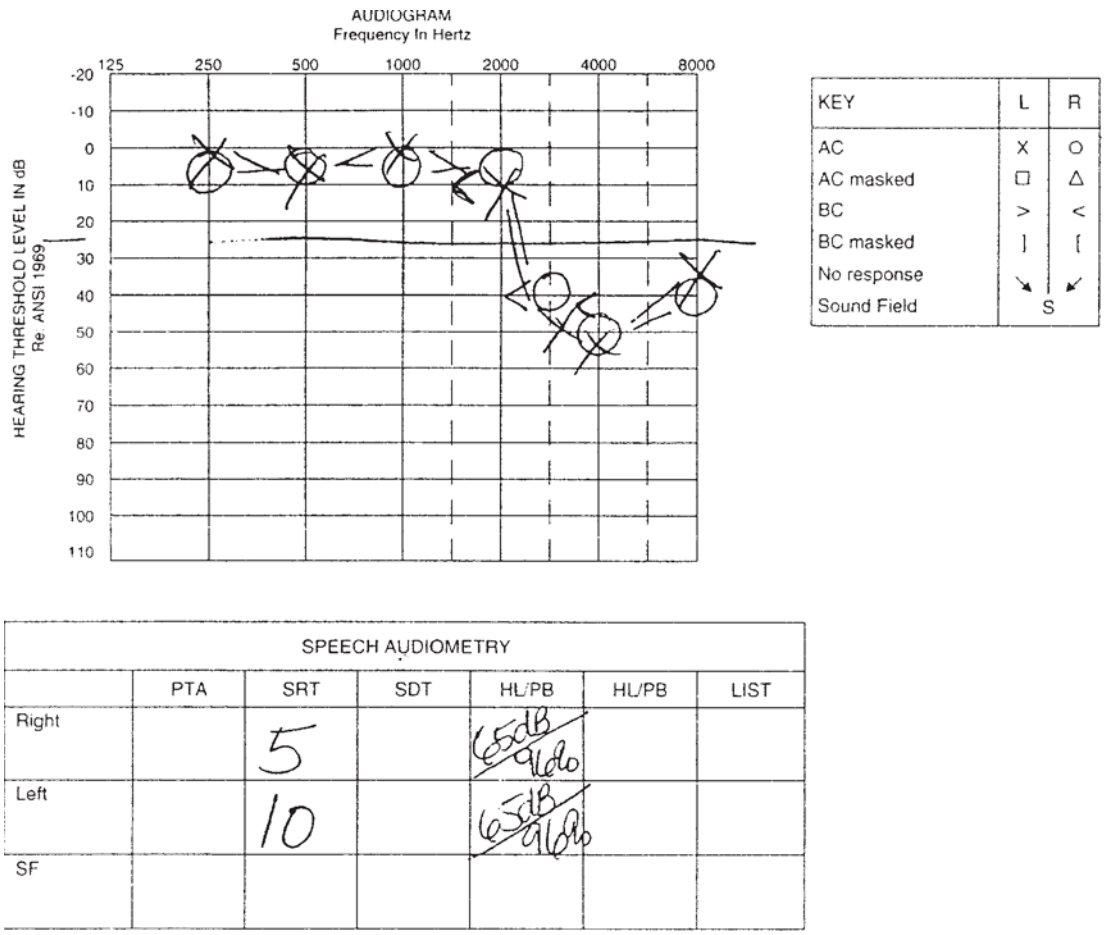

Figure 145.4 Preoperative audiometric findings for the patient in Figure 145.5.

sweeps and averaging. Auditory stimuli are delivered to the cochlea commonly in the form of a click. The two recording approaches for ECochG are transtympanic (TT) and extratympanic (ET). The TT method involves penetrating the tympanic membrane with a needle electrode so that the tip rests on the cochlear promontory. The ET method has recording sites that are peripheral to the tympanic membrane via external auditory canal electrodes. While less invasive compared to the TT counterparts, the increased distance of the ET electrodes from the recording targets minimizes the amplification advantage of this near-field technique (28). Figure 145.6 shows a typical ECochG setup, with an insulated TT recording needle electrode placed on the promontory of the middle ear. To improve stability during testing, the electrode may first be placed through the tragus. Figure 145.7 shows an ECochG tracing from a patient undergoing removal of a vestibular schwannoma. Recording electrodes placed closer to the promontory encounter less noise, resulting in more rapid signal generation (within 10 s) with less required averaging (12). ECochG monitors the cochlear microphonic (CM), as well as the summating potential (SP) and eighth nerve action potentials (APs) arising from a stimulus.

The CM and the SP represent cochlear bioelectric activity: the CM is generated by the outer hair cells in the organ of Corti, and the SP is generated by a complex mechano-electrical transduction process within the organ of Corti. The compound action potential (AP) of the auditory nerve represents the summed response of synchronous discharges from several thousand afferent eighth nerve fibers. The first component of the AP, often referred to as N1, is analogous to wave I of the ABR (11,29). Differentiation of the SP from the AP, which are normally superimposed on each other, may be accomplished by increasing the click rate. With higher click rates, the eighth nerve AP will decrease because the stimulus frequency is shorter than the refractory period for each neuron contributing to the AP. The N1 latency is inversely related to the stimulus rate, whereas its amplitude is directly related to the stimulus rate (11).

Clinically, ECochG may be used to predict postoperative audition and is sensitive to changes in cochlear blood supply. Reduced amplitude or loss of the ECochG AP is believed to indicate direct injury to or vasopasm of the labyrinthine (internal auditory) artery (29). Change in the CM may indicate cochlear pathophysiology. Because less signal averaging is required, surgeons are alerted to damaging maneuvers or situations more quickly than with ABR (29). A comparison of monitored and nonmonitored patients undergoing vestibular schwannoma resection demonstrated a significantly improved outcome for those in the monitored group (30).

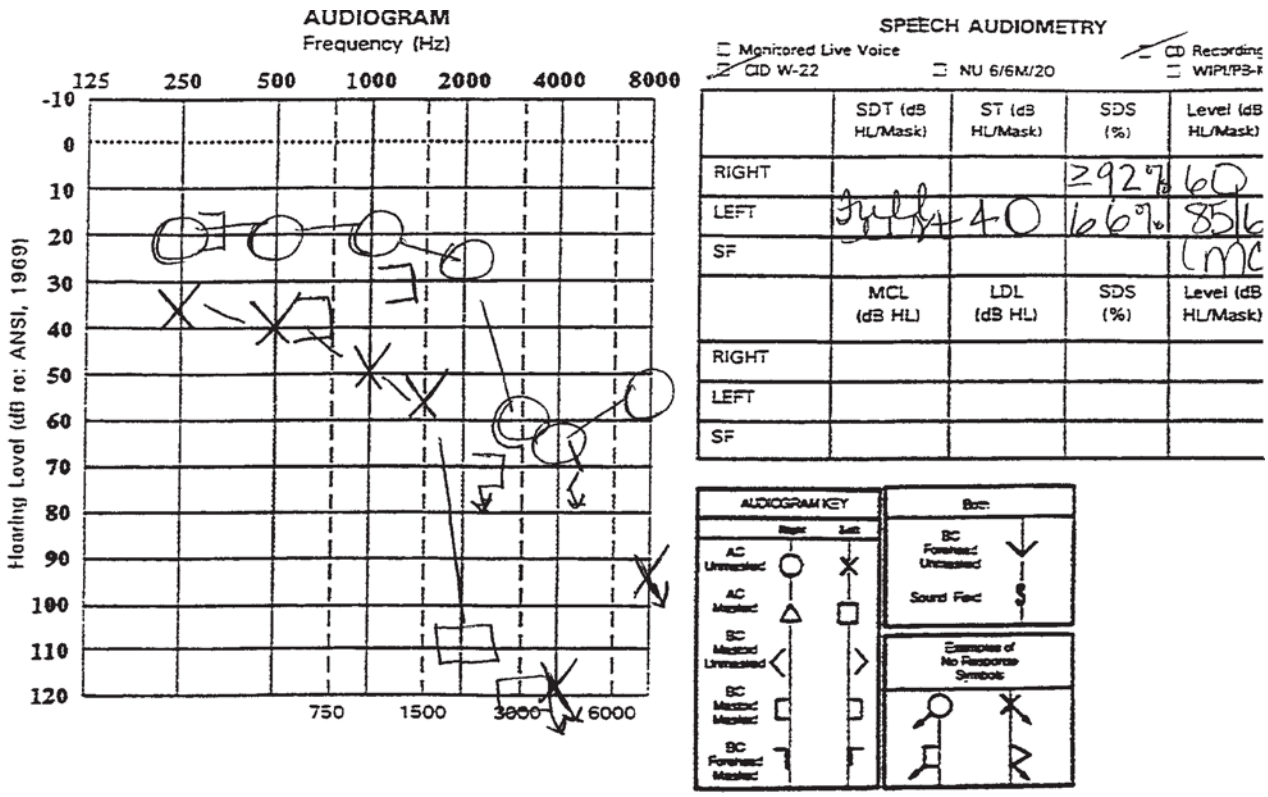

Figure 145.5 Postoperative audiometric findings for patient in Figure 145.4. SF, sound field; MCL, most comfortable loudness; LDL, loudness discomfort level; SDS, speech discrimination score; SDT, speech-detection threshold; AC, air conduction; BC, bone conduction; ST, spondee threshold.

Potential drawbacks of ECochG monitoring arise from its invasiveness, difficulty of appropriate needle placement, and potential for intraoperative dislodgement of the electrode (31). TT needle placement may increase the risk of postoperative cerebrospinal fluid otorrhea (29). More significantly, ECochG may not accurately reflect intraoperative changes that occur medially within the cerebellopontine angle (31). Persistence of ECochG signals after cochlear nerve section has been well documented. Utilizing intraoperative ECochG, Silverstein et al. demonstrated signal persistence for 25 minutes after cochlear nerve section (32), while APs have been documented 3 years after cochlear nerve resection (33). Because of limitations encountered with ECochG use and suspicion that use of ECochG alone may be less effective than other means of monitoring (12), the use of ECochG as the sole method of intraoperative monitoring has been reported with less frequency in recent years. Nevertheless, ECochG may be a useful adjunct to other monitoring techniques to provide a broader picture of the auditory pathway.

Despite its limitations, ECochG, particularly the SP, may be useful in surgery for Meniere disease, as sac decompression precipitates a decrease in previously elevated SPs in several patients (34). Although an abnormal SP/AP ratio has historically been associated with Meniere, recent studies have shown that an elevated SP/AP ratio also is a consistent finding in superior semicircular canal dehiscence (SSCD) (35). Knowing that this SP/AP ratio normalizes after surgery suggests a potential opportunity for intraoperative monitoring with ECochG during repair of SSCD.

DIRECT EIGHTH NERVE MONITORING

Another near-field technique, direct monitoring of the CNAP or ANCAP, seeks to circumvent some of the potential problems with ABR and ECochG recording. Since its introduction by Moller and Jannetta in the 1980s, CNAP has gained increasing acceptance (36). It is the most sensitive modality to monitor the eighth cranial nerve and may be used in patients with poor or absent ABR tracings. One report described a series of nine patients with absent preoperative ABR waveforms who were successfully monitored with CNAP. Seven of the nine patients ultimately achieved hearing preservation (16).

The CNAP positive electrode is placed on the nerve proximal to the tumor or adjacent to the cochlear nucleus once exposed; hence, this type of monitoring is usually restricted to the retrosigmoid approach. However, a few authors have reported the use CNAP monitoring for middle cranial fossa approaches with some benefit (37,38). The negative electrode is placed in the contralateral mastoid tip area and the ground electrode is placed at the vertex (13). Click stimuli are administered to the ear, eliciting a characteristic waveform with an initial positive peak (N1), as in Figure 145.8. Because the compound AP is very

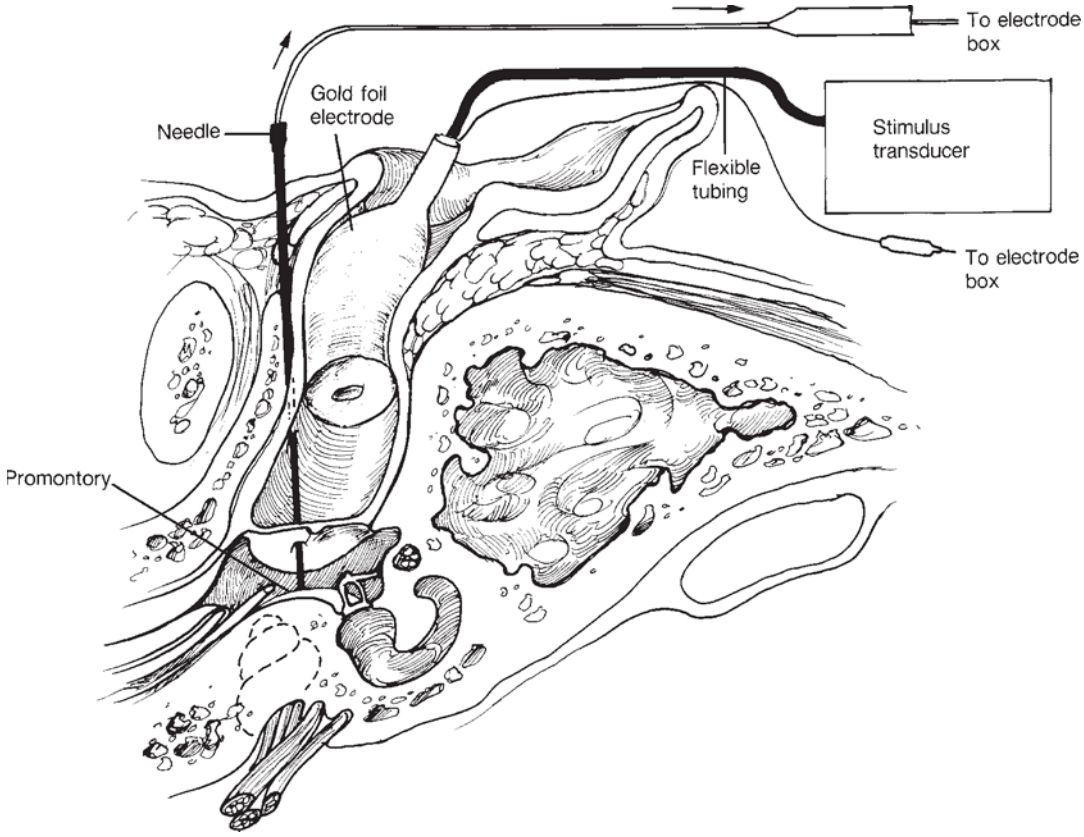

Figure 145.6 Schematic shows placement of intraoperative TT needle electrode through tragus. A gold foil electrode sound delivery system is in the distal portion of the ear canal.

large in this near-field technique, there is little to no need for signal averaging, and the feedback to the surgeon can be nearly instantaneous (12,13).

Analyzing the morphology and latency of CNAP components provides information regarding the mechanism of injury and gives the surgeon insight into which maneuvers are beneficial and which are harmful to hearing (15,39). Moderate injury to the nerve decreases CNAP amplitude, with complete loss of signal in severe contusion or transection. Stretching the nerve increases the N1 latency, and diminished N1 amplitude may be the first sign of mechanical or thermal injury to the nerve (12). Unlike other monitoring techniques, the information provided by CNAP monitoring is presented in real time, allowing the surgeon to correct for the offending maneuver (see Fig. 145.9). Potential difficulties with securing the electrode have largely been overcome utilizing a variety of techniques (13,20). However, placement of the electrode can be challenging and sometimes not feasible when applied to tumors with cerebellopontine angle involvement where exposure may be limited (40).

CNAP monitoring is potentially a sensitive prognostic tool. Preservation of the CNAP has been associated with hearing preservation in one case series in 78% of patients

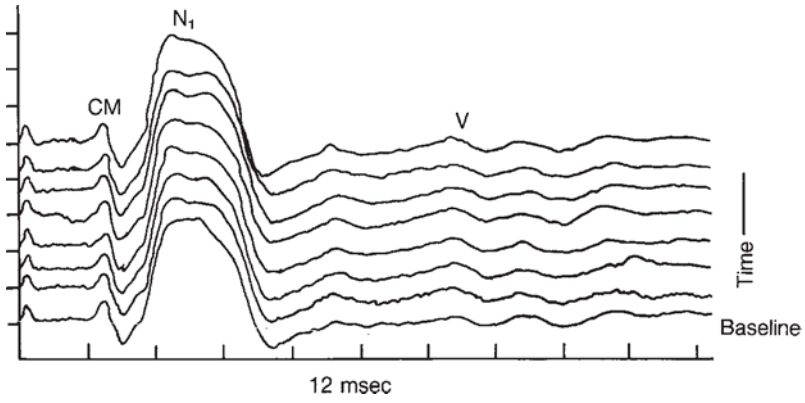

Figure 145.7 Intraoperative TT electrocochleographic recordings of a patient undergoing removal of acoustic tumor. CM, cochlear microphonic; N_1, action potential of eighth cranial nerve.

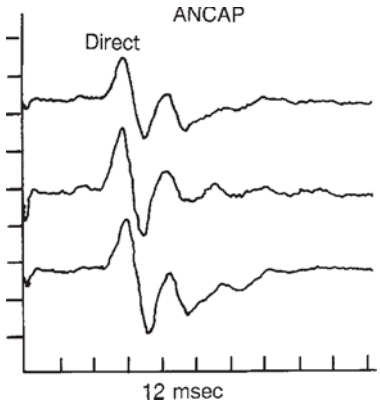

Figure 145.8 Intraoperative recording shows direct ANCAP of a patient undergoing retrolabyrinthine vestibular nerve section.

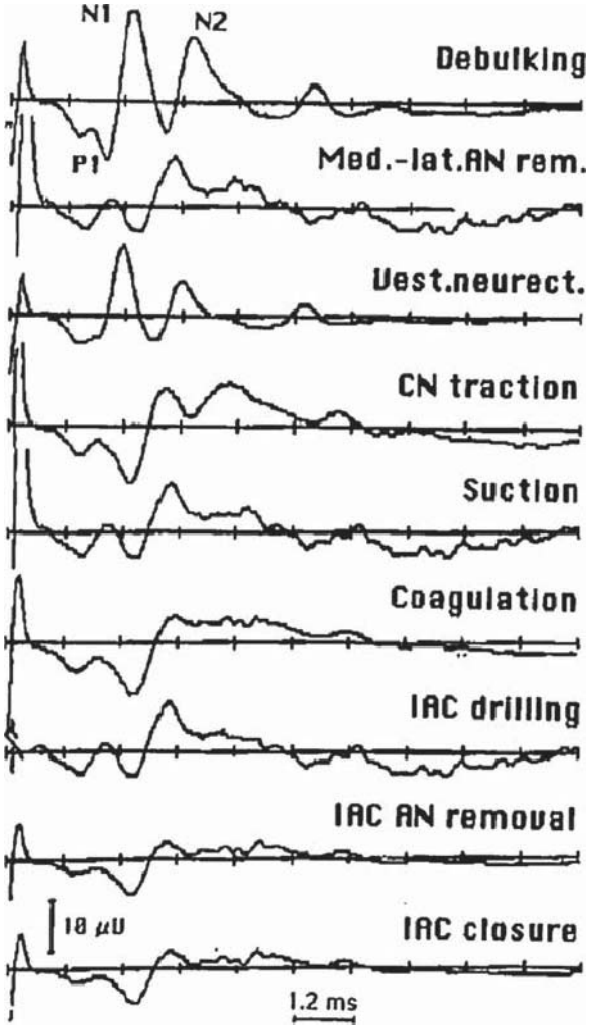

Figure 145.9 Set of CNAPs recorded during retrosigmoid-transmeatal removal of a 19-mm left vestibular schwannoma in a 33-year-old man. Preoperative hearing: PTA 26 dB; SDS 90%. The CNAP changes are shown at different surgical steps. Postoperative hearing: PTA 47 dB; SDS 70%. (Taken from Colletti V, Fiorino FG. Advances in monitoring of seventh and eighth cranial nerve function during posterior fossa surgery. *Am J Otol* 1998;19:503–512, with permission from Lippincott Williams & Wilkins.)

(20); conversely, lack of an AP response at the completion of the procedure carries a very poor prognosis for postoperative hearing preservation (12,20). However, earlier studies have shown that CNAP monitoring did not affect hearing preservation (41,42).

Despite the advantage of more instantaneous feedback with possibly improved likelihood of hearing preservation (40), some surgeons have been reluctant to embrace this technique not only because the electrode can be difficult to place but also, once placed, can become a cumbersome impediment as it lies in the surgical field.

COMPARING THE THREE MONITORING TECHNIQUES

Compared to the use of ABR and ECochG during vestibular schwannoma resection, there has been a trend toward improved hearing outcomes with CNAP monitoring. Additionally, the loss of CNAP N1 at the completion of the surgical procedure is a poor prognostic sign for hearing preservation (12). A study comparing 22 ABR-monitored patients with 44 CNAP-monitored patients reported a statistically significant improvement in hearing preservation rates, which they defined as preservation of any retained hearing in those monitored with CNAP. However, these results did not achieve statistical significance for the preservation of serviceable hearing, but the trend pointed toward CNAP monitoring (27% for ABR, 43% for CNAP) (40). It provides reliable auditory monitoring more frequently than ABR, reflects the intraoperative auditory function almost in real time, predicts postoperative hearing with excellent sensitivity and specificity, and is more useful for monitoring in the removal of small vestibular schwannomas with hearing preservation (15). Others have also concluded that CNAP monitoring offered superior monitoring and improved outcomes compared to other techniques (20,39,40). Despite the perceived superiority of CNAP monitoring, the technical difficulty of placing and operating around electrodes, as well as the limited space available in the setting of large tumors, continue to limit its acceptance (31).

The overwhelming majority of data supporting the use of intraoperative monitoring of the auditory system come from retrospective analyses (40). However, comparing the results of hearing preservation surgeries across studies or institutions is inherently difficult for a number of reasons. First, the selection criteria for patients undergoing hearing preservation surgery can differ dramatically between institutions. Tumor size, preoperative hearing ability, and the surgeon's experience in removing such tumors are other frequently encountered variables. Additionally, the intraoperative monitoring technique, the interpretation, and the surgical response are operator dependent. Lastly, the most significant limitation is how each author defines preservation of hearing. Some studies regard any detectable

TABLE 145.2 AMERICAN ACADEMY OF HEAD AND NECK SURGEONS CLASSIFICATION OF HEARING PRESERVATION SURGERY FOR VESTIBULAR SCHWANNOMA

Class	Pure Tone Threshold	Speech Discrimination (%)
A	≤30 dB	≥70
B	>30 dB, ≤50 dB	≥50
C	>50 dB	≥50
D	Any level	<50

hearing as preservation, whereas others use more selective criteria to include only those with truly functional hearing. A recent review demonstrated that substantial variations in published rates of hearing preservation can be achieved simply by manipulating the definition of success (43). Standardized schemes for reporting results have been developed, but even these are disputed and are not uniformly applied (43,44). According to the guidelines of the American Academy of Otolaryngology–Head and Neck Surgery, hearing preservation is defined as preservation of hearing within normal and social hearing classification, that is, pure tone audiometry ≤50 dB and speech discrimination score ≥50% (10,44,45) (see Table 145.2).

Because of the increased prevalence of contrast-enhanced MRI scanning, today's surgeon encounters a greater number of small tumors and is afforded a greater opportunity to preserve hearing (46). Although comparing studies evaluating the success of hearing preservation surgery remains difficult, the use of intraoperative auditory monitoring has been associated with improved results. Many surgeons have reported monitoring to be useful, and a substantial body of literature supports the use of intraoperative auditory monitoring in the appropriate setting. Consequently, its use has become routine in hearing preservation surgery in many major centers.

COMBINED APPROACHES

Because individual cochlear nerve-monitoring modalities have limitations and weaknesses in their clinical applications, some surgeons have utilized multiple modalities. Combinations of near- and far-field techniques help create a complete picture of the auditory system, from the cochlea and the distal eighth nerve to the brainstem and higher centers. Some investigators have described the simultaneous use of ABR and ECochG to localize the origin of detected changes in the auditory system, whereas others advocate ABR and CNAP monitoring (47,48).

When monitoring patients undergoing vestibular schwannoma removal with both ABR and ECochG, Schalke et al. (29) reported an overall hearing preservation rate of 51%. The loss of ECochG signal in this study coincided with postoperative deafness (26/26 patients). However, serviceable postoperative hearing was maintained in 25% of patients with an absent postoperative ABR but preserved ECochG. Very good rates of hearing preservation have been documented when combining the use of ABR with CNAP (20,39,49). The utility of ABR in cases monitored with CNAP has been called into question, however, as multiple studies have not demonstrated any advantage with the addition of ABR monitoring compared to CNAP alone (15,20). In one study, during the microsurgical tumor removal, reliable auditory monitoring was obtained in 20 of 22 patients (91%) by CNAP and in nine of 22 (41%) by ABR. The same study showed that preserved CNAP at the completion of tumor removal predicted hearing preservation 100% sensitivity and 100% specificity; all 19 patients who had preserved CNAP at the end of the case demonstrated serviceable hearing, while one patient in whom CNAP disappeared lost hearing. It demonstrated that the loss of ABR is not specific for hearing loss; 12 of 14 patients preserved hearing despite the lack of ABR presence at the completion of the case (15).

HORIZONS

Rapid feedback and improved sensitivity of the monitoring techniques have improved the clinical applications of this technology, but all responses must be critically analyzed relative to the surgical procedure. Eighth nerve monitoring cannot serve as a replacement for preoperative planning, meticulous surgical technique, and a detailed knowledge of regional anatomy. Despite the challenges of intraoperative auditory monitoring in otologic and neurotologic procedures, expanding technologic frontiers have emerged because of information obtained from intraoperative auditory monitoring. Nimodipine has been shown to rescue traumatized cochlear neurons from degeneration in rats (50). Subsequently it was demonstrated that prophylactic vasoactive treatment consisting of nimodipine and hydroxyethyl starch (HES) provided significantly better preservation of cochlear nerve function in vestibular schwannoma surgery (6). Bischoff further showed that only patients who had reversible loss of BAEP benefitted from vasoactive treatment (51). Other monitoring techniques such as distortion product otoacoustic emissions (DPOEs) have shown some promising results (52), but further evaluation is required to assess its impact on outcomes.

Armed with an understanding of the fundamental techniques of intraoperative auditory system monitoring, the surgeon may then decide which modalities, if any, will be applicable to the planned surgical procedure. Although the future appears bright for eighth nerve monitoring, it still trails facial nerve monitoring in applications and acceptance.

INTRAOPERATIVE FACIAL NERVE MONITORING

Facial nerve injury with resultant paresis or paralysis is a devastating and one of the most feared complication of otologic surgery. It is also one of the more common reasons for malpractice litigation in otolaryngology (53). Morbidity from this injury depends on the site of the injury as well as the degree of injury to the facial nerve, ranging from a mild, partial paresis of brief duration to permanent injuries with significant sequelae. Temporary or partial paralysis may result in long-term cosmetic deformities, including synkinesis, atrophy, or bothersome facial twitching. Permanent facial paralysis may result in extensive cosmetic deformity or severe functional deficits, leading to oral incompetence and, in extreme cases, corneal injuries and blindness as well as significant psychological effects on the patient. Although facial nerve injury can occur during any otologic or neurotologic procedure, certain procedures such as vestibular schwannoma excision, revision mastoid surgery, and repair of congenital malformations carry a greater risk. While most otolaryngologists are familiar with normal facial nerve anatomy, the nerve may run an aberrant course or be obscured by tumor, fibrosis, cholesteatoma, granulation tissue, bleeding, and even spinal fluid. The incidence of facial nerve paralysis resulting from otologic and neurotologic procedures has declined over the past decades likely because of the advent of the operative microscope, high-speed surgical drill, and advanced microsurgical techniques. Prior to these advances, the incidence of facial nerve paralysis following mastoid surgery was as high as 15% (54). A more recent estimate of facial nerve paralysis found an incidence of 1.7% in 1,024 consecutive mastoidectomies (55).

The importance of facial nerve monitoring during otologic and neurotologic surgery extends beyond merely avoiding untoward outcomes. Because of its intricate involvement with the structures of the temporal bone, the facial nerve often serves as an invaluable landmark in performing certain operations. Identification of the facial nerve promotes orientation in the complex three-dimensional anatomy of the temporal bone and comprises an essential step in many otologic and neurotologic procedures.

FACIAL NERVE INJURY

There are many mechanisms by which the facial nerve can be injured during otologic and neurotologic surgery. Possible sources of trauma are listed in Table 145.3.

TABLE 145.3 TYPES OF FACIAL NERVE INJURY

Transection
Direct trauma from surgical dissection
Direct trauma from surgical drill
Stretch
Compression
Thermal damage from drilling, cautery, laser, irrigation
Vascular compromise
Direct or indirect injury from the ultrasonic aspirator
Edema of the nerve in the fallopian canal from surgical dissection

Resection of vestibular schwannomas places the facial nerve at the greatest risk, primarily because of the limited access to the intracranial facial nerve, the narrow confines of the IAC, the absence of a fibrous protective layer of epineurium, and the tendency for the tumor to splay the nerve fibers. Most facial nerve injuries during resection of vestibular schwannomas occur medial to the porus acousticus at the mid-cerebellopontine angle, where it may be injured from surgical dissection or compression by the mass (56). Additionally, bone surrounding the mastoid, tympanic, and labyrinthine segments is often thinned to maximize exposure of the IAC. In a series that looked at facial nerve injury in vestibular schwannoma resection, the facial nerve was preserved in 95% to 100% of all patients with tumors less than 1 cm, 80% to 92% of patients with tumors measuring 1 to 2 cm, and 50% to 76% of patients with tumors greater than 2 cm (6). Another study showed interruption of the facial nerve in 2% to 10% of patients who underwent resection of vestibular schwannomas (57).

Excluding vestibular schwannoma surgery, the most common site of iatrogenic injury during otologic surgery occurs in the tympanic segment followed by the mastoid segment and second genu (58). In a review of the experience at the House Ear Clinic, 57% of the iatrogenic facial nerve injuries occurred during the mastoidectomy, with or without tympanoplasty. Of note, 14% of the patients studied sustained an injury to the facial nerve during tympanoplasty, and an additional 14% were injured during the removal of bony exostoses from the ear canal (59). Intraoperative facial nerve monitoring serves as a useful adjunct to a detailed knowledge of normal and variant temporal bone anatomy, careful preoperative planning, and meticulous surgical technique to minimize the chance of inadvertent injury to the facial nerve.

HISTORY

Krause reported the first case of facial nerve monitoring during a neurotologic procedure 1898. He noted that electrical stimulation of the nerve resulted in facial movement (60). Throughout the first half of the 20th century,

other surgeons used similar techniques, employing either direct observation of the facial muscles or having an assistant manually palpate the face during dissection or electrical stimulation. In 1965, Jako developed a photoelectric sensing device that detected light transmission through the cheek when placed inside the mouth, activating an audible signal (61). Some surgeons went as far as securing bells to the their patients' faces hoping that facial movement would produce an audible alert (62). Hampered by poor sensitivity and reliability, few of the early devices gained widespread acceptance.

Electromyography (EMG) was first employed as a method of facial nerve monitoring in 1979. Intraoperative stimulation of the nerve triggered responses that were detected by surface electrodes and displayed on an oscilloscope (63). To improve recognition of facial nerve stimulation, Sugita and Kobayashi devised a method to transduce facial movement into an auditory signal that could be heard by the surgeon and operating room personnel (64). In 1984, Moller and Jannetta (65) combined EMG, a constant voltage stimulator, and auditory signal in IOFNM. Combining visual and auditory signals to represent facial nerve stimulation and the use of insulated stimulator probes has not only increased the utility of facial nerve monitoring but also simplified the practical application of such technologies.

FACIAL NERVE MONITORING SYSTEMS

Several types of facial nerve monitors are currently available. Most of these systems monitor facial nerve integrity by detecting facial muscle contractions. Some systems utilize mechanical pressure sensors to detect facial muscle activity from manipulation, trauma, or directed stimulation of the nerve with a specially designed probe; others rely on video analysis of facial movements (66,67). Still others examine facial nerve APs, recorded either in an orthodromic (proximal-to-distal) or antidromic (distal-to-proximal) manner. Currently, the most common method of IOFNM measures EMG potentials, which has been shown to be more sensitive than movement sensors. By monitoring the electrical activity of the target muscles, EMG systems reflect the activity and integrity of the innervating nerve (68). Video analysis, although not as sensitive as EMG, also remains an area of active research (66,67,69). Regardless of the system used, intraoperative monitoring systems should meet certain criteria (Table 145.1) and assist in performing certain tasks (Table 145.4) (39).

ELECTROMYOGRAPHY AND EVOKED ELECTROMYOGRAPHY

EMG is performed by placing a pair of needle electrodes into a target muscle of the monitored nerve. In IOFNM, the facial musculature, typically the orbicularis oculi and orbicularis oris in the two-channel setup, is monitored; a third channel placed in the contralateral face or the trapezius muscle may be used as a reference electrode. The potential difference between each electrode pair is subsequently amplified and displayed on an oscilloscope. Electrical activity of the muscle will appear as biphasic waveforms on the oscilloscope tracing. The motor unit potential reflects the electrical response of a single muscle fiber to a single efferent nerve fiber. When the response of an entire muscle group to an efferent motor nerve is considered, it is termed the collective action potential (CAP) or the compound muscle action potential (CMAP). Changes in neural activity may occur during operative dissection near the facial nerve and during manipulation of the nerve, altering the baseline neural activity and propagating compound action potentials that appear as deflections on the oscilloscope (56).

There are two types of electrode placement described in the literature: the bipolar technique recommends the use of electrode pairs in each muscle and the unipolar technique suggests one electrode per muscle. When these two techniques were compared during vestibular schwannoma resection, the bipolar technique was found to be significantly more sensitive to A-trains and thus recommended as the setup of choice for continuous EMG monitoring (70). Four-channel EMG, which monitors the frontalis and platysma in addition to the orbicularis oris and oculi, has been shown to improve muscular activity detection and allow a more precise determination of stimulation thresholds than the two-channel EMG (71).

Direct electrical stimulation with acoustic loudspeaker monitoring has been the technique of choice for intraoperative monitoring of the facial nerve in the last 25 years.

TABLE 145.4 OBJECTIVES OF INTRAOPERATIVE FACIAL NERVE MONITORING

Early identification of the facial nerve in the temporal bone, IAC, cerebellopontine angle, or extratemporal portion during surgical dissection
Differentiation of the facial nerve from other structures in the surgical field, such as tumor, granulation tissue, or fibrosis
Differentiation of the facial nerve from other nerves in the cerebellopontine angle (trigeminal, cochlear, superior, and inferior vestibular nerves)
Rapid notification of the surgeon about trauma or pending trauma to the nerve
Reduction of trauma to the nerve during dissection of acoustic neuroma or cholesteatoma, as well as during procedures that require transposition or rerouting of the nerve
Early warning to the surgeon of an aberrant course of the nerve, or of unsuspected dehiscence of the nerve
Evaluation of nerve integrity at the completion of the procedure and prediction of postoperative function
Efficient identification of the site and degree of neural degeneration in patients undergoing facial nerve exploration for mass or paralysis[a]

[a]Silverstein H, Smouha EE, Jones R. Routine intraoperative facial nerve monitoring during otologic surgery. *Am J Otol* 1988;9:269–275.

EMG activity can appear in a variety of forms including random muscle activity, a pulsed response coinciding with electrical stimulation, repetitive (train) activity, and nonrepetitive (burst, neurotonic discharge) activity. Train activity manifests as multiple responses from multiple motor units following a single stimulus. Such repetitive activity occurs following stretch injury or transmitted thermal injury to the nerve, actions that precipitate prolonged depolarization of the facial nerve beyond its threshold for generating an action potential. In this setting, the nerve will continue to fire until repolarization occurs or when nerve activation can no longer be sustained. In 2000, a classification system based on analysis of EMG tracings with respect to waveform characteristics, frequencies, and amplitudes was developed (68). This classification divided train activity into three subgroups. One of these particular patterns, the A-train, described as a sinusoidal pattern of high frequency and homogenous appearance, demonstrated to be the sole pattern clearly associated with postoperative paresis with high sensitivity and specificity. Additional characteristics are sudden onset and sudden termination. Its duration varies between milliseconds and several seconds. The normal amplitudes of A-trains are comparatively low, usually presenting between 100 and 200 μV (72). This study also concluded that bursts, spikes, and other train-type activities were of no significance in determining facial nerve function (68). Understanding and incorporating these waveform characteristics into monitoring technology has the potential to improve surgical outcomes by amending direct electric nerve stimulation with its real-time capabilities (68,72).

Conversely, nonrepetitive EMG activity closely follows direct mechanical or electrical stimulation, allowing otologic and neurotologic surgeons to locate and identify the facial nerve and, ideally, lead to its preservation (31). Stimulation probes deliver a stimulus of preset intensity and pulse duration to the facial nerve and are designed to function in a constantly changing surgical environment. The effects of bleeding or accumulation of other fluids such as irrigation, perilymph, endolymph, and cerebrospinal fluid may be minimized by insulating the probe flush to the tip (73). The stimulus intensity level is chosen to elicit a neuromuscular response with the least amount of delivered current. When the nerve is directly stimulated by the probe via a depolarizing current, the resulting compound action potential of the facial muscle is recorded by EMG, confirming the location of the facial nerve (see Fig. 145.10). To achieve this aim, either monopolar or bipolar stimulating probes may be used.

Bipolar probes offer the advantage of being more selective limiting the passage of current to a smaller surface area, allowing for more precise localization. Unfortunately, bipolar stimulation depends on appropriate alignment of the bipolar tip in contact with the nerve. Such precise orientation is difficult, if not impossible, to achieve in the tight confines of the posterior fossa or on a small exposed area of the intratemporal segment of the facial nerve. Despite

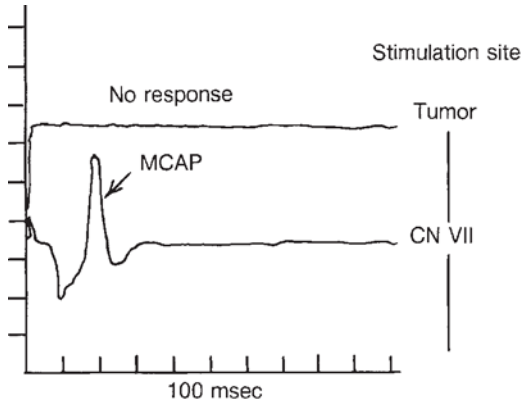

Figure 145.10 Intraoperative recordings of evoked EMG of the facial nerve in response to stimulation of the seventh cranial nerve and tumor.

the theoretical advantage, practical application of bipolar stimulators in otologic and neurotologic surgery has been limited (3,56).

Because the selectivity offered by the bipolar stimulator is not critical in surgical fields containing one, or few, nerves of interest, monopolar stimulators are more widely used in facial nerve monitoring. When stimulus intensity approximates the nerve threshold level, a monopolar electrode can achieve spatial orientation of less than 1 mm. Several methods of monopolar stimulation have been developed. A thin, malleable probe that has been insulated to the tip resembling an unsharpened pencil was fashioned to deliver a stimulus with minimal risk of collateral spread (74,75). An alternate probe with a ball electrode capping an insulated, flexible platinum–iridium tip, was developed allowing for stimulation of the nerve in obscured areas where the flush tip may not be able to gain sufficient contact with the nerve (3). A set of dissecting instruments that allow for simultaneous operating in the surgical field and stimulation of the facial nerve has also been developed (76). By applying continuous electrical current to the drill burr and insulated microsurgical instruments, the armamentarium of intraoperative facial nerve monitoring has been further advanced (77).

Stimulating probes may either have a constant current or constant voltage source. Bleeding, soft tissue, tumor, cholesteatoma, and spinal fluid may shunt current from the stimulus probe away from the nerve, creating variations in electrode impedance. To continue to depolarize the nerve, the constant current stimulator must be increased to higher levels in the face of increased resistance. Potential damage to the nerve may occur when the stimulus current remains elevated but the resistance in the operative environment is reduced by suctioning or controlling nearby bleeding. On the other hand, constant voltage systems deliver current based on the intrinsic resistance of the nerve according to the Ohm law, adjusting current accordingly and limiting the effect of shunting on these systems. Although the total current changes as the operative milieu changes, the current delivered to the nerve remains more stable in constant

voltage systems (3). Despite the theoretical differences in the two systems, no specific clinical advantage of either system has been found (74).

DIRECT FACIAL NERVE MONITORING

In addition to EMG monitoring during facial nerve stimulation, techniques for direct monitoring of neural transmission exist. Unlike EMG, direct monitoring systems follow CNAPs as they progress down the nerve itself in a orthodromic, or proximal-to-distal, direction. Antidromic, or distal-to-proximal, potentials may also be monitored, allowing real-time detection of facial nerve injury or conduction blockade (78,79). Direct monitoring does, however, require the attachment of electrodes to the nerve directly, a technically challenging and potentially deleterious activity. Additionally, direct monitoring of CNAPs is limited by the smaller field potentials created by depolarization of nerve fibers, resulting in diminished sensitivity.

ANESTHESIA AND FACIAL NERVE MONITORING

In the course of general anesthesia, anesthesiologists commonly use muscle relaxants that affect the postsynaptic nicotinic receptors. These agents act as antagonists (nondepolarizing) or agonists (depolarizing) at the muscle end plate receptor. Nondepolarizing agents may be short acting or long acting. Atracurium, vecuronium, and mivacurium typically induce paralysis for up to 30 minutes, whereas effects from pancuronium and tubocurarine may last up to 1 hour. Meanwhile, succinylcholine, the most common depolarizing agent is extremely short acting, exerting its effects for 5 to 10 minutes. Paralysis from the use of these agents interferes with the recording of EMG potentials. Therefore, nondepolarizing agents are typically contraindicated in cases in which intraoperative facial nerve monitoring is planned. Succinylcholine is used for induction because of its short duration of effect with complete recovery from neuromuscular blockade within 15 minutes.

Local anesthesia can also impair the use of facial nerve monitoring. Many otologic surgeons routinely use lidocaine with epinephrine at the beginning of the procedure, both at the site of the postauricular incision and in the ear canal when indicated. The advantages of this injection are improved hemostasis and analgesia, possibly limiting the amount of narcotic analgesia required for patient comfort. To avoid potential paralysis of the facial nerve that could interfere with facial nerve monitoring, the surgeon's index finger is placed on the mastoid tip during injection to avoid deep injection of lidocaine near the stylomastoid foramen. Care is also taken to not over aggressively inject the ear canal, especially in the posteroinferior aspect. Many surgeons have encountered the unnerving transient postoperative facial paralysis that resolves within several hours that is attributed to the activity of the local anesthetic (80).

We have utilized this method of anesthesia with great success in operations in which IOFNM is used. Partial muscle paralysis is not used during monitored cases at our institution. Because a partially paralyzed muscle fatigues rapidly, multiple successive stimuli may lead to progressively smaller evoked EMG amplitudes, resulting in diminished sensitivity of the continuous EMG monitor and potential problems using the stimulus probe.

INDICATIONS FOR INTRAOPERATIVE FACIAL NERVE MONITORING

A list of surgical procedures that should be considered for intraoperative facial nerve monitoring can be found in Table 145.5. We have applied the routine use of the facial nerve monitor in all otologic and neurotologic cases, as the facial nerve is potentially at risk in all such situations. The use of IOFNM in vestibular schwannoma resection is routine at many institutions and should be employed when possible (81). A significant and substantial reduction (14.5% to 3.6%) in the frequency of facial nerve paralysis following the implementation of monitoring in cerebellpontine angle surgery has been reported (82). While the benefits of IOFNM for vestibular schwannoma surgery and posterior fossa surgery have been established, the role of monitoring in routine otologic procedures is less well defined. The use of monitoring in such cases is not universal. A recent survey of 223 American otolaryngologists showed that 66% use IOFNM at least some of the time for otologic procedures such as chronic ear surgery or stapedectomy (83). In this same survey, they found that 46% of surgeons never use facial nerve monitoring for such cases (83). Similarly, a study of surgeons in the United Kingdom similarly found that a substantial percentage of surgeons never use monitoring for mastoidectomy (38%) or stapedectomy (85%) (84). Whether IOFNM should be employed in "routine"

TABLE 145.5 POTENTIAL INDICATIONS FOR INTRAOPERATIVE FACIAL NERVE MONITORING

Mastoidectomy
Tympanoplasty
Canalplasty
Stapedectomy
Parotidectomy
Excision of glomus tumors

otologic cases has been questioned. The fear that surgeons may gain a false confidence in their skills and knowledge based on their use of intraoperative facial nerve monitors reflects a broader concern from many in the otolaryngology community that overreliance on this technology could, in fact, lead to iatrogenic facial nerve injuries, particularly in situations when the monitor fails to recognize the nerve. In addition, there has been some reluctance in the otolaryngology community to declare IOFNM as the standard of care in otologic surgery. However, the use of the facial nerve monitor can never replace careful planning, experience, and a thorough knowledge of the anatomy of the temporal bone and posterior fossa. Several general principles regarding the facial nerve during otologic and neurotologic surgery should be employed:

1. Obtain and maintain thorough knowledge of the ear, temporal bone, and posterior fossa. Temporal bone lab dissection is essential in gaining this knowledge and expertise. Understand the three-dimensional anatomy of the facial nerve in the temporal bone. Appropriate courses are available throughout the United States for practicing physicians if they have no routine access to a formal temporal bone lab.
2. Treat the facial nerve as if it is dehiscent until proven otherwise, especially in the tympanic segment.
3. Expect any type of anatomic variation of the facial nerve, especially in revision cases.
4. Use meticulous technique at all times.
5. Always be well prepared—identify preoperatively cases in which the facial nerve may be at greater risk (i.e., congenital atresia).
6. Routinely examine the monitoring system to ensure that all parts are in working order, and understand the physiologic basis of your particular system.

BENEFITS AND APPLICATIONS

Numerous studies support the use of intraoperative facial nerve monitoring in performing vestibular schwannoma and skull base surgery, but the utility of this technology extends beyond the IAC and cerebellopontine angle. Facial nerve monitoring has been reported as beneficial in nearly all surgical procedures that place the facial nerve at risk. The benefits of such adaptations have been well documented.

REMOVAL OF VESTIBULAR SCHWANNOMAS AND TUMORS OF THE CEREBELLOPONTINE ANGLE

Intraoperative facial nerve monitoring allows identification of the nerve in the IAC or cerebellopontine angle before the nerve is clearly visualized through the use of stimulating probes; similar techniques allow mapping the course of the facial nerve during dissection. Based on feedback provided by the monitoring system, the surgeon may adjust the microsurgical technique to minimize injury or trauma to the nerve. Since the advent of IOFNM, several reports have extolled the advantages of facial nerve monitoring in cerebellopontine angle surgery, each citing improved facial nerve outcome, especially in removing large tumors (82,85–87).

Additionally, IOFNM may be used to predict postoperative facial nerve function (71,88–93). After resection of the vestibular schwannoma, the facial nerve is stimulated with a facial nerve probe at the lowest stimulation threshold at the brainstem and medial to the tumor dissection. The stimulation threshold is determined by first applying 0.05 mA and increasing in 0.05-mA increments until response amplitude is obtained. The response amplitude as well as lowest stimulation threshold can then be used as a predictor of postoperative facial nerve function with lower thresholds reflecting better facial nerve function. A ratio of response amplitude recorded from stimulating the nerve both proximal and distal to the tumor dissection of 0.1 or less has been shown to correlate with a poor facial functional outcome in 75% of patients at 6 months (93). Furthermore, a small tumor size along with a stimulus threshold less than 0.05 mA has been shown to correlate with a House-Brackmann grade of III or less in 88% of patients in the initial postoperative period (88). Another study showed that a stimulus threshold of 0.05 mA or less and a response amplitude of at least 240 μV predict a House-Brackmann grade I or II facial nerve function with 98% probability (90).

The A-train has been shown to be the only intraoperative EMG pattern associated with deterioration of facial nerve function (68). Subsequent studies have investigated the correlation of intraoperative EMG parameters and their ability to predict facial nerve outcomes. Reports demonstrate a strong correlation between the length of train time and postoperative facial nerve function (94). Patients with normal preoperative facial nerve function could tolerate up to 0.5 seconds of train time. However, at 10 seconds of train time, postoperative facial nerve function could potentially deteriorate by 1 House-Brackmann grade (94).

Not only has IOFNM improved results and helped predict postoperative facial nerve function but IOFNM has given surgeons insight into which patients may benefit from intraoperative prophylactic medication. Clinical trials medicating patients who develop reversible pathognomonic intraoperative A-train EMG activity with a combination of intravenous HES, a vasoactive agent, and nimodipine have shown improvement in long-term functional facial nerve results (6,95,96).

POSTERIOR FOSSA, MIDDLE FOSSA, AND SKULL BASE PROCEDURES

Vestibular nerve section; microvascular decompression of the fifth, seventh, and eighth cranial nerves; and other lateral skull base surgical procedures constitute additional areas in which IOFNM is beneficial. Extrapolating from the benefits of identification and limited damage offered by IOFNM, Moller and Jannetta described a method of microvascular decompression of the facial nerve for hemifacial

spasm that utilizes the monitoring system. The details of this procedure may be found elsewhere, but simply stated, the ongoing presence of abnormal responses to facial nerve stimulation indicates continued compromise of the nerve. Decompression, therefore, is continued until the abnormal responses abate, indicating removal of the offending vessel from the nerve (97,98). Facial nerve monitoring promotes improved identification of the offending vessel, decreasing the need for re-exploration. In addition, IOFNM has been shown to improve facial nerve function following the infratemporal fossa approach for extirpation of lesions of the lateral skull base (99,100).

CHRONIC EAR SURGERY AND REVISION MASTOID SURGERY

Previous operations and alterations in normal landmarks increase the level of difficulty in revision mastoidectomy. Cholesteatoma, otorrhea, granulation tissue, fibrosis, and other disease processes that necessitate the procedure also can obscure the facial nerve and its landmarks. The facial nerve can be dehiscent in up to 57% of patients without cholesteatoma or prior operations (101). Exposure of the nerve during prior operations or from erosion of the fallopian canal by cholesteatoma further heightens the likelihood of encountering an exposed facial nerve. Intraoperative facial nerve monitoring will alert the surgeon to the presence of dehiscent nerve segments and aid in mapping the nerve to allow focused surgical dissection (102). Some studies suggest that monitoring in this setting will often detect a dehiscence before it is visualized (103). The success of monitoring in this setting has been documented, and one group has reported 1,200 consecutive cases without facial nerve injury (102). Additionally, a recent cost-effectiveness study concluded that using facial nerve monitoring in both primary and revision surgery was the most cost-effective approach (104). Our current practice is to utilize IOFNM monitoring for all chronic ear cases, including tympanoplasty and mastoidectomy, both initial and revision.

STAPEDECTOMY

The most common site for a dehiscence in the fallopian canal occurs in the tympanic segment. The intimate relationship between the oval window and this segment of the facial nerve demands that extreme caution be exercised in performing a stapedectomy. Although a dehiscent facial nerve is not a contraindication to performing the operation, IOFNM may alert the surgeon to a dehiscent nerve during surgical dissection or laser stapedectomy. Injuries to the nerve during this procedure are rare, but have been reported (101). Any steps taken to minimize this occurrence, including IOFNM, may be beneficial to the patient. Although each individual surgeon may choose whether or not to use of IOFNM for otologic surgery, our current practice is to use facial nerve monitoring in all middle ear cases, routine or complicated, including stapedectomy.

PEDIATRIC OTOLOGY

Iatrogenic facial nerve injury is equally, if not more, devastating in the pediatric population. Although the physical consequences of such an injury are the same, the emotional damage may be magnified in children. The facial nerve occupies a similar position in children as in adults, but some subtle differences related to development exist. The development of the facial nerve is intimately related to the development of the temporal bone; therefore, the facial nerve will not typically reach its adult course until mastoid development is complete (age 2). Facial nerve development is complete by approximately age 4 (105). Any abnormality of the inner, middle, or external ear, or of the mastoid, may imply an abnormal course for the facial nerve (106). Given the potential for an aberrant nerve course, combined with the long-term consequences of an iatrogenic injury, intraoperative facial nerve monitoring may be beneficial in any pediatric otologic procedure, except in tympanostomy and tube placement.

CONGENITAL AURAL ATRESIA

Iatrogenic facial nerve injury comprises the greatest concern held by parents, patients, and surgeons during repair for congenital aural atresia. This risk, particularly in unilateral cases, dissuades many otologic surgeons from attempting these complicated operations. In these patients, the facial nerve is typically located more anterior and superior than in normal subjects. A wide range of other anomalies have also been reported (107). The incidence of iatrogenic facial paralysis in congenital aural atresia surgery ranges from 0% to 8% (108). Published reports primarily reflect the experience of the authors in their own series, most with extensive experience in this type of surgery. One surgeon describes five instances where the facial nerve is vulnerable to injury during atresia surgery (Table 145.6). From his experience, the nerve is most likely to be injured during canalplasty when drilling through the inferoposterior aspect of the dense atretic bone (108). IOFNM is routinely employed during these operations (109).

Preauricular soft tissue dissection for auricular repositioning during mastoidectomy

MONITORING OTHER CRANIAL NERVES

Although much of this chapter has focused on intraoperative monitoring of CN VII and VIII, skull base surgery can also endanger other cranial nerves, namely, CNs III, IV, V, VI, IX, X, XI, and XII. While the literature is scant, there are studies that have extended the positive experiences with IOFNM to these cranial nerves.

Cranial nerves III, IV, and VI are especially at risk during resection of tumors involving the anterior cranial fossa, the cavernous sinus, the adjacent petroclival region, and the orbit (110). Electrodes were placed into the individual extraocular muscles and spontaneous muscle activity and CMAPs were recorded, demonstrating that intraoperative EMG recordings following bipolar electrical stimulation could identify CN III in 5 out of 7 cases and CN VI in 12 out of 18 cases. However, reproducible recordings from CN IV were unable to be obtained nor were they able to predict postoperative outcomes for CN III or VI (110).

Cranial nerves IX to XII are at risk during operations on large tumors in the cerebellopontine angle, the petroclival region, the rhomboid fossa, the brainstem, the jugular foramen, and the foramen magnum. Damage to these cranial nerves can lead to dysarthria, dysphonia, dysgeusia, and dysphagia, with a potential permanent risk of aspiration (111). Similar to the study of CNs III, IV, and VI, intraoperative EMG was used to monitor these lower cranial nerves (LCN). For EMG monitoring of CN IX, a pair of electrodes was placed (at a distance of 2 to 3 mm) into the lateral aspect of the soft palate ipsilateral to the tumor. A pair of electrodes were placed into the ipsilateral vocalis muscle, trapezius, and tongue in order to monitor CNs X, XI, and XII, respectively. To allow intraoral placement of the electrodes, the patients were intubated transnasally. Intraoperative EMG monitoring proved to be a safe tool for the identification and localization of the LCNs and contributed to their anatomical and functional preservation. However, the predictive value of standard neurophysiologic parameters for functional outcome was limited (111). A study in which 123 skull base cases in which LCNs were monitored concluded that immediate feedback obtained with intraoperative monitoring helps reduce LCN morbidity and assists in gross tumor removal (112).

EMG via contact electrodes integrated into the endotracheal tube (ETT) has been used to monitor the recurrent laryngeal nerve (CN X) and has been extensively used and validated during thyroid and parathyroid surgery (113). Its ease of use makes it an attractive option for intraoperative CN X monitoring during skull base surgery. The main disadvantage of a monitoring ETT is related to the fact that the quality of recording depends on maintaining contact with the vocal cords, and if contact is lost secondary to ETT movement during surgery, the recording may not be interpretable (114). When compared to electrodes placed directly into the vocalis muscle, the monitoring ETT exhibited a lower rate of false-positive response but a lower sensitivity (115). Despite these disadvantages, intraoperative neural monitoring of CN X with a monitoring ETT has gained much support due to its familiarity by anesthesiologists and otolaryngologists during thyroid and parathyroid surgery and its ease of use.

CONCLUSIONS

Intraoperative neurophysiologic monitoring has undergone significant improvements since its nascence in the 20th century, with its applications continuing to grow. Preservation of hearing and facial nerve function is paramount in many otologic and neurotologic procedures. Although the preservation of hearing has yet to reach the same level of success achieved in preservation of the facial nerve function, the technology and our understanding of the neurophysiologic basis of hearing is advancing, and further improvement seems likely. Intraoperative monitoring of the facial and auditory nerves is now in increasing use around the world. Efficacy has been established in improving functional outcomes in cerebellopontine angle tumors and many experts favor its routine use in a wide array of both otologic and neurotologic surgeries, especially when the risk of nerve injury is considered to be high. As we expand neurophysiologic monitoring to other cranial nerves, its role in the preservation of these nerves may prove useful in quality of life outcomes and likely will play a larger role in neurotologic surgery in the future. Regardless, intraoperative neurophysiologic monitoring should serve only as an adjunct to, not a replacement for, extensive preoperative planning, a thorough knowledge of temporal bone anatomy and its common variants, and meticulous technique.

HIGHLIGHTS

- Auditory compromise during surgery can occur via direct injury to the cochlea, internal auditory artery, or the labyrinthine artery, or as a result of cochlear nerve stretching, compression, transection, or thermal injury.
- ECochG, ABR testing, and DENM, often referred to as CNAP, are all techniques used in intraoperative auditory system monitoring.
- ECochG best measures the integrity of cochlear blood supply.
- DENM, or CNAP, monitoring can be used in patients who have an absent preoperative ABR.
- ABR is a far-field technique, whereas ECochG and DENM are near-field techniques.
- Facial nerve injury may occur as a result of transection; direct trauma from drilling, using the ultrasonic aspirator, or dissection; stretch; compression; thermal injury from drilling, cautery, or the laser; vascular compromise; or edema of the nerve from regional dissection.

- The facial nerve may be monitored by mechanical pressure sensing devices, EMG, or direct monitoring of action potentials.
- The A-train as the only intraoperative EMG pattern corresponding to deterioration of facial nerve function.
- Monitoring systems may be augmented by the addition of stimulating probes and dissecting instruments that help identify and map the facial nerve.
- IOFNM should assist the surgeon in identifying the facial nerve, rapidly notify the surgeon when trauma occurs, warn the surgeon as to an aberrant nerve course, evaluate neural integrity at the conclusion of the procedure, and help predict postoperative facial nerve function.
- The use of nondepolarizing muscle relaxants during anesthesia should be avoided in cases where IOFNM is being utilized. Succinylcholine can be used for induction because of its short duration of effect with complete recovery from neuromuscular blockade within 15 minutes.
- IOFNM has proven useful in improving facial nerve outcomes during removal of acoustic neuromas and tumors of the crebellopontine angle, particularly in large tumors.
- Additional applications of IOFNM include vestibular nerve section, skull base surgery, microvascular decompression, cochlear implantation, repair of congenital aural atresia, stapedectomy, and chronic ear surgery.
- Monitoring cranial nerves other than CNs VII and VIII is effective in reducing LCN morbidity and assists in gross tumor removal.
- CN X can be monitored intraoperatively via the recurrent laryngeal nerve with a monitoring ETT.

Diseases of the External Ear

146

Christopher J. Linstrom *Frank E. Lucente*

INFECTIONS OF THE EXTERNAL EAR

Otolaryngologists see many patients with infections of the external ear. The infections may be classified by location, cause, and time course as acute, subacute, and chronic. Before discussing the individual disease processes, we review the normal anatomy and physiology of the external ear.

ANATOMY AND PHYSIOLOGY

The external ear is composed of the auricle and external auditory canal (EAC). Both contain elastic cartilage derived from mesoderm and a small amount of subcutaneous tissue, covered by skin with its adnexal appendages (1,2). There is fat but no cartilage in the lobule. The auricle is derived from six hillocks, three each from branchial arches I and II (Fig. 146.1). During normal gestation, the cartilaginous hillocks merge to form the auricle, and with selective growth of the mandible, the auricle rises from its original position near the lateral commissure of the mouth to the temporal area. The tragus and antitragus form a partial barrier to the entrance of macroscopic foreign bodies.

The EAC is derived from the first ectodermal branchial groove between the mandibular (I) and hyoid (II) arches (2,3). The epithelium lining this groove contacts the endoderm of the first pharyngeal pouch, thus forming the tympanic membrane (TM), the most medial extent of EAC. Connective tissue of mesodermal origin is found between ectoderm and endoderm and becomes the fibrous layer of the TM (2). Because of its origin, the EAC, including the lateral surface of the TM, is derived from ectoderm and is lined by squamous epithelium.

The process of canalization is complete by about week 12 of gestation, at which time the canal fills with epithelial tissue. The canal ordinarily recanalizes by about week 28 of fetal life (3).

The EAC may be thought of in two sections. The outer 40% of the canal in its anterior and inferior aspect is cartilaginous and contains a thin layer of subcutaneous tissue between the skin and cartilage. The inner 60% is osseous, is formed primarily by the tympanic ring, and contains very scant soft tissue between the skin, periosteum, and bone. The average length of the adult EAC is 2.5 cm. Because of the oblique position of the TM, the posterosuperior part of the canal is about 6 mm shorter than the anteroinferior portion (1). The junction of the cartilaginous and bony portions of the canal is a narrowed section termed the isthmus.

Laterally to medially, the canal curves slightly superiorly and posteriorly in a gentle S shape. The canal can be thought of as pointing toward the nose; thus, pull the auricle gently upward, outward, and backward to straighten the canal for examination. Three macroscopic defense mechanisms protect the EAC and lateral surface of the TM: the tragus and antitragus, the skin with its cerumen coat, and the isthmus of the canal.

The skin of the cartilaginous canal contains many hair cells and sebaceous and apocrine glands such as cerumen glands (Fig. 146.2). Together, these three adnexal structures provide a protective function and are termed the *apopilosebaceous unit*. Glandular secretions combine with sloughed squamous epithelium to form an acidic coat of cerumen, one of the primary barriers to infection of the canal. An invagination of the epidermis forms the outer wall of the hair follicle, and the hair shaft forms the inner wall. The follicular canal is the space between these two structures. The alveoli of the sebaceous and apocrine glands empty into short straight excretory ducts, which drain into follicular canals. Obstruction of any part of the ductal system predisposes to infection.

The canal is normally a self-protecting and self-cleansing structure. The cerumen coat gradually works its way past the isthmus to the lateral part of the canal and

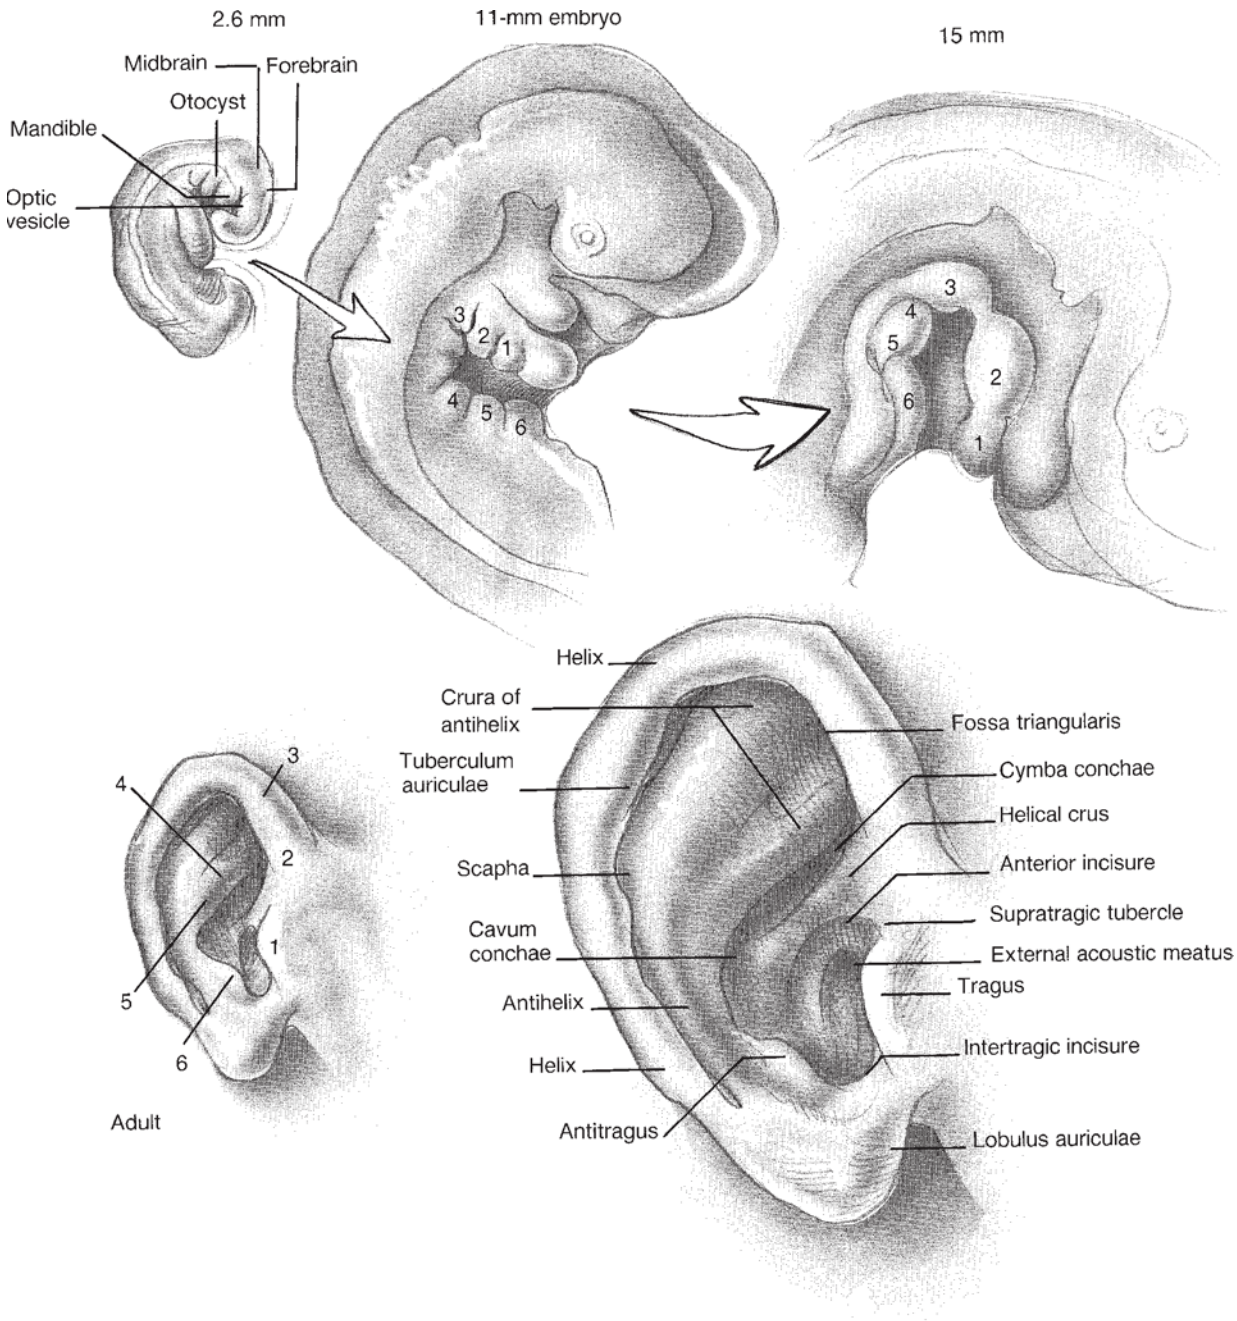

Figure 146.1 The auricle is formed from six auricular hillocks, three each from branchial arches I and II.

sloughs externally. Instrumentation and excessive cleansing of the canal disturb this primary protective barrier and may lead to infection. Individual variations in the anatomy of the canal may predispose some people to wax accumulation.

The canal interfaces on all but its lateral surface. Medially, it is bound by the TM, which when intact is a good barrier to the spread of infection. In the presence of a TM perforation, infection may spread back and forth from the middle ear cleft to the EAC. The horseshoe-shaped tympanic ring separates the canal from the middle cranial fossa. Rarely is this the direct mechanism of intracranial extension of infection. The posterior bony canal serves as the anterior boundary of the mastoid cavity. Several vessels penetrate the canal, especially along the tympanomastoid suture. These may be involved in the hematogenous extension of infection from the canal to the mastoid segment. Posterior to the cartilaginous canal lies dense connective tissue overlying the mastoid, which may become secondarily infected.

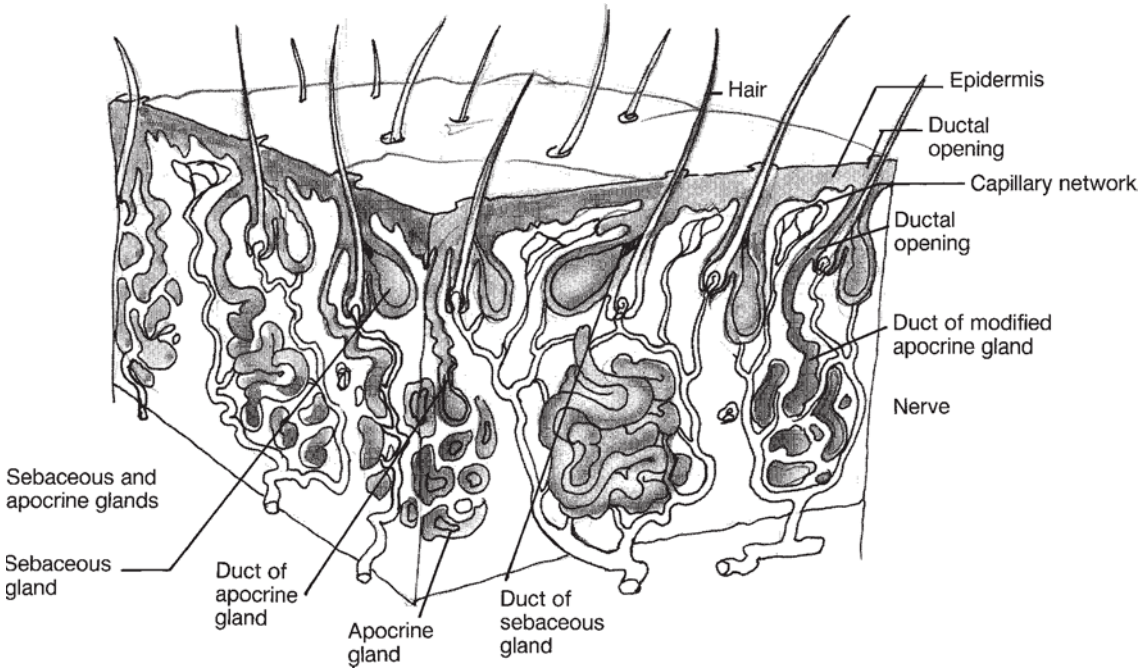

Figure 146.2 Microscopic view of the normal apopilosebaceous unit demonstrating drainage of the secretions of the sebaceous and modified apocrine glands into the follicular canal of the hair.

Superiorly, the canal is bound by the middle cranial fossa and inferiorly by the infratemporal fossa and base of the skull. Infections extending through the roof of the canal may extend into these structures. Anteriorly, the canal is bordered by the temporomandibular joint and the parotid gland.

The lymphatic drainage of the canal is an important channel for the spread of infection. Anteriorly and superiorly, the canal drains to the preauricular lymphatics in the parotid gland and the superior deep cervical nodes. The inferior portion of the canal drains into the infra-auricular nodes near the angle of the mandible. Posteriorly, the lymphatics drain into the postauricular nodes and the superior deep cervical nodes. The auricle and EAC receive their arterial supply from the superficial temporal and posterior auricular branches of the external carotid artery (1). Venous drainage from the auricle and meatus is via the superficial temporal and posterior auricular veins. The former joins the retromandibular vein, which usually divides and joins both jugular veins; the latter joins the external jugular but may also drain to the sigmoid sinus through the mastoid emissary vein (1).

Sensation to the auricle and EAC is supplied from cutaneous and cranial nerves, with contributions from the auriculotemporal branches of the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X) nerves and the greater auricular nerve from the cervical plexus (C2 to C3). The vestigial extrinsic muscles of the ear, anterior, superior, and posterior auricular, are supplied by the facial nerve (VII) (1).

OTITIS EXTERNA

Otitis externa is a spectrum of infection of the EAC. The appearance of the canal varies according to the time course of infection: acute, subacute, or chronic.

Acute otitis externa (AOE) is a bacterial infection of the canal caused by a break in the normal skin/cerumen protective barrier in the milieu of elevated humidity and temperature. Although commonly called "swimmer's ear," AOE may be caused by anything that results in the removal of the protective lipid film from the canal, allowing bacteria to enter the apopilosebaceous unit. It usually begins with itching in the canal and is commonly caused by instrumenting the canal with a cotton swab or fingernail. This temporarily relieves itching but allows proliferation of bacteria in locally macerated skin and sets up an itch–scratch cycle. The warm, dark, moist setting of the canal is now a perfect medium for rapid bacterial growth. Later, pain ensues as the swollen soft tissues of the canal distract the periosteal lining of the bony canal. As the disease progresses, purulent discharge begins, and the auricle and periauricular soft tissues may become involved.

In patients in whom the disease does not resolve after treatment, a subacute or chronic form may occur. This condition may be likened to eczema and is a spectrum of disease ranging from mild drying and scaling of the canal skin to complete obliteration of the canal by chronically infected hypertrophic skin.

HISTORY

The history and functional inquiry should include information regarding the length of time, the number of occurrences, the nature and severity of pain, antecedent otologic disease, previous auricular instrumentation or trauma (especially the use of cotton-tipped applicators), and any predisposing factors such as diabetes or radiotherapy or any condition causing immunosuppression. Any previous otologic or head and neck surgery is noted.

Pain, fullness, itching, and hearing loss are the four major symptoms of external otitis, although not every patient has each symptom (4). Throughout the examination, the examiner should remember the innervation of the EAC and recall that pain from other areas of the upper aerodigestive tract may be referred to the ear.

PHYSICAL EXAMINATION

On initial inspection, look at the ear itself and then at its relation to the head. Is it red, swollen, or protruding? Is there obvious discharge? Are the auricle and periauricular tissues normal in appearance or lichenified, with a heaping up of the normal epidermal architecture? Is there erythema or cellulitis spreading to the periauricular tissues, face, and neck? A gentle tug upward and backward will usually confirm the clinical suspicion. Although not an infallible rule, the patient with AOE usually will not tolerate this maneuver; patients with acute otitis media often will.

To make the correct diagnosis of infections of the external canal and to follow the clinical response to treatment, clean the canal thoroughly and examine it under good illumination. A handheld otoscope will often suffice for a quick examination, but all instrumentation of the ear is best done under the microscope with the patient lying supine in the chair in anticipation of a possible vasovagal response mediated by Arnold nerve, a branch of cranial nerve X.

Although topical and local anesthesia may be tried before cleansing, they are usually of little effect in hyperemic macerated tissue and no substitute for reassurance and patience. Using graduated specula will often ease the patient into a complete examination. The canal may be cleaned with suction, a cerumen loop, or alligator forceps. Gentleness and thoroughness in cleaning the ear are very important.

BACTERIOLOGY

The usual pathogens responsible for AOE are *Pseudomonas aeruginosa*, *Proteus mirabilis*, staphylococci, streptococci, and various gram-negative bacilli. For the mild or uncomplicated infection, culture of the canal is ordinarily not taken, because it will usually demonstrate a mixed pattern of growth. For recalcitrant infections, culture may identify a predominant organism and assist in the choice of antibiotic therapy.

STAGING

The clinical course of external otitis may be divided into the following stages: preinflammatory; acute inflammatory, which can be mild, moderate, or severe; and chronic inflammatory. Typically, the preinflammatory stage begins when the stratum corneum becomes edematous due to the removal of the protective lipid layer and acid mantle from the canal, resulting in plugging of the apopilosebaceous unit. As obstruction continues, a sense of fullness and itching begins. The disruption of the epithelial layer allows invasion of bacteria that either reside in the canal or are introduced on foreign objects inserted into the canal, such as a cotton swab or a dirty fingernail. This produces the acute inflammatory stage, which is accompanied by pain and tenderness of the auricle. In the earliest stage, the skin of the EAC shows mild erythema and minimal edema (Fig. 146.3). A small amount of clear or slightly cloudy secretion may be seen in the canal. As pain and itching increase, the patient progresses to the moderate stage, in which the canal shows more edema and a thicker more profuse exudate (Fig. 146.4). Further progression of the inflammation in the absence of treatment produces the severe inflammatory stage, characterized by increased pain and obliteration of the lumen of the canal. A profuse, purulent exudate and edema of the canal skin may obscure the TM. In addition, small white papules are often visible on the surface of the canal skin. *P. aeruginosa* or another gram-negative bacillus can almost always be cultured at this stage. In the severe stage, the physician often sees evidence of extension of infection beyond the canal to involve the adjacent soft tissues and cervical lymph nodes (Fig. 146.5).

In the chronic inflammatory stage, the patient experiences less pain but more profound itching. The skin of the external canal is thickened, and superficial flaking may be seen (Fig. 146.6). The auricle and concha often show secondary changes such as eczematization, lichenification, and superficial ulceration. This condition is likened to eczema and may range from mild drying and thickening of the canal to complete obliteration of the external canal by chronically infected, hypertrophic skin (Table 146.1).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of conditions that are similar to external otitis is large and includes necrotizing otitis externa, bullous external otitis, granular external otitis, perichondritis, chondritis, relapsing polychondritis, furunculosis, and carbunculosis, as well as many dermatoses, such as psoriasis and seborrheic dermatitis. All have features in common with acute and chronic external otitis,

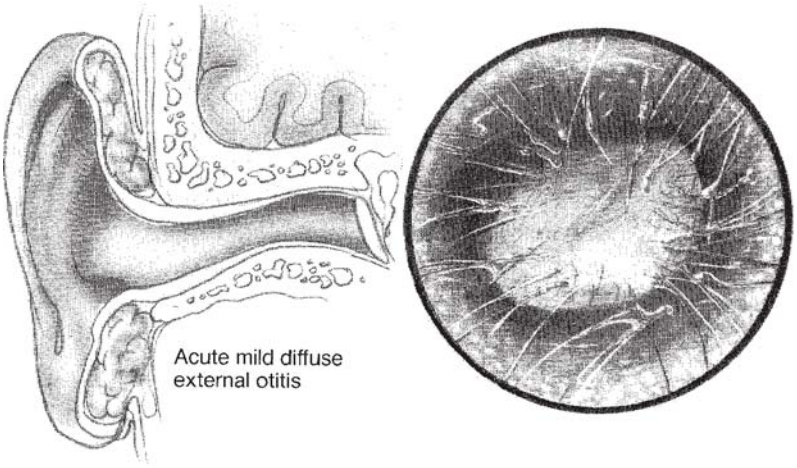

Figure 146.3 Otitis externa, acute inflammatory stage. Mild erythema and edema of the canal skin are seen. Clear secretions may be seen in the canal. (From Senturia BA, Marcus MD, Lucente FE. *Diseases of the external ear*, 2nd ed. New York: Grune & Stratton, 1980, with permission.)

yet have enough dissimilarities to be considered distinct clinical entities.

Carcinoma involving the EAC may present as infection and in its earliest stages is often mistaken for infection and treated inappropriately. The most common malignant neoplasm of the external ear is squamous cell carcinoma, although other primary carcinomas, such as basal cell carcinoma, malignant melanoma, ceruminous adenoma or adenocarcinoma, and adenoid cystic and metastatic carcinomas to the temporal bone with extension to the EAC such as breast, prostatic, small (oat) cell, and renal cell carcinomas, have been described. The occurrence of pain in an old previously stable mastoid cavity is the hallmark of carcinoma and must be excluded by biopsy and other investigations.

NATURAL HISTORY

The natural history of untreated AOE is one of increasing pain, swelling, and discharge from the canal. The infection may spread to the adjacent periauricular soft tissues, face, and neck. In an immunocompromised patient, what began as an isolated superficial infection of the apopilosebaceous unit of the EAC may progress to perichondritis, chondritis, cellulitis, and erysipelas. Rich lymphatic and hematogenous drainage pathways favor the spread of infection to local and regional sites in the head and neck. Few patients progress to such an advanced stage before seeking medical attention.

The natural history of chronic otitis externa is far less dramatic than its acute counterpart. The chronic scaling and itching in the canal predispose to manipulation of the canal, excoriation, and repeated episodes of AOE. With time, the canal skin may become lichenified, and ultimately the canal may become completely obliterated.

MEDICAL TREATMENT

The four fundamental principles in the treatment of external otitis in all stages are frequent and thorough cleaning, judicious use of appropriate antibiotics, treatment of associated inflammation and pain, and recommendations

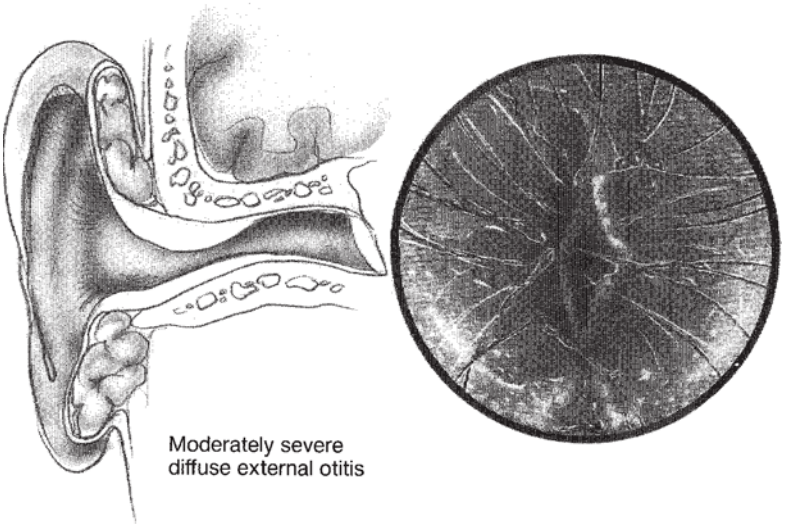

Figure 146.4 Otitis externa, moderate acute inflammatory stage. The EAC is more edematous than in the acute stage, approaching obliteration of the lumen, with a more profuse exudate. regarding the prevention of future infections. In any stage of infection, thorough cleaning is a priority. Meticulous debridement of exfoliated debris, purulence, and cerumen will do as much if not more than simply placing the patient on ear drops. In the preinflammatory stage, a complete cleaning may be all that is required. In the absence of purulence, a brief course of an acidifying drop such as aluminum sulfate–calcium sulfate (Domeboro) is efficacious in discouraging bacterial or fungal growth.

Treatment of the acute inflammatory stage varies with the extent of disease. In the mildest form, cleaning as above is indicated. An antibiotic otic drop is recommended to cover what is probably a *Pseudomonas infection*. At this stage, edema of the EAC should not be severe, and the patient should be able to instill drops into the ear by tilting the head to the side or by lying down with the involved ear upright.

MODERATE STAGE

In the moderate stage of inflammation, edema of the canal may interfere with the instillation of drops. The physician should then insert a wick into the canal and instill drops on it. Often the canal may accommodate two or even three wicks. As the wick expands, it presses the soft tissues and periosteum toward the nondistracted position; this alone may relieve pain. All instrumentation of the ear is best done under the microscope. The wick is removed by the

physician at the time of reexamination. If the edema has not been significantly reduced, repacking is indicated. Antibiotic drops should be continued for at least 2 to 3 days after the cessation of pain, itching, and drainage so that complete eradication of infection may be ensured.

In the moderate stage, an oral analgesic is often prescribed because pain can be pronounced. Caution the patient to avoid manipulation of the canal. Swimmers should be taught to towel dry the concha and lateral canal, to shake water out of the canal, or to instill an acidifying drop after swimming. If the infection has not spread beyond the boundaries of the external canal, the use of oral antibiotics will be of little if any value. A final office visit is important to ensure that the infection has completely resolved and the canal is back to its normal state.

SEVERE STAGE

In the severe stage, infection usually extends beyond the limits of the canal. In addition to the cleaning, packing, and use of antibiotic drops as discussed previously, attend to any soft tissue involvement by using an oral antibiotic with broad-spectrum coverage. Successive generations of the cephalosporins widen gram-negative coverage at the expense of gram-positive coverage.

In addition to anti-*Pseudomonas* ear drops, common choices of oral antibiotics are one of the antipseudomonal fluoroquinolones such as ciprofloxacin or levofloxacin, antistaphylococcal penicillins, or cephalosporins. The fluoroquinolone antibiotics are effective against *Pseudomonas* species. In children under 12 years old, one should check with the pediatrician prior to starting oral fluoroquinolones.

Warm soaks (normal saline or a mild aluminum sulfate–calcium acetate solution) are also useful in the treatment of the crusting and edema involving the auricle and surrounding skin. Culture of the canal for aerobic bacteria and/or fungi is indicated only for the severe stage or for patients who have previously been treated without resolution. Treatment is generally continued for 10 to 14 days if there is a good response. In rare patients who do not respond to this regimen, hospitalization, vigorous daily local care, repeat culturing, and intravenous antibiotics are indicated.

CHRONIC STAGE

The chronic stage of external otitis is manifested by marked thickening of the skin of the EAC due to long-standing infection. Examination reveals flakes of dry scaly skin in the canal. Although removal of debris is recommended, this may be difficult due to the narrowing of the lumen of the canal. Repeated cleaning and instillation of antibiotics and steroids are indicated. Triamcinolone acetonide 0.25% cream or ointment (Kenalog), fluocinolone 0.01% oil (DermOtic), or dexamethasone sodium phosphate 0.1% ophthalmic drops (Decadron, Pred Forte 1%) may be used.

In all cases of acute or chronic external otitis, instruct the patient to avoid future infections by not instrumenting the ear. Foreign objects such as Q-tips often excoriate the canal skin and push debris further into the canal rather than remove it. Patients who have repeated infections despite adhering to these measures are best advised to use an acidifying drop composed of equal measures of vinegar and water, or ethyl alcohol and water, when exposed to high humidity. One should suspect otomycosis if all other reasonable measures have failed and should treat with drying agents, especially powders. Custom-made ear molds are useful for these patients.

RECALCITRANT OTITIS EXTERNA

The physician will be able to judge very quickly which patients are responding. Prolonged antibiotic drops may suppress the normal flora of the external canal from returning and lead to a fungal superinfection. This should be suspected, especially if a grayish matted discharge is found in the ear, even if telltale hyphae are absent. A culture may have already been taken, and the result should help to direct treatment. Again, the ear must be thoroughly and meticulously cleaned, and if a fungus has been cultured such as *Candida*, this should be treated appropriately with drying agents such as powders and an antifungal drop or even systemically with an oral antifungal medication such as fluconazole. If no progress is made in the office, the rare patient may have to be admitted as an inpatient. Examine the ear under a microscope and carefully clean it frequently. Look for subtle signs of chronic middle ear disease—granulation tissue or the opening of a tiny perforation. The latter may be obscured by a swollen TM, giving a "fish-mouth" appearance to the perforation. A "sewer cap" of crust on the drum may reveal a cholesteatoma underneath. Examine every part of the auricle carefully. Look for signs of underlying chondritis or perichondritis, especially diffuse crusting or exudative weeping. Culture the ear (for aerobes, anaerobes, and fungi). Examine the periauricular tissues carefully to look for signs of spreading infection. Computed tomography of the temporal bones may give additional information. Look for opacification of the mastoid and signs of bony erosion.

Place the patient on daily aural drops, preferably one covering *P. aeruginosa*, and intravenous antibiotics with gram-positive and gram-negative coverage. One may wish to try intravenous ciprofloxacin to start. In very rare cases, a cephalosporin together with an aminoglycoside is a logical combination if monotherapy does not improve the ear. Therapy should be tapered according to culture and sensitivities. Severely swollen ears may calm down with steroids.

TABLE 146.2 COMPLICATIONS OTITIS EXTERNA

- Cellulitis
- Erysipelas
- Perichondritis
- Chondritis
- Chronic nonresolving rate

Many recalcitrant infections occur because of noncompliance or chronic instrumentation of the canal skin. The patient should be counseled to amend bad habits. The rare patient will need to be admitted for intravenous antibiotics and daily aural toilet (Tables 146.2 and 146.3).

SURGICAL MANAGEMENT OF HYPERTROPHIC CHRONIC OTITIS EXTERNA

When such local measures are insufficient to eradicate infection and reestablish the lumen of the canal, it is necessary to remove the involved canal skin and any adjacent involved cutaneous or cartilaginous tissue. This is very rarely required and may be performed through the canal but is better done through a postauricular incision, which allows visualization of the involved tissues. A generous amount of conchal cartilage is removed to effect a wide meatoplasty. The bony canal is enlarged with a drill. Take care to protect the facial nerve in its vertical segment; the use of an intraoperative facial nerve monitor facilitates this. The canal is resurfaced with a split-thickness (8:1,000 inch) skin graft that is temporarily held in place with stents or packing.

It is the experience of many otolaryngologists that even the most recalcitrant infection can be managed if the four basic principles—thorough cleaning, antibiotic treatment, pain control, and instruction of the patient—are meticulously followed. There is no substitute for thorough and repeated local care (Table 146.4).

SKULL BASE OSTEOMYELITIS, FORMERLY NECROTIZING (MALIGNANT) OTITIS EXTERNA

This potentially life-threatening disease should be viewed within the larger context of osteomyelitis of the temporal bone and skull base. Thanks in large part to newer anti-*Pseudomonas* antibiotics, chief among them the fluoroquinolones, skull base osteomyelitis (SBO) is not as prevalent as it was even a decade ago. By no means is it a disease of the past, especially among diabetics, the immunocompromised, and the elderly. The otolaryngologist must still keep SBO within the differential diagnosis of a refractory external ear infection in the patient at risk.

Toulmouche (5) described a case of progressive osteomyelitis of the temporal bone in 1838 that was probably the first reported case of necrotizing external otitis (NEO). In 1959, Meltzer and Kellemen (6) described a case of progressive *Pseudomonas osteomyelitis* of the temporal bone and skull base. Chandler (7–11) is credited with the clinical description of what he termed malignant otitis externa in 1968 and thereafter. Although many early cases ended in the death of the patient, the entity does not ordinarily involve carcinoma, and thus, the more appropriate term used today is SBO, which is a proper description of the pathophysiology and clinical entity.

DIAGNOSIS

The diagnosis of SBO is made in a patient with the appropriate history, physical examination, and supporting laboratory findings. Four salient features are found (12): persistent, deep-seated severe otalgia for longer than 1 month; persistent purulent otorrhea with granulation tissue for several weeks; diabetes mellitus, another immunocompromised state, or advanced age; and cranial nerve involvement.

Other diseases to be included in the differential diagnosis include severe AOE, squamous cell carcinoma,

glomus jugulare tumor, cholesteatoma, nasopharyngeal carcinoma, Hand-Schüller-Christian disease, eosinophilic granuloma, Wegener granulomatosis, clival chordoma, and meningeal or squamous cell carcinoma (13,14). The physician's index of suspicion should be high so that no patient is denied aggressive treatment when appropriate (Table 146.5).

CLINICAL AND RADIOGRAPHIC FINDINGS

SBO usually begins as an acute external otitis that does not resolve despite medical therapy, as described previously. The history is significant for a long-standing infection of the external canal accompanied by aural discharge and severe deep-seated pain. The disease is usually found in elderly diabetic patients in poor metabolic control, although it may be found in any chronically ill, debilitated, or immunocompromised patient (15). The HIV status of the patient should be known.

On physical examination, most patients with SBO have granulation tissue visible in the inferior aspect of the canal or even extruding from it. This may obscure the TM. It is rare to see granulation tissue in patients with routine otitis externa; however, granulations are common in an acute exacerbation of chronic otitis media with perforation of the TM. The skin of the canal is often erythematous, indurated, and sometimes macerated. Purulent secretions are common.

The causative organism is almost always *P. aeruginosa*, although other organisms such as *P. mirabilis, Aspergillus fumigatus, Proteus* sp., *Klebsiella* sp., and *Staphylococcus* sp. have been isolated (8,14).

The natural history of SBO is one of relentless progression to involve the cranial nerves, especially the facial nerve. Pain is inexorable and is deep seated. Damiani et al. (16) reported that the most commonly involved cranial nerves were VII (75%), X (70%), and XI (56%). More recent reports have estimated the facial nerve to be involved in at least one-fourth of patients, with less frequent involvement of cranial nerves IX, X, and XI (17).

Computed tomography of the temporal bone with contrast is the initial radiograph to be done, yielding excellent bony detail with less precise information about soft tissue. It may define subtle bony changes such as erosion of the anterior canal wall with involvement of the temporomandibular joint and erosion of the tympanic ring and base of the skull. It may demonstrate soft tissue thickening and mastoid clouding (18).

Magnetic resonance imaging without and with gadolinium enhancement may be advantageous in defining the medial extent of disease at the skull base. Dural enhancement and involvement of the medullary bone spaces are seen with central skull base invasion. Underlying cerebral involvement is easily visualized with gadolinium-enhanced magnetic resonance imaging. Magnetic resonance imaging yields very imprecise information about bone. The patency of the dural sinuses and great vessels of the neck may be assessed in a noninvasive fashion with magnetic resonance angiography or venography (19). Changes seen on MRI do not quickly resolve with clinical improvement. Thus, MRI is a useful diagnostic tool to assess the extent of disease but less useful to follow the clinical course of SBO (20).

Tc-99m bone scanning and Ga-67 scanning have been advocated in the evaluation of SBO (17,21). Their sensitivity for the presence of infection is far greater than their specificity for the cause. Tc-99m scanning gives excellent information about bone function but poor information about bone structure. A positive scan is thought to represent osteoblastic activity as little as 10% above normal. The scan is positive in acute and chronic osteomyelitis and in areas of active bone repair without infection, as in trauma. Its use in the evaluation of SBO is complementary to that of Ga-67 scanning. Ga-67 is thought to be incorporated into proteins and polymorphonucleocytes at sites of active infection as a Ga-67–lactoferrin complex. It will highlight an acute infective focus but not the full extent of an osteomyelitic process. As treatment progresses, the Ga-67 scan will revert to normal (negative). The Tc-99m scan will lag behind for many months. Baseline studies of both are thus recommended, and sequential imaging is used to monitor the response to therapy. Indium-111–labeled leukocyte (In-WBC) planar scintigraphy has been demonstrated to yield better results for the detection of osteomyelitis than either planar or tomographic Ga-67 and/or Tc-99m-methyline diphosphonate and may replace the former two radionuclide modalities in the evaluation of

SBO-suspected patients (17,21). It is best to consult with nuclear medicine to determine which of these various choices will be best.

MEDICAL TREATMENT

Swab and/or tissue cultures of the EAC should be obtained. If present, granulations should be biopsied and sent to rule out carcinoma or another pathologic entity. *P. aeruginosa* is almost always cultured. Because *Pseudomonas* is so frequently the predominant organism, the patient is treated with anti-*Pseudomonas* antibiotics for an extended period, often for 6 weeks or more. Two antibiotics, one an antipseudomonal antibiotic and the other an aminoglycoside, that is, each from a different class, are ordinarily chosen because of the synergy achieved with the use of two antibiotics and to avoid the emergence of a resistant strain of bacteria. Monotherapy is discouraged in the treatment of SBO. Usually two anti-*Pseudomonas* antibiotics are chosen from several alternatives, including gentamicin or tobramycin with or without ticarcillin or piperacillin. Alternative antibiotics include mezlocillin or azlocillin, ceftazidime, imipenem, aztreonam, amikacin, norfloxacin, and ciprofloxacin or any of the other appropriate anti-*Pseudomonas* fluoroquinolones (22). If an aminoglycoside is chosen, peak and trough levels and hearing must be carefully monitored. It is wise to treat in concert with an infectious disease colleague to help select those medications that will be of greatest benefit with the least toxicity.

Because of the high tissue levels seen with oral fluoroquinolones, the apparent incidence of SBO has fallen. However, the physician should not be lulled into a false sense of security. Many patients with poor microvasculature, especially diabetics, may achieve cidal concentrations of an antibiotic solely with intravenous administration. Patients refractory to intravenous administration of antibiotics may require surgical control of the infected site. Emergence of resistance to ciprofloxacin has been reported in 20% of long-term (6 weeks or more) therapy for osteomyelitis (21).

Certainly if the ear remains purulent despite adequate intravenous antibiosis and local care, repeat cultures should be taken to look for the emergence of a resistant organism.

An early clinical feature of success in treatment is the cessation of pain, and patients may be tempted to discontinue therapy once this occurs. Regardless of the choice of medication or mode of delivery, patients must understand that they will require meticulous aural toilet and antibiotic treatment for at least 6 weeks and vigorous management of the serum glucose.

Either in the hospital or in the office, the ear is debrided carefully under the microscope on a regular basis until granulations have subsided. The patient is placed on anti-*Pseudomonas* otic drops and appropriate systemic antibiotics. Diabetes is aggressively managed, usually with the aid of an internist or endocrinologist. The diet is carefully monitored with the aid of the nutritionist.

Hyperbaric oxygen has been advocated by Shupak et al. (23). Hyperbaric oxygen is thought to facilitate osteoneogenesis and to promote repair of diseased bone and thus may be of value in the most severe cases. The cost and inconvenience of hyperbaric oxygen therapy have limited its availability. Its use is recommended for advanced disease with significant skull base or intracranial involvement, recurrent disease, and infections refractory to antibiotic treatment (17,23).

Surgical Treatment

Most patients can be managed medically, and the role of surgery in SBO remains controversial. Surgical debridement of tissue and osteomyelitic bone is usually reserved for patients who do not respond to conventional therapy. Tissue may be obtained for culture in these refractive cases to look for resistant organisms or for a new organism such as an invasive fungus. Progression of pain despite aggressive medical therapy, persistence of granulations, and the development of cranial nerve involvement are all ominous signs that call for more aggressive medical therapy and possibly surgical intervention.

With the onset of clinical facial paralysis, early surgical removal of granulations and, when necessary, decompression of the descending facial nerve have given excellent return of function. The primary surgical goal is to relieve the entrapped nerve and to allow its natural return of function. Serial electroneuronography (ENOG) has been used to determine the electrical degeneration of the VII nerve in patients with clinically complete facial paralysis. An ENOG showing greater than 90% electrical degeneration of the facial nerve may support surgical decompression of the involved segment of the nerve. The entire concept of facial nerve decompression in the context of SBO remains controversial. The mainstay of therapy for SBO is medical and not surgical.

John and Cheesman (24) have advocated wide local excision of infected cartilage and soft tissues if pain persists after medical treatment or if facial palsy occurs. Reines and Schindler (25) have reported three cases in which subtotal temporal bone resection was performed to gain access to the primary focus of infection and provide adequate drainage. Surgical treatment including abscess drainage, debridement of sequestra, and more extensive resection should be individualized depending upon the patient's overall health status and response to more conservative measures (26).

The first author performed his very first mastoidectomy under *local* anesthesia in a 90-year-old lady with SBO and a large abscess of the surrounding bone and soft tissues. She had failed two previous 6-week courses of intravenous

antibiotics. Her family was very involved and requested surgical intervention. She improved, was discharged, and lived another 4 years after surgery. She died of old age and not of SBO.

Mortality remains significant, especially in the immunocompromised patient. Progression of disease results in severe unremitting pain within the ear and at the base of the skull and extension of infection to the mastoid, parotid, lower cranial nerves, and transverse and sigmoid sinuses. Osteomyelitis of the skull base may lead to meningitis, brain abscess, and death. Poor prognostic factors include facial paralysis, polyneuropathy, and intracranial extension (27).

The diagnosis and management of patients with SBO remains an otolaryngologic challenge. Perhaps the greatest advance in its treatment has been the recognition of SBO as a distinct entity and a clear understanding of its pathophysiology. A team approach involving the cooperation of otolaryngology, endocrinology, and infectious disease may enhance the overall outcome (Tables 146.6 to 146.8). The devastating disease reported by Chandler (7) in his classic 1968 article has significantly changed. The advent of the fluoroquinolones and other anti-*Pseudomonas* antibiotics has significantly lowered the morbidity and mortality associated with SBO.

Conditions Related to External Otitis

Several other infectious and inflammatory diseases are included in the differential diagnosis of otitis externa.

Radiation-Induced Otitis Externa

Another form of otitis externa occasionally occurs after radiotherapy of the region of the external ear. The predominant symptoms result from the inflammation and infection that occur when radiotherapy weakens local defense mechanisms and resident bacteria flourish. When limited to the skin of the EAC, treatment measures with particular attention to water avoidance are appropriate. In the worst form of osteoradionecrosis with purulent infection, sequestra of devitalized tissue should be removed and replaced with vascularized tissue. The removal of what has become the nidus of infection is a basic surgical principle. This is fortunately a very rare thing.

- Progression despite aggressive local care (to mastoid, parotid, lower cranial nerves, base of skull, dural venous sinuses, brain)
- Meningitis
- Brain abscess
- Death

Bullous External Otitis

Bullous external otitis is a very painful condition in which vesicles or bullae are noted in the bony portion of the external canal. The vesicles are commonly hemorrhagic and should not be ruptured, because secondary infection may ensue. Because *Pseudomonas* may be one of the causative organisms, appropriate otic drops are recommended. Packing and irrigation of the canal should be avoided, because they tend to prolong the course of this disease.

Granular External Otitis

Granular external otitis often resembles the earliest stage of NEO in that there may be small granular plaques or pedunculated granulations in the external canal. This condition may occur in patients who have not been fully treated for a previous episode of external otitis. It may also occur as a result of contact dermatitis, for example, exposure to hairspray. After topical or local anesthesia, removal of granulation tissue, placement of a wick in the canal, and the instillation of antibiotic drops will usually resolve the problem. Oral antibiotics should be given if the infection extends beyond the canal. If the patient is diabetic or debilitated, the diagnosis of NEO is entertained and treated appropriately.

TABLE 146.8 EMERGENCIES NECROTIZING EXTERNAL OTITIS

Any complications in Table 146.7 (in living patient)
- Change antibiotic
- Increase level of daily care
- Consider surgery

Perichondritis and Chondritis

Perichondritis, inflammation of the perichondrium, and chondritis, inflammation of cartilage, may follow or complicate infections of the EAC or result from accidental or surgical trauma to the auricle. The condition is painful, and the patient often complains of severe itching deep within the canal. With time, the skin over the affected area becomes crusted with squamous debris, and the involved cartilage begins to weep. The ear is indurated and erythematous; often the canal swells shut. The surrounding soft tissues of the face and neck may become involved.

In the mildest stages, thorough debridement and treatment with topical and oral antibiotics are generally sufficient. If these measures do not succeed, the ear is debrided again, and cultures are taken. Appropriate treatment for common pathogens, especially *Pseudomonas*, is begun and tapered according to culture results. Ciprofloxacin is a logical choice for moderate stages, combined with an anti-*Pseudomonas* drops such as gentamicin or a fluoroquinolone drops.

If the infection spreads to involve regional soft tissues and lymphatics, the patient should be hospitalized and parenteral treatment with adequate coverage for *Pseudomonas* begun. In difficult cases, the ear should be cultured before starting treatment. With recalcitrant infections, the help of an infectious disease consultant is necessary. At every stage of the disease, frequent and thorough debridement of the canal is essential. The metabolic requirements of cartilage are low, and its blood supply is appropriately diminished. Once infection has become established in the perichondrium or cartilage, it is extremely difficult to treat. If subacute or chronic infection evidenced by inexorable weeping continues, surgical intervention is indicated. This is best done in the operating room under controlled conditions.

The affected area is cleansed and injected with local anesthetic containing epinephrine. Skin flaps are appropriately planned and the dissection taken down to the affected cartilage. If it has lost its normal "pearly white" appearance, it is most likely necrotic and should be excised. Often necrosis extends farther than that which can be grossly visualized. Small irrigation drains are placed beneath the flaps and sutured to the skin. The skin flaps are closed. The drainage ports are irrigated with antibiotic irrigation such as bacitracin (50,000 U of bacitracin dissolved in 250 mL of normal saline). The drains are advanced as the condition resolves. Parenteral antibiotics, otic drops, and aggressive local care continue until the infection has resolved.

Relapsing Polychondritis

Relapsing polychondritis is an intermittently progressive disease marked by inflammatory destruction of cartilage. Although thought to be an autoimmune disorder, the exact cause is unknown. Cartilage of the external ear, larynx, trachea, bronchi, and nose may be involved. Symptoms are episodic, with fever, anemia, erythema, swelling, pain, and an elevated sedimentation rate during acute episodes. As the disease progresses, symptoms of increasing respiratory obstruction become apparent. Labyrinthine disturbances are rarely present. The diagnosis is made on the basis of the history and physical examination, supported by an elevated sedimentation rate. Biopsy of involved cartilage may show necrosis, inflammation, and fibrosis. Treatment is with oral corticosteroids, rarely with intravenous steroids.

Furunculosis and Carbunculosis

Furunculosis and carbunculosis are conditions resulting from gram-positive infections, usually staphylococcal, of the hair follicles. The primary lesion is usually a small well-circumscribed pustule that may enlarge to become a furuncle or merge with several similar lesions to form a carbuncle. The infection occurs most commonly at the junction of the concha and canal skin.

For treatment to be successful, any accumulated infectious material must be removed. Spontaneous drainage can often be encouraged by the use of warm soaks, supplemented by topical and oral antibiotics and wicks if necessary. If this fails to relieve obstruction of the canal, incision and drainage (I & D) under local anesthesia are indicated.

Infectious Eczematoid Dermatitis

Infectious eczematoid dermatitis results from the drainage of contaminated or purulent material from the middle ear into the floor of the external ear and adjacent infra-auricular skin (Fig. 146.7). This drainage causes a secondary infection or an autosensitization phenomenon manifested by crusted plaques in the canal. Treatment is directed at control of the underlying middle ear infection. Supportive treatment of the external canal reaction consists of removal of accumulated debris, application of sterile saline soaks to the crusted areas, and application of an antibiotic cream or ointment.

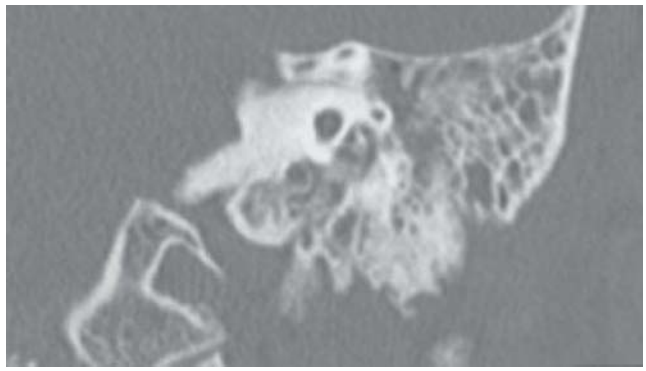

Figure 146.7 Infectious eczematoid dermatitis with inflammation and crusting of the skin of the canal and auricle secondary to drainage of purulent material through a TM perforation in a patient with chronic otitis media.

Otomycosis

Otomycosis is a fungal infection of the skin of the external canal. Although fungi may be the primary pathogens, they are usually superimposed on chronic bacterial infection of the external canal or middle ear. Secondary otomycosis tends to recur if the underlying primary infection is not controlled. All fungi have three basic growth requirements: moisture, warmth, and darkness. Altering moisture will discourage fungal growth. *Aspergillus* species are the most common, usually *A. niger.* If aural culture should grow *A. fumigatus or A. flavus*, one would be concerned about a more invasive infection.

Pruritus is the primary clinical complaint. The otoscopic examination commonly reveals a white, black, or dotted gray membrane. Thorough cleaning under a microscope with the patient supine to remove any fungal debris is the first and absolutely most important step in therapy. Thorough aural toilet is supplemented by the topical application of an acidifying solution such as aluminum sulfate–calcium acetate (Domeboro) or by a drying powder such as boric acid. Clotrimazole cream or solution (Lotrimin) may also be used. In the presence of a TM perforation or a patent ventilation tube, clotrimazole drops or lotion may be very painful. Thorough cleaning and drying therapies such as powders are best. Metacresyl acetate (Cresylate) may be painted on the margin of a perforation or an infected ventilation tube. This is best done under the microscope. This medication should not enter the middle ear cleft because it is quite irritating. In recalcitrant infections, a foreign body such as a ventilation tube acts as the nidus for infection and should be removed. Tympanoplasty is best performed to close a perforation that intermittently drains with a superimposed fungal infection.

Gentian violet is usually well tolerated in patients with mastoid cavities, although it is best left out of the middle ear cleft in the presence of a perforation. Because it will permanently stain skin and clothing, small amounts are used with adequate protection of the surrounding area.

Treating physicians should realize that all drops are formulated with moisture and do not persist indefinitely in an homogenized state. Eventually, the water component will separate from the precipitate of the active medical ingredient. Water is exactly what fungi need to grow. Adding drops indefinitely to an ear with otomycosis may prove counterproductive. In these cases, an acidifying powder such as boric acid or a compounded powder, as described below, will often help dry up a refractory ear.

Many patients with refractory otomycotic infections may have had previous mastoid surgery. Often the canal wall is down. Due to moderate to severe hearing loss, the patient may need to wear a hearing aid with a closed mold. This is a significant problem because the patient relies on the aid virtually all day and is reluctant to leave the instrument out. Careful instruction to the patient, meticulous debridement of the ear, and the use a drying agent such as boric acid powder, Chloromycetin–sulfanilamide–Fungizone (amphotericin B) powder or Chloromycetin–sulfanilamide–Tinactin (tolnaftate) powder will often help clean up the cavity. Ointments in cavities with closed hearing aids may promote fungal growth due to the accumulation of moisture. In refractory cases, gentian violet or metacresyl acetate (Cresylate) is used topically.

Herpes Zoster and Herpes Simplex

Herpes zoster and herpes simplex are viruses known to affect the EAC. The patient initially experiences a period of burning, pain, or localized headache, and vesicles usually appear within several days. When vesicles coalesce and rupture, crusts are formed. Herpes zoster tends to appear unilaterally in a dermatomic distribution. Involvement of the facial nerve may produce paresis or paralysis (herpes zoster oticus or Ramsay Hunt syndrome), named after Dr. James Ramsay Hunt (1872 to 1937), of late termed Hunt Syndrome. Treatment is supportive, with topical application of a drying agent, such as hydrogen peroxide for crusts. The status of the facial nerve is carefully followed; surgical decompression of the facial nerve may be a consideration if it is clinically paralyzed and electrical criteria are met by ENOG testing. Many patients excoriate the blisters, and bacitracin ointment or a suitable substitute should be applied to prevent superinfection. Acyclovir, famciclovir, and valacyclovir have been shown to ameliorate herpetic infections, especially herpes zoster oticus. The latter two have easier dosing schedules and are better absorbed orally than acyclovir. Also, famciclovir may reduce the duration of post herpetic neuralgia. However, it will cause a transitory rise in hepatic enzyme production and must be used with caution.

Dermatoses

Allergic and irritant contact dermatoses may mimic diffuse external otitis. These result when the susceptible patient comes in contact with any type of agent that can produce a cutaneous response. Irritants may be absolute, so noxious that a reaction occurs in everyone exposed (e.g., strong acids or alkalis), or relative, noxious to susceptible individuals, usually after repeated exposures (e.g., various soaps, the plastic mold of a hearing aid). Allergic contact dermatitis refers to delayed hypersensitivity reactions resulting from substances such as poison ivy, nickel compounds (earrings), and rubber compounds (headphones). The typical reaction presents as erythema, weeping, and vesiculation accompanied by itching. The patient may produce a secondary infection by scratching. Treatment consists of removal of the causative agent and the use of topical steroids and astringents. Topical or systemic antibiotics are indicated for the treatment of infection. Systemic steroids may be indicated for severe cases. In rare cases, for example, the patient with a cochlear implant and hypersensitivity to

plastic, the external, ear-level receiver/stimulator may be painted with a different material or covered with a cloth casing to separate it from the skin.

External Ear Disease and HIV Infection

Among the external ear manifestations in HIV disease is Kaposi sarcoma, which presents with reddish-blue lesions typically described as hemorrhagic nodules (28). The lesions may be discrete or confluent. Although chemotherapy, radiotherapy, and interferon-α have been used for therapy, treatment of auricular and canal lesions is rarely necessary. Infections of the external ear in HIV-infected patients include both typical and atypical pathogens. Recurrent herpetic infections and *Pneumocystis carinii*–infected aural polyps have been reported in the EAC as a result of chronic otitis media (29).

Another external ear manifestation of HIV disease is seborrheic dermatitis, which tends to be more widespread and refractory to treatment than the same condition in HIV negative patients. NEO in the HIV+ patient adds another level of concern regarding its treatment. An infectious disease consultant should be involved in the overall care of the HIV+ patient. The advent of the protease inhibitor medications in the mid-1990s not only saved lives and emptied the infectious disease wards of most hospitals but also made these otologic manifestations exceedingly rare.

Traumatic Disorders of the External Ear

Blunt Injuries

Shearing forces to the auricle, commonly seen in sports such as boxing and wrestling, may disrupt the normal perichondrium of the auricular cartilaginous framework, causing seroma or hematoma formation. The lobule is composed primarily of fat covered with skin and is less susceptible to injury. Because it is malleable throughout life, auricular cartilage is more likely to be injured by shearing forces than blunt trauma. It rarely fractures.

If uninfected, a small seroma of the auricle may be observed, a larger one aspirated. If the seroma reaccumulates, it should be treated under sterile conditions with drainage and a bolster type dressing using dental rolls and through-and-through, nonabsorbable sutures placed to obliterate the potential space for reaccumulation of the seroma. If infected, there is a risk that cartilage itself may become necrotic and lost. The ear must be incised and drained with broad-spectrum antibiotic coverage; drains may need to be placed. The goal is to prevent loss of the cartilaginous frame.

The same principles apply to hematoma of the auricle, except that observation is rarely an option. Because the cartilaginous frame is at greater risk, the hematoma should be drained and a compressive dressing applied with dental rolls sutured on either side. If the hematoma reaccumulates or is very large, drains should be placed, and the ear should be treated until the skin flaps remain flat. Preservation of the cartilaginous framework with prevention of a "cauliflower" or "boxer's" ear is the goal.

Of recent note, young male pugilists may consider a malformed auricle a "mark of prowess" (athletic, sexual, and otherwise) and will not seek medical attention for shearing injuries to the auricle. Unfortunately, once auricular cartilage has been lost and reparative scarring has begun, the auricle is doomed to reparative malformation. Intervention must be given soon after any injury if it is to be effective.

Sharp Trauma to the Auricle

Sharp trauma to the auricle may be as small as a torn ear lobe piercing to complete avulsion of the auricle, usually as a result of motor vehicular trauma. The auricle has a plentiful blood supply and as a general rule will heal if the cartilaginous and soft tissue structures remain even partly attached, less so if complete avulsion has occurred. If remnants or the entire auricle can be salvaged, these should be cleansed and an attempt made to reimplant in the acute situation.

Torn lobules may occur by gravity in which a heavy earring works its way over time through the lobule or by acute injury in which an earring is torn through the lobule. Inflammation and infection should be treated. The torn lobule may be repaired in the office; the lobule may be repierced at a later stage.

Animal and human bites of the auricle are by definition contaminated. The edges of the wound must be decontaminated with local antisepsis. Tetanus toxoid should be given. Broad-spectrum antibiotic coverage for the most likely oral flora including microaerophilic streptococci and anaerobes such as *Bacteroides* is indicated. If remnants of the auricle have been salvaged, these may be thoroughly washed, decontaminated and reattached with sutures. If only the auricular cartilage remains, it should be cleaned of soft tissue attachments, decontaminated, and buried in a subcutaneous pocket (postauricular, forearm, abdomen, etc.) for later use.

Shearing avulsions are much more difficult to treat. The auricular remnant, if found, may be mangled, torn, abraded, etc. If part or whole of it appears viable, it is worth an attempt at surgical reattachment, obeying all rules of antisepsis.

If however, it has been lost or is beyond retrieval, the edges of the EAC should be freshened, tacked away, and the canal packed with gelfoam or another material to help prevent acquired stenosis of the EAC. The patient must then be counseled regarding the main steps of auricular reconstruction (costochondral cartilage harvest, sculpture, and subcutaneous implantation; lobular transposition; auricular lateralization) as required. Another very good option in these severe cases is the insertion of osseointegrating

titanium posts for the anchoring of an auricular prosthesis. A well-made auricular prosthetic for the properly selected patient is an excellent option with very acceptable cosmetic results. On the contrary, flexible hydroxyapatite (Porex), even if covered with a vascularized temporoparietal flap, has in many cases proven extremely difficult in the event of subsequent trauma or surgical manipulation of the auricle with resultant stenosis of the EAC. This type of repair must be chosen carefully with regard to the age and usual activities of the recipient.

Thermal Injuries (Thermal Burns, Frostbite)

Burns of the auricle are classified by nature of the burn (thermal, ultracooling due to frostbite) and the degree of the injury to the skin: first degree leading to erythema, second degree (blistering), and third degree (full thickness). In first- and second-degree burns, pain is present; in third-degree burns, the sensory nerve endings have been destroyed, and the affected area is anesthetic. It is of great importance to elicit a detailed history about the nature and time course of the injury.

Upon inspection, the area may be erythematous and blistered (first- and second-degree burns), blackened with eschar (third degree), or white, hard, and cold (frostbite) due to extreme vasoconstriction. It is important to suspect that the extent of the injury extends greater than that apparent on inspection. This is especially true in electrical injuries. Cooling a thermal burn should be done quickly with cold/iced compresses to waste the built-up heat within the tissue in an attempt to prevent necrosis by cell expansion and disruption. Frostbite is rewarmed more slowly with warming compresses. If frostbite extends to larger areas of the body, the patient may be placed in a warming bath or warming intravenous solutions may be used. The extremity should not be rubbed, lest shearing forces cause further damage.

Broad-spectrum antibiotic coverage against expected organisms such as *Pseudomonas* sp. and common skin flora (gram+ cocci and rods) should be given. Topical ointments and creams such as 1% silver sulfadiazine creams may be used. Surgical debridement should be delayed until the wound "declares itself" and a line of demarcation between healthy and dead tissue becomes apparent. Once this has happened, debridement of dead tissue and the application of topical antiseptic ointments may encourage healing in first- and second-degree burns. More severe burns may require split- or full-thickness grafting. There is no reason to rush into repair until the full extent of the injury is obvious. A physician or surgeon experienced in the care of burns and in reconstructive surgery is an important colleague in the care of thermal and frostbite injuries to the auricle and EAC.

Acid Burn of the EAC and Auricle

This rare occurrence causes massive denaturation of skin, surrounding soft tissue and supporting cartilage, and may result in partial or complete loss of the auricle and EAC. Acids of industrial concentration such as sulfuric acid or other fortified acids (or alkalis) are the usual agents. The injury is almost never accidental but is part of a criminal assault. As with any chemical burn, the caustic agent must be removed with copious and prolonged irrigation.

If the auricle has been severely damaged, it may ultimately undergo partial or complete autoamputation. Hypertrophic and/or keloid formation will inevitably ensue and is treated with compressive dressings and/or steroid injections (triamcinolone 10 or 40 mg/mL), as necessary. The injured auricle may be allowed to "declare itself" as with thermal and frostbite burns. It is important to inspect the EAC and the TM and to make every effort to flush any noxious agent from these areas and to attempt to salvage as much normal tissue as possible. The EAC may be packed with medicated gelfoam or another packing.

Having worked in a large inner city E.R. and burn unit, the first author's experience is that these types of injuries are almost never isolated but are often part of a much larger picture including inhalation injuries and trauma to vital internal organs and the extremities. It is important to think "beyond the ear," especially if there has been a history of smoke inhalation. These patients are properly assessed by the trauma and burn services as well as otolaryngology.

Fractures of the EAC

Foreign objects placed into the EAC may cause lacerations of the canal. These types of injuries are rare. Far more common are injuries to the EAC caused by trauma to adjacent structures. The anatomic boundaries of the EAC make it susceptible to injuries of the temporomandibular joint (e.g., a blow to the jaw) and of fractures to the temporal bone, most commonly longitudinal fractures.

Inspection of the EAC reveals a "step" deformity of the canal. A flail piece of bone may be seen, with or without an accompanying laceration. Passive movement of the jaw may cause the bone fragment to move.

The patient should be inspected for additional areas of injury, both for fractures of the jaw and for other areas of otologic injury such as traumatic perforation of the TM, damage to the ossicular chain, facial nerve injury, or injury to the vestibular labyrinth. A tuning fork test should minimally be done. If possible, at least a screening audiogram should be performed.

Radiographic studies (mandibular views, panorex, CT of the petrous temporal bones, etc.) are obtained as indicated.

Treatment is of the underlying cause: If the mandible has been fractured, this must be reduced and the patient usually placed in intermaxillary fixation (IMF), as per oral surgery protocol. Temporal bone fractures, even with CSF otorrhea, are ordinarily observed with the patient placed in bed at about 45 degrees, until CSF otorrhea subsides. The ear should not be manipulated. If there is witnessed and progressive facial nerve dysfunction, in which case

the likely site of injury is at the geniculate ganglion, the nerve is followed clinically and electrically with serial ENOG and/or needle EMG studies and may need to be decompressed.

If a flail piece of bone in the EAC, usually at the scutum or tympanomastoid suture lines, becomes infected or otherwise bothersome, it may be removed. It is rarely necessary to repair soft tissue lacerations. The EAC may be packed with gelfoam moistened with otologic drops or another packing material.

Noninflammatory Lesions of the External Ear

A. *Lesions of the auricle*
   1. *Congenital lesions of the EAC*
      a. *Microtia/congenital auricular atresia*
         The reader is referred to Chapter 148, Congenital Aural Atresia, by Dr. Paul R. Lambert MD.
      b. *Preauricular skin tag(s), accessory auricular remnants*
         These consist of redundant tissue, usually comprised of skin and fat, found near or just anterior to the tragus. If the mass contains cartilage, it is a remnant of auricular tissue, left over from auricular development. It may be a duplication of one or several of the ectodermal hillocks of His. Preauricular skin tags or auricular remnants are nonfunctional, and most parents request that they be removed. However, they may carry with them cultural connotations, such as a child being "favored." Care should be taken in the excision of them. If held on with only a soft tissue stalk, the skin tag may be lassoed with a silk suture, tied at the base and allowed to necrose and fall off. If cartilage is found within the lesion, excision should be done in the operating room, with the knowledge that the facial nerve may be very superficial in young children. The patient is seen as necessary until the scar has healed. Electrocautery is rarely necessary in the excision of these lesions and should be used carefully.
      c. *Preauricular pits*
         These are depressions or sinuses lined with squamous or columnar epithelium and found in front of the anterior root of the helix. They are heritable, thought to be in an autosomal dominant fashion with variable expression; they are often bilateral. They may elaborate keratin and/or mucous and may become infected. If quiescent, they are observed. If filled with uninfected debris, they may be treated with warm compresses and the material expressed from outside the opening. If the pit or sinus becomes recurrently infected, it may require excision. It is important to remove the entire tract if it is excised.
      d. *First branchial cleft cysts, sinuses, and fistulas*
         These result from anomalous duplication of the EAC and may occur between the EAC and structures anterior or inferior to the auricle, including the neck. The classification of Work (30) is commonly accepted. Work type I anomalies contain only ectodermal derivatives and may be thought of as a "parallel" duplication of the EAC. Work type II anomalies contain both ectodermal and mesodermal derivatives and may be found extending between the EAC and the parotid, in any relationship to the extratemporal facial nerve, including bisecting the nerve. Treatment of first branchial cleft cysts, sinus, and fistulas is by excision. These anomalies may contain keratin debris that may become infected. If infected, these may require I & D, but this is not recommended if it can be avoided. The cyst, sinus, or fistula may be gently probed with a sterile, malleable lacrimal probe or another suitable instrument to map out its pathway. The opening may be gently filled with dye such as methylene blue prior to excision. A rim of tissue around the internal opening is resected with the specimen and every attempt is made to excise the tract *in toto*, leaving none of it behind. If the tract is suspected to course in any relation to the extratemporal facial nerve, the excision should be done in a more formal way. A modified Blair incision is made, and the parotid is exposed as is the facial nerve at least from the stylomastoid foramen to the *pes anserinus* and distal branching points, with the use of intraoperative facial nerve monitoring. The cyst, sinus, or fistula must be carefully dissected from the intact and stimulated facial nerve. The first attempt at excision is usually the most thorough because the anatomy of the lesion is the most preserved. With each I & D and each subsequent surgical attempt at removal, this anatomy becomes more distorted and the chance of complete resection less.
      e. *Cutaneous cysts*
         Cysts of ectodermal and sebaceous origin may be found in any relationship the auricle. If growing and painful, they should be excised by including a fusiform "stamp" of skin over the lesion as a soft tissue "handle" leading toward excision of the cyst with its tract and surrounding soft tissue. It is important to make every attempt to identify and excise every bit of the cyst lining, as there always is one. If the cyst has become acutely infected and ready to burst, the patient is treated with oral antibiotics and warm soaks. The cyst may need to be incised and drained, but this is not optimal. Once the acute infection has subsided, the cyst should be excised.

2. *Acquired lesions of the EAC*
   a. *Chondrodermatitis nodularis chronica (Winkler nodule)*
   This is a benign lesion that appears as a "punched-out crater," found most commonly in older men at the rim of the helix. It may be found in other areas of the auricle. It is thought to be caused by the breakdown of elastic fibers due to chronic sun exposure. The lesion may be painful to touch or pressure, for example, sleep in on the ear. This distinguishes it from other dermatologic lesions such as senile keratosis, keratoacanthoma, cutaneous horn, and skin cancer (squamous or basal cell), which are usually painless.

   Treatment is by full-thickness excision including supporting cartilage with reconstruction of the defect with a full-thickness skin graft or local advancement miniflaps.

   b. *Gouty tophi of the auricle*
   These are deposits of uric acid in crystalline form in the auricle, often at the helix. The patient will have hyperuricemia and should have other markings of gout: arthropathy(ies), involvement of the great toe(s), etc. Serologic markers for uric acid will confirm the suspected underlying diagnosis. If quiescent, the nodule may be observed. If painful or inflamed, it is removed under local anesthesia. Histopathologic examination will reveal fusiform, washed-out casts of monosodium urate with an accompanying inflammatory surround: polymorphoneucleocytes, histiocytes, foreign body giant cells, etc.

   The patient should be treated by the internist for gout with daily administration of allopurinol and colchicine and other antiinflammatory medications for acute exacerbations.

   c. *Keratoacanthoma*
   This is also known as a self-healing basal cell carcinoma. It is caused by actinic (sun) exposure and may arise from hair follicles. It may be rapidly growing, raised, and circular with a central crater usually containing a keratin plug. On histologic exam, this crater is seen to be filled with desquamated debris and parakeratin cells. If it is undergoing gradual resolution, it may be observed. However, because this lesion resembles other skin cancers, it will usually be biopsied to yield a definitive diagnosis.

   d. *Bacterial perichondritis*
   This is distinguished from relapsing polychondritis, which is a nonbacterial autoimmune condition treated with steroids. Bacterial perichondritis is distinguished by crusting, by weeping and exudate from the auricle, and by pus. If there are signs of bacterial infection, the ear must be treated with antibiotics.

   Infection of the perichondrium of the auricle and supporting cartilage is an urgent problem and may be a sequela to otologic surgery and trauma or may follow external otitis. Predisposing factors include diabetes and any cause of relative immunosuppression. The patient presents with a swollen, painful, erythematous auricle, usually crusting and weeping. Swabs are taken for gram stain, culture, and sensitivity. The most common organism isolated is *P. aeruginosa*. Oral antibiotics with good gram-negative coverage such as fluoroquinolones should be started along with warm soaks. Treatment may begin at home, but the patient must be seen frequently, even daily, until the ear either improves or it fails to, the patient should be hospitalized, broad-spectrum intravenous antibiotics started, and drains should be placed under the skin of the auricle and irrigated with an antibiotic solution such as bacitracin. Diabetic patients must be brought under strict control, often requiring a sliding scale of insulin. Necrotic cartilage should be excised and every effort taken to save as much of the cartilaginous auricular framework as possible.

   e. *Sebaceous cysts*
   These true cystic collections occur as a result of sebaceous gland obstruction. They have a true lining and may occur anywhere in the head and neck. The scalp, nape of neck, and auricle are favored sites. If small and nonpainful, they may be observed. The acutely infected sebaceous cyst is treated with a broad-spectrum oral antibiotic and may occasionally have to be drained. If it becomes larger and painful, the sebaceous cyst is excised with care taken to remove all of the cyst lining. This is best done when the cyst is distended and noninfected. If any of the cyst lining is left behind, it will likely regrow.

   f. *Hypertrophic scars and keloids (see burns)*

   g. *Neoplasia of the auricle and EAC*
   The auricle and EAC may give rise to both benign and malignant neoplasia, based upon the cell of origin. Benign processes include actinic keratosis, papilloma, and other lesions. Cancers of the auricle and EAC include more commonly basal cell carcinoma, squamous cell carcinoma, and melanoma (melanotic and amelanotic). Rarer cancers of the auricle and EAC include Kaposi sarcoma (now seen with much less frequency in HIV disease after the advent of protease inhibitors and other reverse transcriptase inhibitors) and ceruminous adenocarcinoma (31), seen either alone or in patients with multiple cylindromas of the scalp, face, and EAC.

   Malignancies with hematogenous metastatic potential to spread to the temporal bone but not

necessarily to the auricle or EAC include renal cell carcinoma, small (oat cell) adenocarcinoma of the lung, breast cancer, cancer of the prostate, and cutaneous melanoma.

In the majority of skin cancers, malignancy is an end-stage result of chronic sun (actinic) exposure. Individuals of Northern European origin with fair skin, light hair, and blue eyes or individuals who have genetic defects of skin repair are predisposed to skin cancer. The amount and longevity of sun exposure is of greatest importance. Tanning lotions with protection against the ultraviolet waves of the sun are of relative recent widespread use. Many individuals in North America over the age of 60 can recall spending long summer hours if not whole days with friends at a swimming pool or beach, scantily clad, with no thought given to protection from the damaging effects of the sun. This is where the history leading to actinic changes including skin cancer begins. A thorough history of sun exposure, work history (indoor vs. outside work), and a history of tight-fitting ear molds leading to chronic irritation of the EAC should be elicited. It is wise to enlist the help of a good dermatologist and a dermatopathologist or similarly trained individual who is proficient in Mohs chemosurgery. Many malignancies of the auricle may be treated with local, chemo-controlled excision with the defect repaired via skin grafting or local advancement flaps. Occasional malignancies may respond to topical application of 5-fluorouracil. Unless one is ready to accept all responsibility for the care and follow-up of the lesion, it is wise to refer to the appropriate authority, a dermatologist. Said physician may treat alone or may send the patient back with a biopsy-proven diagnosis and request a limited, Mohs-controlled excision. The patient is best served when the otologist works in tandem with these colleagues.

Far less frequently, advanced cancers of the auricle may occur as part of an aggressive picture of skin cancer, especially squamous cell carcinoma of high grade. Conversely, slowly growing malignancies such as basal cell cancer may persist for years before the patient seeks help. In this small number of cases, the auricle and/or skin of the EAC must be partially or completely resected, possibly with a neck dissection, possibly with a lateral temporal bone resection, and the wound closed with local, pedicled, or free vascularized flaps. The extent of the disease by clinical examination, radiographic examination, and histopathologic margins will determine the extent of the dissection. Surveillance and local control may help to avoid these more advanced cases.

The reader is referred to Chapter 147 Neoplasms of the Ear and Lateral Skull Base by Bradley P. Pickett MD.

B. *Lesions of the EAC*

1. *Keratosis obturans*

This is an acute upon chronic condition of the external ear in which the EAC is plugged by an accumulation of dense, inspissated keratin debris leading to secondary, acute infection, swelling, pain, and hearing loss. In very advanced cases, in response to chronic irritation and infection, the normal thin architecture of the squamous epithelium lining the canal may become lichenified (heaped up) and both plugged by dense debris and secondarily stenotic. The typical patient with this problem is elderly, often in a nursing home in which care of the ear is neglected. If and when the ear becomes acutely infected, the patient will be brought to the otologist. It is important to distinguish this entity, if possible, from AOE, osteomyelitis of the skull base, and other plausible conditions. The history usually yields the answer, if it can be accurately obtained.

These ears are tough to treat, in large measure because of pain, but will usually respond well to careful, thorough cleaning. Adding yet another drop or oral antibiotic and discharging the patient back to his or her home is *not* the way to treat this problem. Cleaning should be done carefully, slowly, and thoroughly, under a microscopic vision in the office, rarely in the operating room, very rarely under general anesthesia. These ears are exquisitely painful to clean, and thus, pain must be eliminated prior to aural toilet. The patient may require a four-quadrant block of the EAC with local anesthesia. Most patients will allow the ear to be cleansed in the office. There is usually an "onion skin" appearance to the epithelial debris for it has been collecting for many months to years. Although the diagnosis is apparent with gross inspection, material should be sent for pathologic examination to assure that this is keratin debris and nothing else. The physician may not be able to completely clean the ear in one sitting and may have to bring the patient back for several sessions with the ear medicated with an appropriate acidifying solution between visits.

The important difference between this and other similar conditions such as cholesteatoma of the EAC is that, once completely cleaned and topically medicated, the ear with keratosis obturans will often slowly and gradually revert back toward a healthy appearance. The change toward health may be quite remarkable once aural toilet commences. The inciting event of dense packing of squamous debris and superinfection has been cured and the ear can now resume a more normal appearance. This does not

happen with external ear cholesteatoma. Prevention of reoccurrence is via appropriate ototopic therapy and routine office-based debridement.

2. *External auditory canal cholesteatoma (EACC)*
This is a cyst of squamous debris found in the EAC. It has many features in common with primary acquired cholesteatoma: an active matrix that elaborates keratin debris. It may locally erode bone and soft tissue. Unlike keratosis obturans, it does not revert back toward a normal state once obstruction and local infection have been relieved and treated. There may be an antecedent history of trauma, prior otologic surgery, acquired stenosis, or chronic inflammation, but most patients have no identifiable cause. The tympanic ring, especially its anterior and inferior aspects is a favored site for EACC. The patient may initially present with otologic complaints due to blockage by keratin debris: hearing loss, fullness, symptoms of infection, rarely dizziness or vertigo, and most rarely involvement of the facial nerve.

An edge-enhanced CT of the temporal bones reveals features of cholesteatoma with bony erosion and scalloped edges. It is usually a localized disease process, often unilateral, bilateral in fewer patients. Depending upon the site and size of the EACC, the hearing may be normal, the hearing loss of a conductive or mixed nature, or if there has been violation of the otic capsule, anacusis. Facial nerve involvement is rare.

The mainstay of treatment is routine office-based debridement, advice to the patient about water precautions, and the judicious use of acidifying drops and/or powders as needed. If the EACC becomes obstructed, rendering the ear difficult to clean, limited localized surgery including meatoplasty may be indicated to facilitate aural toilet. Surgery to eradicate all foci of cholesteatoma has proven of little value, and hence, EACC, unlike primary and secondary cholesteatoma of the middle ear and mastoid, is managed medically and not surgically. There is really very little need for surgery in even the most advanced cases (32).

The surgeon must also have a careful mental roadmap of the problem with microscopic detail. This may be facilitated by CT imaging, but there is no substitute for careful microscopic evaluation. In very advanced cases, the jugular bulb, tympanic facial nerve, and structures of the otic capsule may be exposed. Extreme caution must be used in dealing with these most delicate structures.

Softening the squamous debris at home for several days with an organic solvent (baby oil, olive oil, docusate, etc.) prior to scheduled office debridement will greatly facilitate cleaning. If inner ear structures of the vestibular labyrinth have been exposed, the patient may experience precipitous and violent vertigo due to the caloric effect of the suction. It is best to manually debride the ear in the supine position under the microscope, using small tools such as a cerumen loop, round knife, and alligator forceps, and to use a minimal amount of suction just at the end of the cleaning. The occasional patient may bring in a hair dryer to warm the ear prior to suctioning. Because the need to clean may be as often as every 3 to 4 months, the physician and patient must work together to achieve the best system that will keep the erosive potential of EACC in check and cause the least amount of discomfort to the patient.

It is important to be aware of developmental defects in the formation of the tympanic ring, which may lead to chronic irritation, weeping, and the collection of keratin debris, mimicking cholesteatoma of the EAC and other entities. A persistent foramen tympanicum, or foramen of Huschke, is an anatomic variation of the tympanic portion of the temporal bone due to a defect in normal ossification of the tympanic ring during the first 5 years of life (33). It is not a true foramen because no neurovascular structures traverse it, but it is a defect of tympanic bone ossification due to abnormal mechanical forces during early postnatal life or due to genetic factors, thus far undefined. It is located at the anteroinferior aspect of the EAC, posteromedial to the temporomandibular joint (TMJ). From retrospective radiographic series, it has been estimated to occur in 4.6% (33) to 9.1% (34) of individuals, depending upon the method of study and inclusion criteria, with an average dimension of 4.2 mm in the axial plane and 3.6 mm in the sagittal plane. A slight female preponderance was found in one study.

The persistent foramen tympanicum or foramen of Huschke should be kept in the differential diagnosis in cases of refractory chronic otitis externa and especially cholesteatoma of the EAC. It may predispose the patient to injury of the EAC, TM, middle ear cleft, etc., during TMJ arthroscopy and may facilitate spread of infection or tumor from the EAC into the infratemporal fossa and vice versa.

CT of the temporal bone performed at thin intervals (0.6-mm section thickness, 0.3-mm section increment) with an ultra–high-resolution filter will best image this entity if it is present.

3. *Cerumen impaction*
The subject of wax impaction may seem banal, but few other conditions in our specialty can be remedied within a single office visit to the tremendous relief and satisfaction of the patient. Many patients with wax impactions will present with hearing loss, fullness, tinnitus, autophony, and rarely with

imbalance or vertigo. The history and physical exam including tuning fork testing will usually confirm the diagnosis and exclude other causes. Most patients will admit to using cotton squabs and other foreign bodies in the EAC. Patients wearing tightly fitting hearing aid molds or other ear pieces may be predisposed to wax impaction. The care for and prevention of wax impaction, however nonglamorous, is fundamental to what we do, and one should develop a reliable method to care for this most common problem.

Realizing that the ear is exquisitely sensitive, especially an erstwhile normal EAC now impacted with wax, the physician must treat carefully, cautiously, *slowly*, and with reassurance. Patients can tolerate many manipulations of the ear if what will be done is explained to them and is done slowly. A few extra seconds of counsel and reassurance are well worth the effort.

A few basics:

a. Place the patient in a comfortable position. This may vary from sitting upmost to lying flat in a recumbent position. One should anticipate a vasovagal response and be prepared to treat it immediately as it may occur with any instrumentation of the EAC, just as for the treatment of epistaxis. An ounce of prevention is worth a pound of cure.
b. Use a microscope, not a handheld otoscope. It is amazing that many physicians will use advanced fiberoptic imaging techniques for the nasopharynx and larynx but will attempt to remove a cerumen impaction without a microscope. This defies logic.
c. *Explain* what one intends to do: either with curettage or suction, using the microscope. If suction is to be used, the patient must be warned that he or she may experience momentary vertigo due to the caloric effect. Anticipate nausea and/or vomiting. Reassure the patient that if the cleaning becomes painful, the physician will stop and do so if the patient so indicates.
d. Use reasonable techniques for a reasonable length of time. Procedures to the ear performed *slowly* are usually tolerated better than anything done quickly. Do not rush in cleaning: In the long run, it will save time to use caution and to proceed slowly. If the patient is tolerating the cleaning well, proceed until everything has been cleaned. It may happen quickly and the acute problem solved. Other patients may require softening with mineral oil and/or 3% hydrogen peroxide, allowing the organic solvent to work for a few minutes while the patient next door is examined. Returning to the first patient, the impaction may now have softened enough to be removed, usually with suction.
e. Avoid blind, forceful irrigation. In our age of litigation, an iatrogenic perforation of the TM due to forceful ear washing is by and large a plaintiff's verdict. Happily, this is becoming a rare event. It is simply not worth the risk of iatrogenic injury for wax. Most but not all patients can be carefully and thoroughly cleaned in one office setting. Patience, softening, and recurrent attempts to clean as described above will usually be successful.
f. Have gelfoam and alligator forceps readily available. It is not uncommon that either the physician or the hard, impacted wax may abrade the EAC as it is removed. Bleeding may ensue and this may be cumbersome if the patient is on any type of anticoagulation therapy such as aspirin or warfarin. Topical astringents such as $AgNO_3$ or 20% phenol or trichloroacetic acid may be used, but an equally effective way to control bleeding is with a few small "dots" of gelfoam strategically placed. It is very bad form to send a patient from one's office with a profusely bleeding EAC.

The patient who walks into the office with a mild impaction is quite different than the patient brought in from a nursing home a great distance away by a relative or friend with a quality of life change now causing a mixed hearing loss due to wax. The former is of course bothered by the problem, but the latter is incapacitated in terms of communication.

All reasonable attempts should be made to thoroughly clean wax impactions in *one* office visit.

After the ears have been cleaned, inspect all parts of the TM to look for other signs of disease, such as a perforation or attic retraction cholesteatoma. If the ear has been cleaned carefully under microscopic visualization, it is highly unlikely that a perforation now visualized after debridement was due to the MD's manipulations.

Patients should be counseled to avoid placing any foreign body into the ear to clean it. Doing so invites not only wax impaction but also trauma and subsequent infection to the EAC, TM, and structures of the middle ear cleft because it is done blindly. A weekly rinse of 3% hydrogen peroxide or an acidifying drop may help the ear to cleanse itself. However, a small group of patients produce either so much wax or wax with such sticky viscosity that nothing other than manual debridement at regular intervals will suffice. Ten minutes in this MD's office every 6 to 12 months is well worth it. Few other patients we treat will have such an immediate benefit from our ministrations than those with wax impaction.

4. *Foreign body*
   Foreign bodies (FB) in the EAC may be classified into "living" and "nonliving" (organic or inorganic). Several broad principles must be observed in treating a patient with a suspected or known foreign body, all based upon common sense:
   a. For young children, "if one foreign body, there may be two or three." Check the nose in addition to the ears.
   b. Living foreign bodies (usually insects) must be killed and then removed. The patient is usually quite bothered by the beating of an insect's wings or other movement. This is silenced with lidocaine or mineral oil.
   c. Batteries and acid-eluting foreign bodies must be removed as soon as possible because they may cause extensive chemical burns to the EAC. This is a rather urgent otologic situation and the patient should be treated in the office or O.R. without delay.
   d. Hygroscopic means "takes on water." Thus, it is unwise to try to irrigate out foreign objects such as beans or bugs as this may make the FB swell and compound the problem.
   e. The ear is exquisitely sensitive. If the patient is not tolerating pain, this must be controlled lest the patient suddenly move during extraction of the FB with possible injury to underlying structures such as the TM and the ossicular chain. For the uncooperative or hysterical patient, five minutes of general anesthesia is well worth the discomfort of having a swollen, impacted foreign body removed without anesthesia.
   f. In a very cooperative child, one may attempt to remove the foreign body from the EAC(s) and, if successful, have a quick look at the nose and mouth to assure that no other foreign body is present. This is usually wishful thinking and the child must be prepared and taken to the O.R.
   g. Only an experienced MD should attempt to remove any foreign body from the EAC, and it should be done with magnification. Many different instruments are ordinarily available to retrieve FBs in the office. If they are not, the patient should be taken to the operating room or referred to an MD with the requisite tools to care for the FB.
   h. A reasonable attempt to establish audition in the ear in question with at least a tuning fork test should be done prior to the removal of a densely impacted foreign body.
5. *Furuncle*
   (See "Infections of the External Ear.")
6. *Aural polyp*
   Polyps are soft tissue masses, usually circumscribed, glistening, and often obstructing the EAC. An aural polyp may be thought of as a flag: an indicator of underlying disease such as chronic otitis media or cholesteatoma with concomitant inflammation. The polyp usually arises from the middle ear mucosa (respiratory epithelium) but may arise directly from the TM as a reaction to a foreign body such as a ventilation tube.

   An aural polyp is often a physical obstruction to local medical treatment of disease in the EAC. Polyps may be treated in several ways: locally with astringents such as $AgNO_3$, trichloroacetic acid, and 20% phenol to reduce the mass of the polyp or by removal. Astringents tend to work well because of the myxedematous nature of polyps: They are inflammatory tissue and contain a lot of water. Reducing this fraction alone will shrink the mass and allow topical therapy to start working.

   Removal of an aural polyp must be done with caution. The surgeon should have a clear idea of the most likely site of origin: a perforation, a cholesteatoma, or a foreign body reaction to a tube. If there is any suspicion that the polyp could be attached to a deeper structure, such as the facial nerve, the stapes footplate, and a dehiscence of the vestibular labyrinth, or that it could in fact not by a polyp and instead a herniation of meninges and/or brain (meningoencephalocele, encephalocele), it should be left alone until definitive radiologic studies, CT and/ or MRI ± contrast, will more precisely define the anatomic site of origin.

   The polyp, once grasped with an appropriately sized instrument, should be "smeared" and never forcefully "yanked" or otherwise forcibly removed from the ear. An inflammatory polyp will easily yield to gentle manipulation. Another underlying disease process may be more resistant and should never be removed with force.

   All material removed from the body must be sent for pathologic examination and an aural polyp is no exception. Although the tissue removed may have all of the gross features of a polyp, only properly stained and examined material will definitely identify an inflammatory polyp and exclude other entities such as glial, brain, and cancer tissue. It is simply indefensible that cancer or anything other than an inflammatory polyp be missed because tissue was not sent for pathologic examination.
7. *Dermatologic conditions of the EAC*
   The EAC may be thought of as a blind pouch lined with skin. There are several differences between the skin of the EAC and skin elsewhere in the body. Specialized systems such as the apopilosebaceous unit and ceruminous glands are present in the skin of the EAC but not elsewhere. The EAC is thus susceptible to many of the dermatologic processes found elsewhere in the body. Nuanced dermatologic

descriptions aside, much of what otologists treat may be generally classified as chronic otitis externa. The EAC may manifest purely local problems such as contact dermatitis and neurodermatitis (lichen simplex chronicus). The EAC may also manifest systemic conditions such as psoriasis, eczema, atopic dermatitis, seborrheic dermatitis, acne vulgaris, and sarcoidosis.

Patients typically present with itching, serous or mucous drainage, fullness, and hearing loss. The history is a key feature toward a correct diagnosis. Both ears must be given careful scrutiny under the microscope. The physician will often see a similar state in the EAC for many dermatologic conditions: very dry skin and signs of mechanical excoriation. The patient may present with an AOE. The "good" ear (if it is quiescent) will often "tell the story." The baseline problem is that the skin is too dry, leading to pruritus, scratching, and violation of the skin and its lymphatics with the resultant perfect setup for AOE: warm, moist, and dark—just what bacteria and fungi need for growth. This set of otologic problems is cyclical. The baseline is "too dry," but acute exacerbations may cause the ear to become moist and acutely infected.

As the adage goes: "If too moist, dry it; if too dry, moisten it." It is a fine tuning especially true in ladies who are taking oral birth control mediations with resultant fluctuation in hormonal homeostasis.

Drops do not stay as drops forever. Eventually, they become the residue of the drop and the liquid into which the active ingredient of the drop was dissolved. Hence, drops add fluid and often water to the ear: again, just what bacteria and fungi need to grow. Desiccating powders are often a better choice in the acutely infected, moist ear. Once the ear has reached its "baseline" (check the "good" ear), gentle moistening with steroid oils (e.g., fluocinalone 0.01% oil, prednisolone forte 1% ophthalmologic solution) or creams/ointments (triamcinolone 0.025%) once or twice a week may maintain the ear. The patient must be cautioned not to instrument the ear.

Unfortunately, chronic otitis externa is poorly understood by most general physicians and also by many otolaryngologists. The typical patient has been treated with several different drops in the hope that finding "the perfect drop" will solve the problem. This of course is illusive. Ultimately, there is no *cure* for many of these conditions, but care of acute exacerbations and the judicious use of steroids will go a long way to help care for the patient.

8. *Bacterial and fungal otitis externa* (see "Infections of the External Ear.")
9. *Osteomyelitis of the skull base* (see "Infections of the External Ear.")
10. *Osteoma and exostoses of the EAC*
    Osteoma(s) (Fig. 146.8) of the EAC are true neoplasms, often unilateral, solitary, pedunculated, and not related to cold water or air exposure. They usually occur at the tympanosquamous suture line

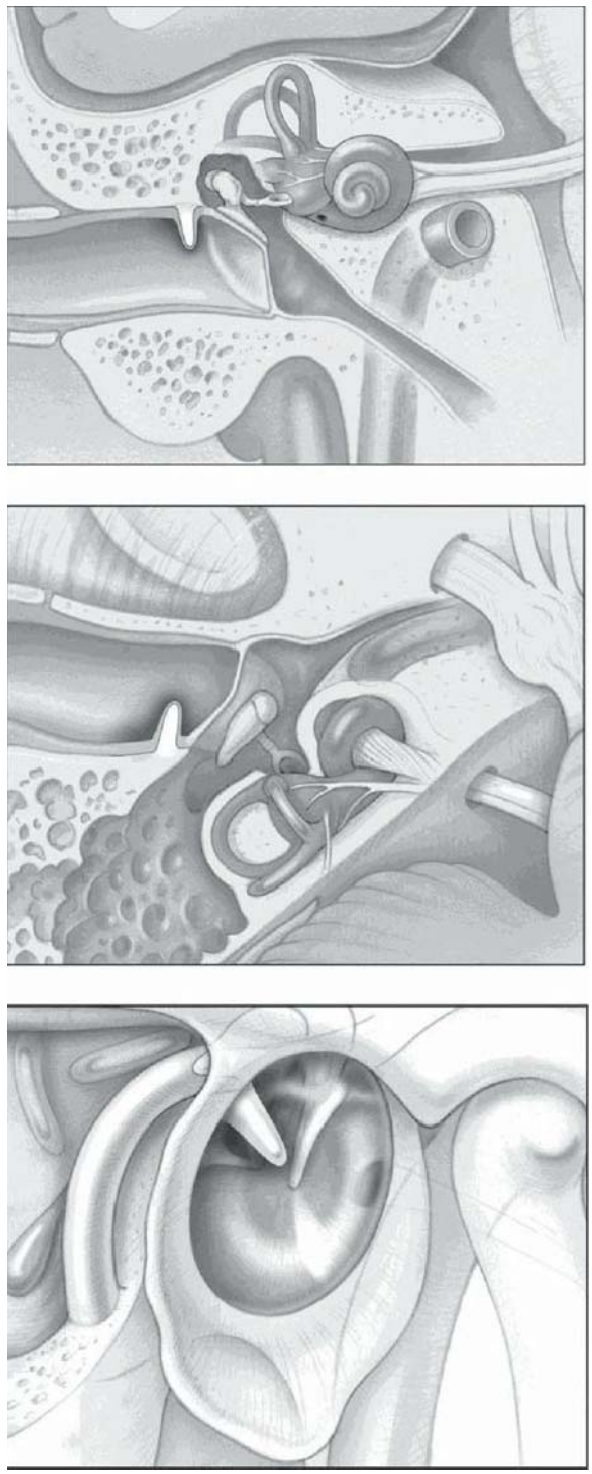

Figure 146.8 **A:** Coronal section of a right ear showing a single stalk of an osteoma. **B:** Axial view of left ear showing a single stalk of an osteoma. **C:** Sagittal section of a right ear showing a single stalk of an osteoma. Figure courtesy of Robert K. Jackler MD.

and are found more lateral than exostoses. A solitary, large osteoma may fill a good portion of the EAC, causing all of the problems of advanced exostoses. On CT, the osteoma may be more heterogeneous with areas of cancellous bone, less dense than an exostosis. There is usually a stalk leading to the osteoma that can be seen under microscopic exam or on CT.

Exostoses (Figs. 146.9 to 146.11) of the EAC are acquired, benign, broad-based growths of bone occurring within the EAC found most often near the tympanomastoid or tympanosquamous suture lines. They are often bilateral with one ear more advanced than the other. Exostoses are not true neoplasms. They are bony calluses or hyperostoses arising from the tympanic ring. They typically do not have a stalk. The presumed pathophysiology is refrigeration osteitis, the effect of chronic cold water or air to the bone of the EAC in activities such as swimming, surfing, skiing, or boating (35). Many but not all patients with exostoses will have a corroborating history.

If the one or several bony lesions are small and most of the TM is clearly visible, the ear is observed. There are several reasons to shave down an exostosis or to remove an osteoma:

1. Recurrent infections of the EAC. Trapped squamous debris and wax will become a nidus of recurrent EAC infections, and the obstruction should be removed.
2. Conductive hearing loss due to wax/debris impaction. With severe obstruction(s), even a small amount of wax and debris will cause conductive hearing loss.
3. The usual bony and soft tissue landmarks are becoming lost. It is not wise to wait this long because the surgeon must rely upon landmarks of the EAC to perform the surgery.
4. To allow a patient to be properly fitted with a hearing aid

Exostoses may occur along with other conditions, for example, otosclerosis. If the exostoses are too large to allow for the usual transcanal approach, the ear with the greater hearing loss should have the exostoses removed, be allowed to heal, the hearing retested, and then the stapedectomy performed.

All patients being considered for surgery must have a formal hearing test and an edge-enhanced, noncontrast CT of the temporal bones to look for landmarks around the bony lesion(s): the TM, the middle ear and ossicular chain, and the tympanic and vertical course of the facial nerve. The surgeon should have a very good idea in the preoperative preparation not only of what the ear looks like under the microscope but what radiologic landmarks will help to guide the dissection.

Surgery may be done through the EAC or through a postauricular approach. The important word is to "shave"

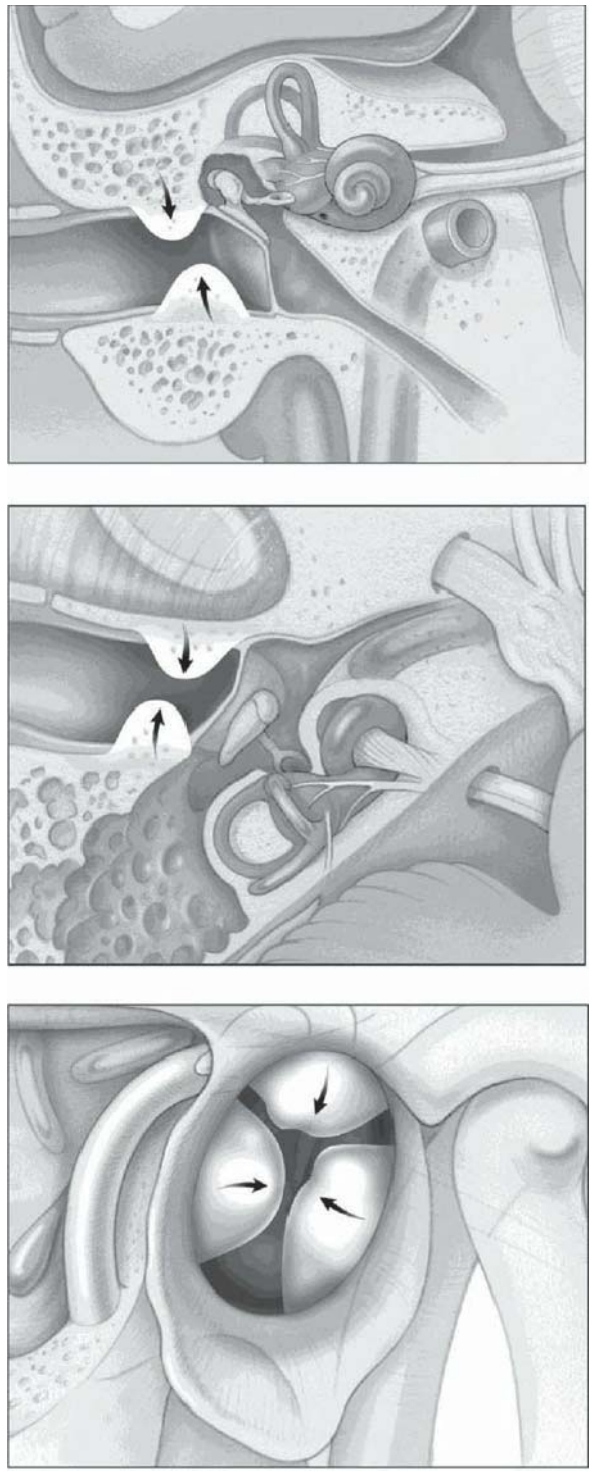

Figure 146.9 **A:** Coronal section of a right ear showing multiple growth centers of exostoses. **B:** Axial view of left ear showing multiple growth centers of exostoses. **C:** Sagittal section of a right ear showing multiple growth centers of exostoses. Figure courtesy of Robert K. Jackler MD.

the exostosis(es) carefully. Exostoses do not develop in a month. By the time the patient requires surgery, these lesions have been present for many years if not many decades. It is highly unlikely that they will grow back any quicker the second time than the first. Hence, there is no

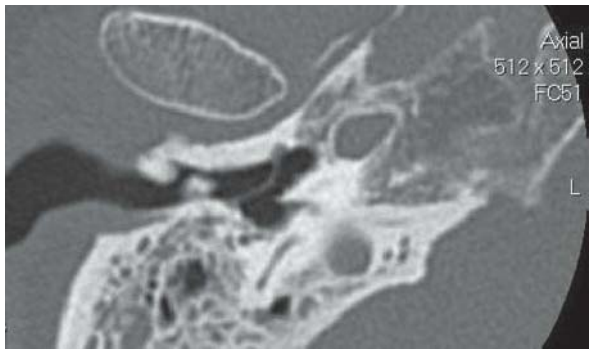

Figure 146.10 Right axial temporal bone CT showing exostoses.

need to "go for broke" and try to remove every millimeter of neo-ossification. A reasonable goal is to be able to see most of the perimeter of the TM and to know that the EAC, after it heals, will be large enough to hold an ITC (in the canal) hearing aid mold. Because of the proximity of the vertical facial nerve and of the TM, nothing more than shaving the bone need be done. Certainly the tympanic ring does not need to be "overcorrected." It is wise to perform this surgery under general anesthesia and to monitor the facial nerve with an EMG needle system. The prevention of an iatrogenic facial nerve injury is worth any and every surgical and monitoring precaution.

In extremely rare cases in which all landmarks have been lost, it is best to stay "high and anterior," that is, where the facial nerve would be unlikely to be found, to find a known landmark such as the TM and then to proceed. Approaching from behind with the vascular strip retracted with a Penrose drain or another suitable retractor may also provide landmark clues. It is usually not necessary to perform a mastoidectomy for landmarks. There are usually enough landmarks in the EAC available for the surgeon.

The surgical technique for the removal of an osteoma is somewhat more straightforward and simple than for exostoses. The lesion is ordinarily removed via a transcanal approach, but a postauricular approach may be required for extremely large osteoma. Because there is ordinarily a stalk leading to the osteoma, it can be tapped with a 2- to 4-mm nasal osteotome and the osteoma delivered. The remaining stalk can be shaved down with a diamond burr. The remainder of the care is the same as with exostoses.

Although the patient is ordinarily consented for a split-thickness skin graft, this is almost never necessary due the redundancy of skin over the exostoses or osteoma. The skin of the EAC is incised in a horizontal fashion around the midpoint of the lesion(s) with a round knife or similar instrument and the skin is "window-shaded" fore and aft away from the bony growth, which is then shaved with an appropriately sized diamond burr or tapped out with an osteotome. Once the bony growths have been reduced and the TM easily seen, the remaining skin is placed back flat, trimmed if necessary, and the EAC is packed for about 3 to 4 weeks. (One hint to help prevent the ingrowth of soft tissue into packing material is to line the whole canal with a sleeve of moistened gelfilm or very thin silastic and then to pack the ear.) The patient must be advised that the ear will take about 6 to 8 weeks to heal properly. It is extremely rare to have to revise this type of surgery if it is done carefully and conservatively.

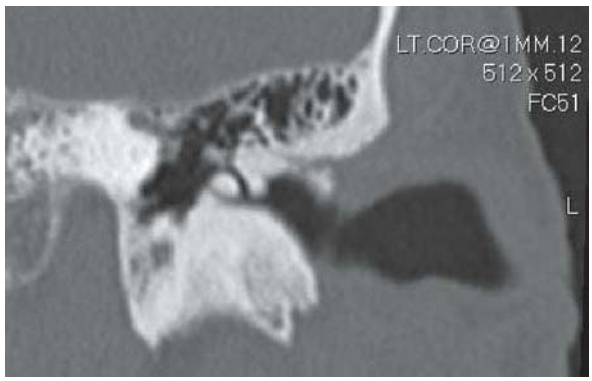

Figure 146.11 Left coronal temporal bone CT showing exostoses.

CONCLUSION

With a thorough knowledge of the normal embryology, anatomy, and physiology of the external ear, together with an understanding of the natural history of the various common disease processes that occur in this location, treatment of the patient with external ear disease becomes logical. However, it is not always easy. Most conditions can be managed with the recommendations outlined in this chapter. There is no substitute for patience and thoroughness.

HIGHLIGHTS

- An understanding of the various disease entities occurring in the external ear is predicated on a knowledge of the embryology, anatomy, and physiology of the canal.
- Infection and blockage of the apopilosebaceous unit are the precursors of infectious otitis externa.
- Otitis externa presents as a spectrum of disease and may be classified into preinflammatory, acute inflammatory, and chronic inflammatory stages.
- Four principles form the basis of treatment for all stages of infection of the external ear: thorough cleaning, antibiotic therapy, control of inflammation and pain, and recommendations to prevent infection. Of these, the first is the cornerstone of therapy.

- Recalcitrant and recurrent otitis externa must be treated aggressively with daily local care and antibiotics, often in the hospital. Patience and thoroughness are needed for successful treatment.
- Surgery is rarely indicated for infections of the external canal but may be required to reverse the natural course of chronic disease.
- NEO is a disease occurring in immunosuppressed patients. It must enter the differential diagnosis of any patient with nonresolving acute external otitis.
- There are four hallmarks of NEO: persistent otalgia; persistent otorrhea and granulation tissue; diabetes mellitus, advanced age, or immunocompromised state; and cranial nerve involvement.
- NEO must be treated aggressively with proper radiographic imaging to map the extent of disease, meticulous local care control of diabetes or immunodeficiency (when possible), and antibiotics. Surgery is rarely required. Mortality remains significant with cranial nerve involvement.
- Many infectious and inflammatory conditions related to external otitis occur in the ear. Therapy is based on treatment of the underlying condition.

147 Neoplasms of the Ear and Lateral Skull Base

Bradley P. Pickett *Brianna K. Crawley*

This chapter provides an overview of neoplasms that affect the temporal bone and the external ear. These neoplasms can be classified on the basis of their location or by their cell of origin. Classification based on location offers a relatively straightforward outline of tumor types that is useful in the differential diagnosis (Table 147.1, Fig. 147.1). Neoplasms of the pinna, the external auditory canal, the middle ear and mastoid, the temporal bone, and the cerebellopontine angle are discussed in this context. When extensive neoplasms occupy more than one anatomic location, however, or when the same pathology arises in more than one location, classification based solely on the site of origin of the neoplasm becomes confusing. In these instances, it is more appropriate to classify tumors based on the cell type that gives rise to the neoplasm. Paragangliomas and hemangiomas are examples of this type of neoplasm. Because a detailed discussion of each neoplasm is beyond the scope of this chapter, the reader is encouraged to examine the recommended readings and references. It should be borne in mind that the causes of neoplasms of the temporal bone and the external ear are in most instances unknown. Therefore, the growth patterns of neoplasms, the prognosis for individuals affected by them, and current modes of surgical and medical therapy are the principal areas of concern in this chapter.

NEOPLASMS OF CELL-SPECIFIC ORIGIN

Paraganglioma

Paragangliomas are the most common true neoplasm of the middle ear and are considered the most frequent pathologic condition involving the jugular foramen. Paragangliomas are generally slow-growing, benign neoplasms with an interval between initial symptoms and diagnosis measured in years, and an estimated doubling time of 4.2 years. The growth patterns of temporal bone paragangliomas often follow the path of least resistance and are therefore greatly influenced by the site of tumor origin and regional anatomy. Paragangliomas that originate in the middle ear are termed glomus tympanicum tumors. Paragangliomas that originate in association in the jugular fossa are termed glomus jugulare tumors. Clinical manifestations are related to tumor extent and vascularity, as are treatment options.

Paragangliomas of the temporal bone arise from glomus bodies occupying the adventitia of the jugular bulb, along the course of the tympanic branch of the glossopharyngeal nerve (Jacobson nerve) or the auricular branch of the vagus nerve (Arnold nerve). Glomus bodies are groups of chemoreceptor cells belonging to the diffuse neuroendocrine system that are found in collections within the jugular foramen and middle ear, carotid bodies, the adrenal medulla, and along the aorta and vagus nerve. Histologically, they are identical to the carotid body and are similar to the autonomic ganglia of the adrenal medulla. Glomus bodies consist of clusters of chief cells supplied by a network of arterioles, venules, and both afferent and efferent nerve terminals. They are of neural crest derivation, migrating during embryogenesis to concentrate around autonomic ganglia. They are more accurately referred to as paraganglia, because they appear to play a role as neuromodulators or monitors of vascular activity. Chief cells have neurosecretory granules that contain norepinephrine, dopamine, and epinephrine, suggesting that the release of granule contents into the vascular system helps to regulate cardiorespiratory function, modify local blood distribution, and maintain thermoregulation. Unlike the carotid body and the adrenal medulla, however, paraganglia of the temporal bone play an uncertain role in these neuroendocrine functions. Paraganglia of the temporal bone are distinguished from other components of the diffuse neuroendocrine system, such as the adrenal medulla, by their lack of affinity for chromium salts used in certain histologic stains. They

TABLE 147.1 NEOPLASMS OF THE EAR AND LATERAL SKULL BASE

Neoplasms of cell-specific origin
Paraganglioma
- Glomus tympanicum
- Glomus jugulare

Epidermoid
- External auditory canal and middle ear (cholesteatoma)
- Internal auditory canal, petrous apex, and cerebellopontine angle

Vascular neoplasm
- Hemangioma
- Hemangiopericytoma

Hematologic malignancy
- Lymphoma
- Plasmacytoma
- Leukemia

Neoplasms of the pinna and external auditory canal
Cutaneous carcinoma
- Squamous cell carcinoma
- Basal cell carcinoma

Malignant melanoma
Glandular neoplasm
- Ceruminous adenoma
- Ceruminous adenocarcinoma
- Pleomorphic adenoma
- Adenoid cystic carcinoma

Osteoma and exostosis
Miscellaneous neoplasm
- Merkel cell carcinoma
- Squamous papilloma
- Pilomatrixoma
- Myxoma
- Auricular endochondral pseudocyst
- Chondrodermatitis nodularis chronica helicis (Winkler disease)

Neoplasms of the middle ear, mastoid, and temporal bone
Adenomatous neoplasm
- Benign middle ear adenoma
- Endolymphatic sac tumor

Langerhans cell histiocytosis
- Eosinophilic granuloma
- Hand-Schüller-Christian disease
- Letterer-Siwe disease

Sarcoma
- Rhabdomyosarcoma
- Chondrosarcoma
- Ewing sarcoma
- Osteogenic sarcoma
- Fibrosarcoma

Chordoma
Congenital neoplasm
- Dermoid
- Teratoma
- Choristoma

Cholesterol granuloma
Neoplasms of the internal auditory canal and cerebellopontine angle
Schwannoma
- Vestibular schwannoma
- Facial nerve schwannoma
- Trigeminal schwannoma
- Jugular foramen schwannoma

Meningioma
Lipoma
Metastases

are therefore categorized as nonchromaffin paraganglia. Adult temporal bones usually have only two or three paraganglia, but on occasion, there may be more, particularly during the fifth decade of life. Most paraganglia of the temporal bone are found in the anterolateral region of the jugular fossa and within the middle ear. Neoplastic transformation of paraganglia can occur in either location, indicated by local tumor invasion or metastatic spread. Metastases of head and neck paraganglioma are uncommon and are more frequently associated with non–carotid body paragangliomas of the head and neck. They occur in only 0.016% cases of paragangliomas and are most often found in the cervical lymph nodes, followed by lungs, liver, spleen, and bone (1).

Paragangliomas represent 0.6% of all head and neck tumors, with a reported incidence range of 1 in 30,000 to 100,000. They occur more frequently on the left side, and females are affected by paragangliomas more frequently than males, 4-6:1. Living at high altitude is also a risk factor. Although the peak incidence occurs during the fifth decade of life, paragangliomas may present from infancy to old age. Tumors that arise in very young patients should generate additional concern, because they tend to be more aggressive, are more commonly multifocal, and are more likely to secrete vasoactive substances (2). Approximately 5% to 10% of patients with paragangliomas eventually present with multiple tumors, but when paragangliomas occur as a familial form of an autosomal dominant disorder (about 10% of patients), multicentricity may occur in as many as 78% (3). Mutations of loci encoding succinate dehydrogenase have been implicated in the development of familial paragangliomas (4). Succinate dehydrogenase is an intracellular enzyme that plays a critical role in cellular energy production, and if the enzyme is inactive, succinate is allowed to accumulate, producing pseudohypoxic conditions that inhibit some neuroendocrine apoptotic factors. This may be the trigger that leads to proliferation of paraganglia.

On gross examination, paragangliomas are deep red, firm, rubbery masses that bleed profusely upon manipulation. The histologic appearance of paraganglioma is distinctive. Nests of argyrophilic chief cells, termed *zellballen*, are septated by a prominent fibrovascular stroma, though this characteristic appearance is occasionally not evident in temporal bone paragangliomas (Fig. 147.2). Unmyelinated nerve fibers may be identified, but they are scarce when compared with normal paraganglia. Nuclear pleomorphism and hyperchromatism are prominent in chief cells but do not appear to indicate malignant growth. Electron microscopy reveals neurosecretory granules within chief cells that store catecholamines. Variable cranial nerve invasion may occur, a feature that has significance during surgical removal of the tumor mass.

Glomus tympanicum tumors usually originate on the promontory of the cochlea. As they grow, they follow the path of least resistance. First, the tumor enlarges to fill the middle ear and to envelope the ossicles. Patients present at this stage with conductive hearing loss and

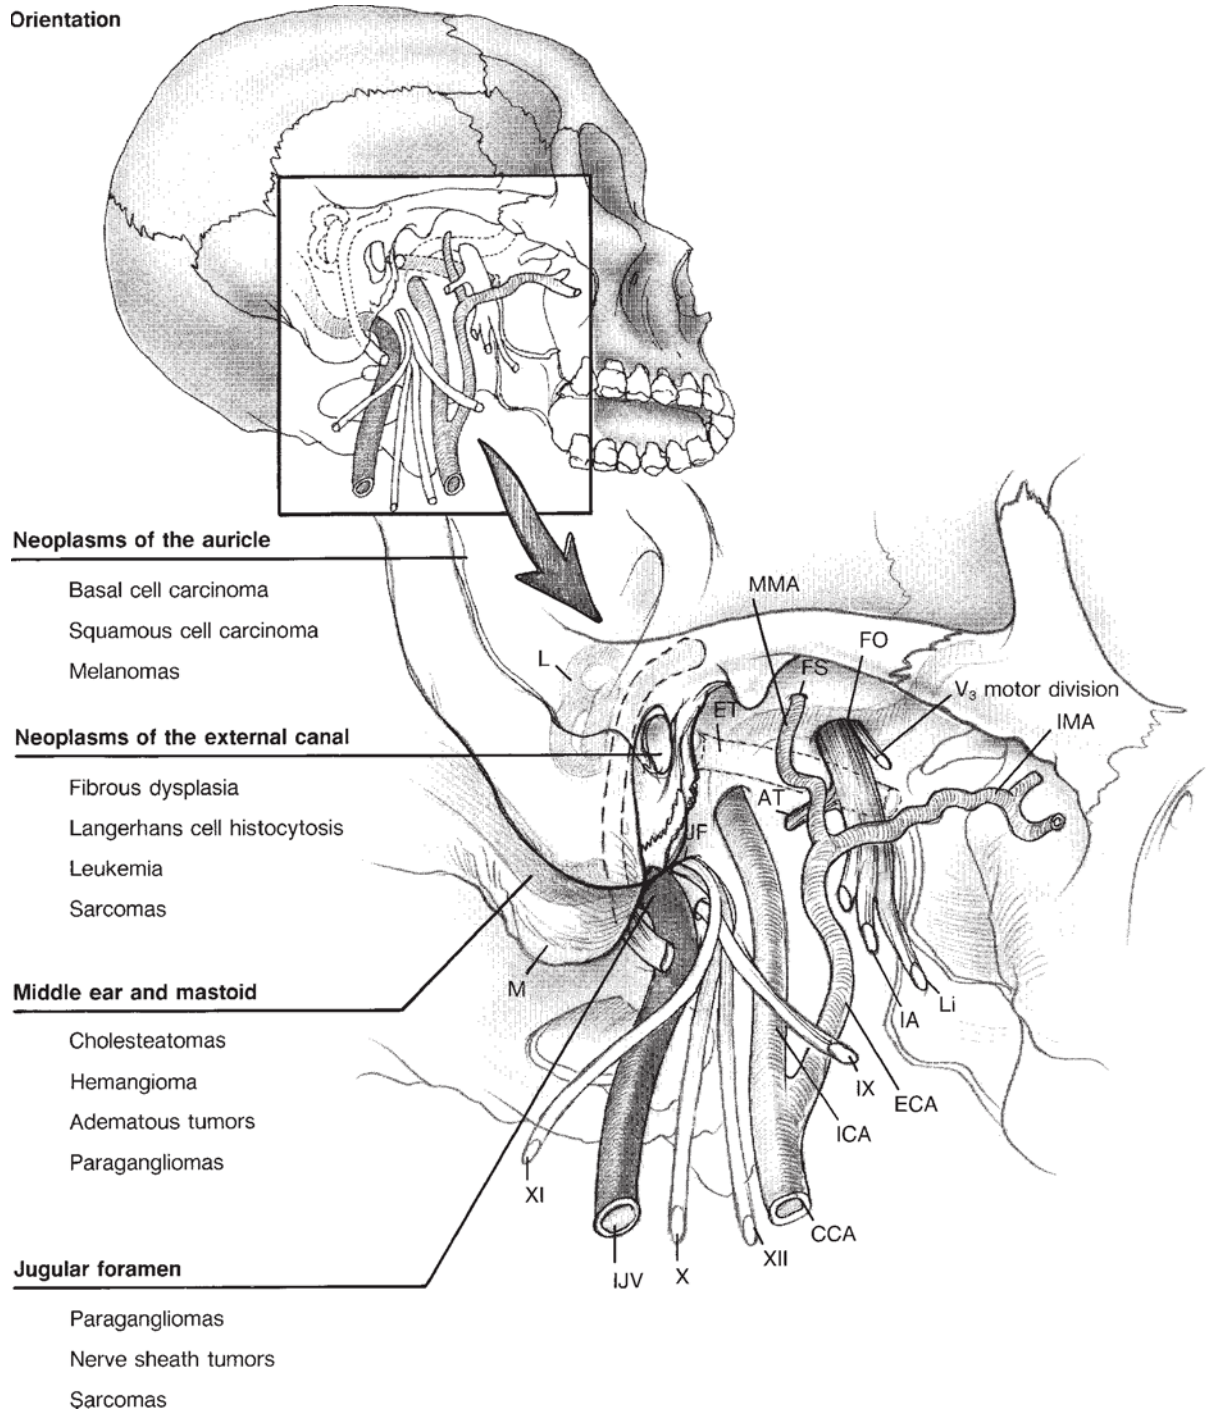

Figure 147.1 Anatomy of the lateral skull base and common locations of neoplasms found in this region. AT, auriculotemporal nerve; CCA, common carotid artery; ECA, external carotid artery; FO, foramen ovale; IA, inferior alveolar nerve; ICA, internal carotid artery; IMA, internal maxillary artery; JF, jugular foramen; JV, jugular vein; L, labyrinth; Li, lingual nerve; MMA, middle meningeal artery; IX, glossopharyngeal nerve; X, vagus nerve; XI, accessory nerve; XII, hypoglossal nerve.

pulsatile tinnitus caused by direct transmission of vascular pulsations from the highly vascularized tumor to the ossicles. Pulsatile tinnitus is the most common presenting symptom for patients with temporal bone paragangliomas. Because glomus tympanicum tumors enlarge within the middle ear cavity, patients with these tumors generally present with pulsatile tinnitus at an earlier stage than patients with glomus jugulare tumors. The tympanic membrane often remains intact as a glomus tympanicum tumor grows, but the tumor may displace the membrane laterally. If tumor extends through the tympanic membrane into the external auditory canal, patients may present with otalgia or bloody otorrhea. As glomus tympanicum tumors enlarge further, they may extend into the mastoid antrum

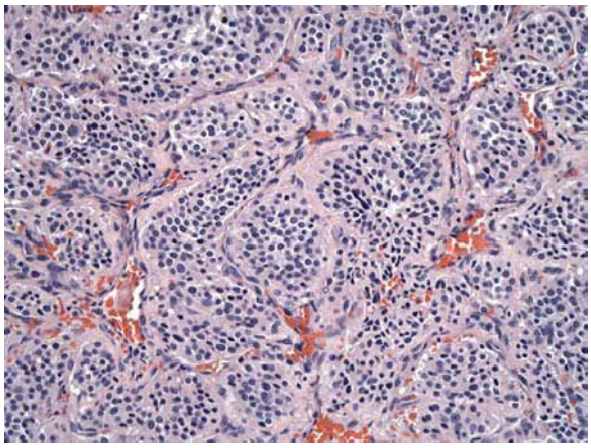

Figure 147.2 Paraganglioma: Histologic section showing tumor cells organized into nests, termed *zellballen*, separated by fibrovascular stroma.

via the aditus ad antrum, into the facial recess, or into the retrofacial air cell tract. At this stage, the tympanic and mastoid portions of the facial nerve may become involved with tumor. The tumor may grow anteriorly into the eustachian tube and inferiorly into the infralabyrinthine air cell tract. When the tumor causes bone erosion in the hypotympanum, the jugular fossa or the vertical portion of the petrous carotid artery may be exposed. It is difficult to distinguish an extensive glomus tympanicum tumor of this kind from a glomus jugulare tumor. Patients with extensive tumors may present with multiple cranial nerve neuropathies.

Glomus jugulare tumors arise in the jugular fossa and are usually large before patients become symptomatic. These are more likely to secrete catecholamines than the glomus tympanicum variety. Compression of neurovascular structures in the jugular fossa and extension medially along the skull base to the hypoglossal canal can lead to cranial nerve neuropathies manifesting as dysphagia, dysphonia, aspiration, and dysarthria. Erosion of the jugular fossa anteriorly and superiorly exposes the petrous carotid artery and allows tumor to invade the middle ear, causing conductive hearing loss and pulsatile tinnitus. Intracranial extension occurs when glomus tumors grow into the eustachian tube and extend into the peritubal air cell tract or follow the petrous carotid artery into the petrous apex, the cavernous sinus, and the middle cranial fossa, resulting in facial hypesthesia. Glomus jugulare tumors may involve the posterior cranial fossa when they extend medially along the skull base or through the infralabyrinthine air cell tract. A patient with extensive tumor that compresses the cerebellum and the brainstem in the posterior fossa may present with ataxia and imbalance.

Paragangliomas of the temporal bone can usually be diagnosed on the basis of findings on physical exam and characteristic features found on imaging studies. Otoscopic examination of a middle ear paraganglioma frequently demonstrates a reddish-blue pulsatile mass medial to the inferior tympanic membrane. Positive pressure during pneumatic otoscopy causes blanching of the mass, a phenomenon known as the Brown sign. The pulsatile nature of the tumor can be diminished with ipsilateral carotid artery compression, a positive Aquino sign. Objective tinnitus may be apparent if auscultation over the mastoid or infra-auricular area reveals an audible bruit. When tumor extends through the tympanic membrane, otoscopic examination shows a hemorrhagic aural polyp. Tumors involving the jugular foramen can be identified when lower cranial nerve palsies develop. Jugular foramen syndrome, also termed Vernet syndrome, arises when tumor growth affects cranial nerves IX, X, and XI and causes paresis or paralysis of the muscles innervated by these nerves. Villaret syndrome is a combination of jugular foramen syndrome with Horner syndrome in patients with more extensive disease. Patients with paragangliomas that erode the carotid canal and compromise the sympathetic plexus present with Horner syndrome (miosis, ptosis, anhidrosis, and enophthalmos). If facial nerve weakness or paralysis exists, it denotes extensive involvement of the middle ear and mastoid. Tuning fork tests or complete audiometric evaluation in these patients shows conductive hearing loss and on rare occasions sensorineural hearing loss. Ataxia or rostral cranial nerve palsies are disquieting signs that indicate involvement of the posterior cranial fossa or cavernous sinus.

Although the chief cells of paragangliomas have neurosecretory granules that store catecholamines, only 1% to 3% of these tumors actively secrete norepinephrine. Catecholamines are much more likely to be secreted by glomus jugulare tumors than by glomus tympanicum tumors. Opinions vary regarding the need to screen for functionally active temporal bone paraganglioma, but all tumor patients who present with a history of flushing, frequent diarrhea, palpitations, headaches, poorly controlled hypertension, orthostasis, or excessive perspiration should have serum catecholamine levels measured and 24-hour collection of urine for analysis of vanillylmandelic acid and metanephrine.

Diagnostic imaging studies provide essential information for the evaluation of patients with temporal bone paragangliomas. These studies reveal diagnostic facts and details about tumor extent and regional anatomy that are essential in planning surgery. High-resolution computed tomography (HRCT) of the temporal bone uses a thin-section bone algorithm and is usually the first imaging study ordered to evaluate a patient suspected of having a temporal bone paraganglioma. HRCT can identify the tumor origin accurately when the bony partition between the jugular fossa and the hypotympanum is intact. In this instance, a glomus jugulare tumor that erodes the jugular fossa and involves lower cranial nerves can be distinguished from a glomus tympanicum tumor that occupies the middle ear. Without this bony partition, it may be difficult to identify the origin of a temporal bone paraganglioma. Erosion of the caroticojugular spine that separates

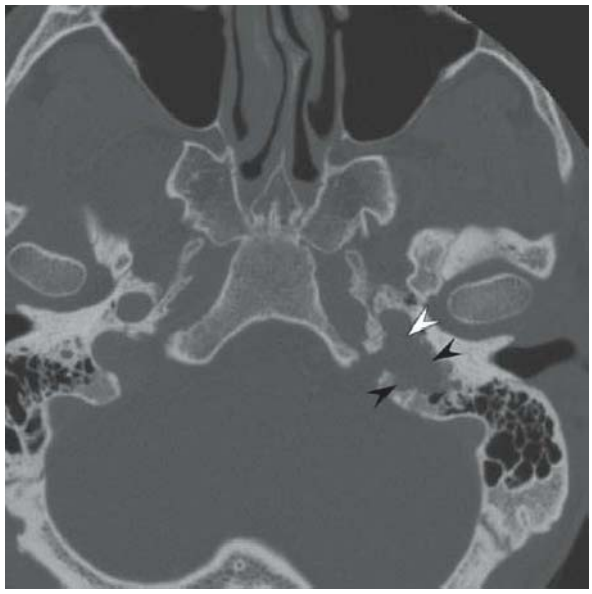

Figure 147.3 Glomus jugulare. Axial CT showing classic bony erosion of the left jugular fossa and caroticojugular spine (*black arrowheads*). The tumor abuts the posterior aspect of the vertical petrous carotid artery (*white arrowhead*).

the jugular bulb and the petrous carotid artery usually indicates a glomus jugulare tumor (Fig. 147.3). If the spine is eroded and the carotid canal is exposed, involvement of the petrous carotid artery is likely. HRCT also helps to identify other lesions that should be excluded, such as a dehiscent jugular bulb or an aberrant internal carotid artery. Obliteration of the fallopian canal indicates adherence of tumor to the facial nerve or invasion of the nerve by tumor. Multidetector CT angiography can diagnose glomus tumors with accuracy and offers information about feeding vessels, venous drainage, and jugular involvement (5). Intracranial extension can also be identified, but magnetic resonance imaging (MRI) is better than HRCT to evaluate the relationship between paraganglioma and adjacent soft tissue structures. MRI will not only identify intracranial extension, but images may help differentiate between intradural and extradural extension. MRI signal characteristics diagnostic for paragangliomas include vascular flow voids within the tumor, the so-called salt and pepper pattern. Pepper refers to the signal voids of large feeding arteries, and salt represents subacute hemorrhage within the tumor. Magnetic resonance angiography and magnetic resonance venography may demonstrate intraluminal involvement of the petrous carotid artery or occlusion of the jugular vein and sigmoid sinus. However, these studies are usually not useful for most large tumors as formal angiography will be necessary. MRI of the neck offers enough detail to screen for multicentric disease such as carotid body tumors or glomus vagale tumors, but other imaging modalities that exploit common features of neuroendocrine tissue may be useful in detecting tumors and recurrences. ^{123}I-MIBG (metaiodobenzylguanidine) scintigraphy and (18)F-DOPA positron emission tomography can be used to detect active tumors, but somatostatin receptor scintigraphy is more reliable for paragangliomas of the head and neck (6).

The principal therapeutic modality is complete surgical excision of the tumor. Secreting tumors must be treated with adjunctive α and β blockade. If surgical therapy is deemed appropriate, small tumors isolated to the promontory can be successfully removed via the transcanal or hypotympanotomy approach. More advanced lesions of the middle ear and mastoid can be exposed with an extended facial recess approach through the mastoid. Large paragangliomas should be evaluated preoperatively with four-vessel angiography. Angiography is combined with embolization using polyvinyl alcohol or intravascular coils 1 or 2 days before surgery to decrease intraoperative blood loss, shorten duration of the procedure, and reduce postoperative morbidity. Devascularization of the entire tumor is difficult, requiring embolization of each vascular pedicle, and may prove impossible in tumors with intracranial extension (7). Sacrifice of the internal carotid artery when invaded by tumor is seldom necessary, and thus, balloon occlusion studies are rarely performed in these patients. Instead, residual mural tumor and tumor that encases the internal carotid artery after subtotal resection is observed or treated with stereotactic radiation surgery (SRS). Glomus jugulare tumors are approached via transmastoid–transcervical exposure of the jugular bulb and jugular foramen. Large tumors require limited facial nerve rerouting or formal infratemporal fossa dissection through this approach. In some cases, more extensive temporal bone dissection is necessary to eradicate tumor that has spread to the petrous apex. This may necessitate removal of part or all of the labyrinth. Intracranial extension requires a combined neurosurgical–neurotologic procedure. Postoperative cranial nerve palsies are not uncommon, and some patients require follow-up care to assist with facial reanimation, deglutition, and phonation. Alternatives to surgical therapy for primary, recurrent, or persistent disease include external beam radiation therapy, intensity-modulated radiation therapy (IMRT), and SRS. Radiation has little effect on the primary tumor cells, the chief cells, but it causes obliterative endarteritis in tumor vessels that can stop tumor growth. One recent meta-analysis suggests that SRS provides better tumor control than surgery, with diminished risk to cranial nerves, but large tumors may require surgical debulking prior to radiosurgery (8).

Epidermoid (Cholesteatoma)

Epidermoids are soft tissue masses resulting from an aberrant accumulation of keratin debris within a sac of squamous epithelium. They are customarily classified as tumors though they are not strictly cellular growths and therefore not neoplastic. Epidermoids may result from squamous epithelial entrapment during embryogenesis, mucosal metaplasia, or, most commonly, with anomalous squamous epithelial migration or deposition. The

nomenclature used to describe these masses is determined based on site of origin and pathogenesis. As an example, masses that arise from congenital epithelial rests in the petrous apex, internal auditory canal, or cerebellopontine angle are generally referred to as epidermoids. Cholesteatoma is the name for epidermoids resulting from the migration of tympanic membrane epithelial cells into the middle ear or from traumatic implantation deep to the skin of the external auditory canal. Congenital cholesteatoma, in contrast, usually refers to an epithelial sac in the middle ear arising from the entrapment of congenital epithelial rests during development. Despite diversity of origin and location, all possess similar histology and growth potential.

Middle ear cholesteatomas are generally divided into two types, congenital and acquired. *Congenital* middle ear cholesteatoma occurs in the presence of an intact tympanic membrane, exclusive of any history of otorrhea, prior otologic intervention, or previous perforation. Theories advanced to explain the origin of these lesions include invagination or implantation into the middle ear, mucosal metaplasia, and epidermoid formation from retained epithelial cell rests. Though the debate persists, the latter is favored as the most likely. Histologic examination of fetal temporal bones has demonstrated epidermoid formation throughout the annular lateral wall region, not solely in the anterosuperior annular region of the tympanic cavity as previously described (9,10). *Acquired* cholesteatomas arise from the transposition of keratinizing squamous epithelium into the middle ear, epitympanum, or mastoid and are often associated with perforation or retraction of the tympanic membrane. These latter are by far the more common of the two, likely resulting from eustachian tube dysfunction or deficiencies in tympanic membrane structure, or a combination. Together, these qualities promote formation of a retraction pocket in the tympanic membrane, trapping epithelial cells within and leading to the accumulation of keratin debris in the middle ear. Acquired aural cholesteatoma may extend to the petrous bone or to the cranial cavity, but most lesions of the petrous apex and the cerebellopontine angle are thought to be of congenital origin. Cholesteatoma of the external auditory canal could conceivably result from congenital rests of tissue trapped deep to the skin of the canal, but most canal wall cholesteatomas occur after traumatic implantation of epithelium subsequent to external trauma or otologic surgery. Patients with cholesteatoma of the middle ear and external auditory canal most often present with purulent otorrhea and conductive hearing loss, while patients with congenital cholesteatoma rarely present with otorrhea as the tympanic membrane is usually intact.

Epidermoids represent approximately 1% of all intracranial tumors, and most occur in the cerebellopontine angle. Squamous metaplasia within the temporal bone or intradural space has been proposed in the histogenesis of these lesions, but it is more likely that developmental entrapment of squamous epithelium from the neural tube is the cause. As squamous epithelium located at the periphery of an epidermoid comprises its only viable proliferating tissue, it grows very slowly in comparison with solid benign neoplasms of similar dimensions. Epidermoids enlarge by expanding to fill empty spaces such as the cerebellopontine angle, the internal auditory canal, or air cells that occupy the petrous apex. These masses are infiltrative, and they grow to a relatively large size before they begin to compress or displace adjacent structures, becoming clinically detectable. Additionally, epidermoids often incite a localized inflammatory reaction that causes the lining to become densely adherent to juxtaposed brainstem or cerebellum. Local neurovascular structures become enveloped by epidermoids instead of being displaced or compressed, and neurologic function may be altered when the vascular supply of a nerve is compromised by the infiltrative process. Most patients become symptomatic in a very gradual manner, their symptoms related to the location of the mass. Patients with internal auditory canal or cerebellopontine angle epidermoids often present with imbalance and hearing loss akin to patients with vestibular schwannoma. However, epidermoids are more likely than vestibular schwannoma to cause facial weakness or hemifacial spasm. Epidermoids are also more likely to compromise the trigeminal nerve causing diminished facial sensation or facial pain. Intracranial extension of these lesions may also manifest as diplopia or headache.

All epidermoids and cholesteatomas exhibit a similar morphologic appearance. The friable lesions are either smooth and cystic with a round or oval appearance or nodular and irregular. The lining of the sac is usually white in color and spongy in consistency. Histologically, the cyst is lined with a benign keratinizing squamous epithelium consisting of three components: the sac or epithelial matrix, the perimatrix, and the contents of the cyst. Typical layers of squamous epithelium may be identified within the epithelial matrix. The contents of the cyst include fully differentiated laminated keratin. Acquired and congenital lesions can often be distinguished histologically by the thicker matrix and more vigorous proliferation of inflammatory cells within the sac and at the periphery of acquired lesions.

The diagnosis of cholesteatoma is usually made during otologic examination, while epidermoids are usually diagnosed with radiographic imaging studies. Congenital epidermoids are frequently identified as an asymptomatic mass in the anterosuperior quadrant of the middle ear. Patients with acquired disease have keratin debris, granulation polyps, or purulent material emanating from the mouth or opening of the sac. Clinical findings in patients with epidermoids include facial weakness or paralysis and sensorineural hearing loss when the lesion involves the internal auditory canal and/or the cerebellopontine angle. Facial hypesthesia and abducens nerve palsy occur when epidermoids invade the anterior petrous apex.

HRCT of the temporal bone in patients with epidermoid disease shows a well-defined homogeneous mass that occasionally contains areas of calcification or has eroded adjacent bony structures. MRI is diagnostic, revealing a well-circumscribed nonenhancing mass that has low signal intensity on T1-weighted images, high signal intensity on T2-weighted images, and hyperintensity on diffusion-weighted image sequences.

Management of cholesteatomas of the external auditory canal and middle ear is addressed in other chapters in this text. Optimal treatment of epidermoids of the skull base consists of total microsurgical resection. This often necessitates a posterior fossa or middle fossa craniotomy, but transtemporal approaches may be indicated, especially in patients with nonserviceable hearing in the ipsilateral ear. Because the capsule of the mass may be densely adherent to the brainstem or intracranial vascular structures, complete removal of skull base epidermoids is extremely difficult or even impossible. Complete excision is achieved in only half of all patients with epidermoids, and additional postoperative cranial nerve deficits are discovered in most of these patients (11). Recurrence can be expected in at least 30% of patients when subtotal removal is carried out. Malignant transformation is very rare, and only 26 cases have been reported.

Hemangioma and Hemangiopericytoma

Hemangiomas are benign vascular proliferations that arise from capillaries, arterioles, or venules. They are classified according to the type of vessel from which they originate: capillary hemangioma, cavernous hemangioma, and venous hemangioma. It is unclear whether they represent true neoplasms or hyperplastic growth of normal tissue occurring in an appropriate anatomic site. Hemangiomas are reported to occur in a variety of locations involving the external ear and lateral skull base, namely, the external auditory canal and tympanic membrane, the middle ear, the internal auditory canal, and the geniculate segment of the facial nerve. Tumors are spongy red or purple nodular masses. On microscopic examination, they show thin-walled vascular channels that contain blood and are small or intermediate in size. These channels are not surrounded by an elastic or muscular layer. Clinical presentation varies depending on tumor location. Hemangiomas of the external auditory canal and tympanic membrane have been reported when patients present with mild conductive hearing loss and aural fullness. Patients with middle ear tumors are often asymptomatic, but they can also present with conductive hearing loss, aural fullness, and pulsatile tinnitus. Otologic examination reveals a vascular intratympanic mass that can be confused with a paraganglioma, an adenomatous tumor, or an aberrant vascular anatomy. Preoperatively, hemangiomas of the internal auditory canal may be difficult to distinguish from vestibular schwannomas when patients present with unilateral sensorineural hearing loss. However, accompanying facial nerve dysfunction is more characteristic of hemangioma, even when tumors are small. CT imaging studies help to differentiate intracanalicular lesions when hemangiomas show calcium stippling, which is characteristic of an osseous hemangioma. On MRI, they are heterogeneously hyperintense.

Geniculate hemangiomas are the most common temporal bone hemangioma and perhaps the most intriguing. They consistently arise from the superior aspect of the geniculate ganglion, probably from vascular plexuses on the surface of the facial nerve, and extend into the floor of the middle cranial fossa. Even though the tumor is generally extraneural, they sometimes infiltrate the nerve or are associated with a localized inflammatory response that causes the tumor to adhere tightly to the nerve sheath. This intimate relationship with the facial nerve accounts for the frequently associated facial nerve dysfunction, manifest by paralysis, twitching, or spasm of the facial musculature, even when tumors are very small.

Depending on their size, location, and the structures they involve, hemangiomas of the ear and temporal bone are either observed or treated with complete surgical excision. Resection of lesions from the external canal and the middle ear is usually straightforward, but it may be unnecessary in pediatric patients who are asymptomatic as these lesions often involute spontaneously. When hemangioma is associated with the facial nerve, however, proper management is controversial. If facial paralysis exists, tumor resection with nerve grafting may be appropriate. If facial nerve function is normal or only mildly compromised, early excision when the tumor can be peeled off the nerve while preserving function may be appropriate. Facial nerve monitoring is used during the surgical resection to help maintain nerve integrity. When left intact, patients generally have superior results when compared to patients who require nerve sacrifice and grafting. In patients who have undergone subtotal resection for nerve preservation, regrowth has not been detected as late as 13 years after surgery. If a cochlear fistula is noted in the setting of serviceable hearing, surgery should be delayed in order to preserve hearing for as long as possible (12). However, most case reports suggest that facial nerve integrity cannot be maintained when removing hemangiomas, and because most geniculate hemangiomas grow very slowly, observation may be the most appropriate management until severe dysfunction or facial paralysis occurs.

Hemangiopericytoma is a rare vascular tumor derived from pericytes that line the outside surface of capillary basal lamina. They can occur wherever capillaries are found. Less than 20% of hemangiopericytomas occur in the head and neck, and fewer than 10 cases have been reported where the tumor originated in the temporal bone. The middle ear, jugular fossa, and petrous bone were the apparent sites of origin of the tumors that occurred in the temporal bone. Symptoms include hearing loss, otorrhea, and cranial nerve deficits. Hemangiopericytoma can

occur in patients of any age with 10% of cases occurring in children, but it is most frequent in patients aged 50 to 70, affecting males and females equally. Tumors are soft or rubbery and pale gray or white in color. The metastatic rate for primary temporal bone tumors is estimated to be 15% to 20%. On microscopic examination, hemangiopericytomas are circumscribed pseudoencapsulated cellular tumors containing thin-walled vascular spaces separated by sheets of polyhedral- and spindle-shaped cells. They do not demonstrate intratumoral calcification. Tumors with malignant behavior may display nuclear pleomorphism, lymphocytic infiltration, and lack of vascular spaces with necrosis and hemorrhage. Wide excision with or without embolization is the treatment of choice, but external beam radiation therapy, stereotactic radiosurgery, or chemotherapy may be used to treat extensive, recurrent, or inoperable tumors. Long follow-up is mandatory secondary to their propensity to recur and metastasize (13).

Lymphoma, Plasmacytoma, and Leukemia

Lymphoma is a neoplasm of the lymphoreticular system that may involve the temporal bone either as a secondary lesion after metastatic spread or as a primary lesion causing focal disease. Neoplastic infiltration of the middle ear, the facial nerve, the eighth cranial nerve, and the bone marrow of the petrous apex is not an uncommon finding during postmortem examination of temporal bones from patients with systemic lymphoma. However, most patients are asymptomatic unless lymphomatous infiltration results in middle ear effusion or hemorrhage and conductive hearing loss. Primary osseous lymphoma represents 1% to 2% of malignant lymphoma, and only 18 cases of primary temporal bone B-cell lymphoma have been reported (14). In these case reports, the most common presenting symptoms were conductive hearing loss, otalgia, aural fullness, and otorrhea. Localized swelling and pain, fevers, sensorineural hearing loss, balance disturbance, and facial and abducens palsies from perineural invasion have also been reported. Physical examination may reveal middle ear masses or effusions and facial paresis. Once diffuse lymphoma has been ruled out, most patients with primary lymphoma of the temporal bone do well after chemotherapy and/or radiation therapy. The role of surgery in these patients is to obtain tissue for diagnosis.

Extramedullary plasmacytoma of the temporal bone is a rare neoplasm that is thought to arise as a clone of malignant plasma cells in the submucosal stroma of the middle ear. These are solitary lesions that occur outside the bony medullary spaces, and they are less likely to develop into disseminated disease or into multiple myeloma when compared with solitary osseous plasmacytomas. The majority of extramedullary plasmacytomas develop in the upper aerodigestive tract with only 1% of these tumors arising in the temporal bone. Patients, more often men over 50, present with aural fullness or otalgia, hearing loss, and tinnitus, and physical examination reveals a thickened tympanic membrane with an intratympanic mass or an aural polyp. Microscopic examination of these fleshy masses reveals sheets of monotonous round cells that are typical of plasma cells. Nuclear and cellular atypia is variable and defines tumor differentiation and grade. Tumor grade, however, is not necessarily predictive of tumor behavior. When biopsy specimens suggest the diagnosis of extramedullary plasmacytoma, patients should be evaluated for disseminated disease or multiple. This evaluation includes complete blood count with differential and smear, erythrocyte sedimentation rate, serum chemistries, creatinine, serum and urine protein analysis for monoclonal antibodies, bone marrow biopsy, and a radiographic skeletal survey. Chemotherapy is indicated for disseminated disease, but extramedullary plasmacytoma isolated to the temporal bone is usually successfully treated with external beam radiation therapy and surgery for radioresistant or very large tumors. Recurrence is rare as is dissemination to multiple myeloma, but the possibility necessitates long-term follow-up (15).

Leukemia may involve the temporal bone by infiltrating marrow spaces and the tympanomastoid cavity or by causing hemorrhage within the middle or inner ear. In leukemia patients, marrow spaces in the temporal bone are frequently infiltrated by leukemic cells, but this rarely results in clinical manifestations. Infiltration of the middle ear and mastoid air cells is less common but may result in symptomatic effusions, often misdiagnosed as otomastoiditis, as these patients are particularly susceptible to infection. Patients with acute or chronic myelogenous leukemia may develop larger consolidated infiltrates that form solid tumors known as granulocytic sarcomas or chloromas. These present with hearing loss, facial palsy, and postauricular and auditory canal swelling and are often first mistakenly treated for infection. The tumors consist of immature granulocytes and contain myeloperoxidase that gives the lesion a green hue, hence the name chloroma. Most chloromas occur in children with leukemia. Leukemic infiltrates can involve the cochlea causing sensorineural hearing loss, but inner ear injury more likely results from local hemorrhage. Diagnosis is best made with biopsy, though this is often not feasible, and MRI is the imaging modality of choice. Treatment of systemic leukemia that infiltrates the temporal bone requires appropriate high-dose chemotherapy and management by a hematologist/oncologist with consideration for radiation therapy. Prognosis is poor, especially in the setting of delayed diagnosis (16).

NEOPLASMS OF THE PINNA AND EXTERNAL AUDITORY CANAL

Cutaneous Carcinoma

Basal cell carcinoma is a cutaneous malignancy that comprises approximately one-fifth of neoplasms that involve the ear and temporal bone. This common lesion is generally

discovered in adult patients and is usually diagnosed for the first time during the sixth decade of life. Most basal cell carcinomas occur on the pinna or in the periauricular area, where they are more common than squamous cell carcinoma, and only about 15% arise in the external auditory canal where squamous cell carcinoma is far more common. Actinic exposure is thought to be the primary factor responsible for initiating this neoplastic transformation because the periauricular areas and the auricular helix, which receive the most sun exposure, are especially susceptible. Males are affected approximately twice as often as females. The noduloulcerative lesion that appears on the pinna is similar to basal cell carcinomas found in other areas of the body. It is characterized by locally infiltrating nodular growth with a rolled border and a central crusting ulcer. This neoplasm appears to be well circumscribed, but there may be subcutaneous extension with indistinct clinical margins. Distant or regional metastases are extremely rare, though they are more common when lesions involve the ear. Histologic examination shows a rim of palisading basaloid cells at the tumor margin with central necrosis and ulceration. Most of the tumor is quite cellular, making it simple to make a diagnosis and to identify the tumor margin (Fig. 147.4). However, 25% of basal cell carcinomas that involve the skin of the external ear are morpheaform or sclerosing subtypes. They are distinguished from the more common noduloulcerative lesions by linear strands of basaloid cells that infiltrate the subcutaneous layers of the skin and are accompanied by a fibrous matrix. The linear strands are diffuse within the fibrous matrix, and consequently the margin of the morpheaform type of basal cell carcinoma is indistinct.

Basal cell carcinoma of the ear is a slow-growing neoplasm, and the diagnosis is readily obtained by inspection and biopsy. If untreated, these low-grade malignancies progressively enlarge and infiltrate peripherally into the periauricular tissues or medially into the external auditory canal, the middle ear, and the mastoid. Morpheaform lesions are especially troublesome because they infiltrate along deep tissue planes. Extension into the temporal bone may remain undetected until the malignancy is far advanced. Basal cell carcinoma is best treated with complete surgical excision. However, the risk of recurrence for auricular basal cell carcinoma is high compared with other sites in the head and neck because deep invasion often occurs. Mohs micrographic surgery appears to be the most successful technique to minimize recurrence and to conserve nonneoplastic tissue. Radiation therapy is used as palliative therapy or as adjunct therapy for extensive or recurrent tumors.

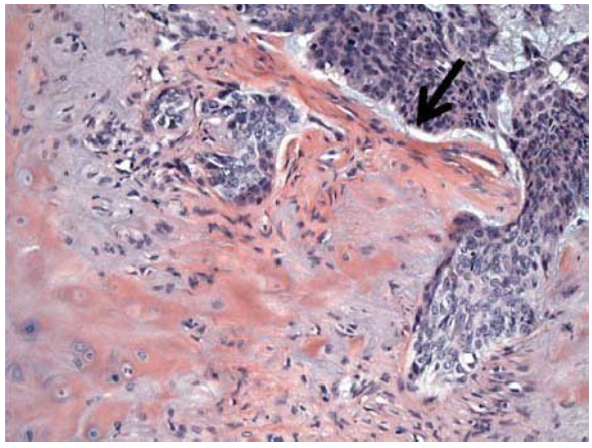

Figure 147.4 Basal cell carcinoma: Histologic section showing basophilic tumor cells invading hyaline auricular cartilage. Palisading basaloid cells are demonstrated adjacent to a clefting artifact (*arrow*).

Squamous cell carcinoma that involves the ear and lateral skull base is most often a cutaneous neoplasm that originates from the skin of the pinna or external auditory canal. These are aggressive tumors with prognoses affected by depth of invasion, cartilage destruction, and lymphovascular invasion. A much smaller portion of these malignancies originates from the middle ear, presumably from metaplastic middle ear mucosa. The average age at diagnosis of squamous cell carcinoma of the pinna is the late 60s, whereas primary external auditory canal lesions generally present 10 to 15 years earlier. Tumors that originate in the middle ear affect adults in an intermediate age group at an average age of 60 years. Patients with squamous cell carcinoma of the ear and temporal bone comprise 24% of patients with squamous cell carcinoma of the head and neck. Most of these tumors originate on the pinna. Like basal cell carcinoma, more than half of these occur on the helix, which receives the greatest actinic exposure. Sun exposure and cold injury certainly predispose patients to this malignancy, but other factors such as radiation exposure and chronic infection are thought to play an etiologic role. For squamous cell carcinoma that originates in the middle ear, chronic otitis media and human papillomavirus are proposed to be important elements in the pathogenesis of malignancy (17).

Squamous cell carcinoma of the pinna is a scaly, irregular, indurated maculopapular lesion. Very often, the surface of the erythematous lesion is ulcerated with either a crust or serosanguinous exudate. Patients with squamous cell carcinoma of the external auditory canal often present with hemorrhagic otorrhea that has been treated for years as otitis externa. In older patients, chronic bloody drainage and sudden onset of deep ear pain suggest an invasive malignancy. Ipsilateral facial nerve deficit is another indication of invasive malignancy. Extensive involvement of the external auditory canal or the middle ear results in conductive hearing loss, but deep invasion that extends into the internal auditory canal, the cerebellopontine angle, or the labyrinthine capsule may cause sensorineural hearing loss. Metastasis to cervical or parotid lymph nodes occurs in approximately 30% of patients with temporal bone invasion, whereas metastatic disease occurs half as often when lesions are limited to the pinna or to the membranous portion of the external auditory canal. Histologic examination shows proliferative pleomorphic spindle-shaped epidermal

cells with keratin pearls and intercellular bridges that are typical features of squamous cell carcinoma. A less aggressive form of squamous cell carcinoma of the pinna, called adenoid squamous cell carcinoma, shows similar histologic features, but there is nodular proliferation of epidermoid cells that show prominent glandular patterns. These lesions are invasive but slow growing, and they rarely metastasize.

The diagnosis of squamous cell carcinoma of the pinna is easily made with a biopsy, but many middle ear and external auditory canal malignancies have advanced significantly by the time of diagnosis. Biopsy is advisable whenever middle ear or external canal infections fail to respond to appropriate medical therapy. Untreated carcinoma of the pinna will likely spread laterally to periauricular areas or medially into the external auditory canal. The prognosis worsens when external canal lesions extend medially into the tympanic bone or through the tympanic membrane and into the middle ear. Tumor in the middle ear extends anteriorly into the eustachian tube and carotid canal and posteriorly into the mastoid air cell system. From the carotid canal, squamous cell carcinoma can invade the petrous apex, the anterior skull base, and the cavernous sinus. The inner ear is generally resistant to invasion, but tumor in the mastoid may penetrate the dural plate and extend into the posterior cranial fossa.

The treatment of squamous cell carcinoma of the ear and lateral skull base, even for less advanced tumors, should be aggressive because recurrence rates are high (18). Complete surgical resection is favored whenever possible. Complete resection of lesions of the pinna is most easily achieved with Mohs micrographic surgical techniques. Carcinoma that invades the cartilaginous portion of the external auditory canal can be excised as a sleeve resection with skin grafting of the defect. Tumors that invade the bony external auditory canal require en block excision with a lateral temporal bone resection. When tumor extends through the tympanic membrane into the middle ear, expands into the mastoid air cells, or invades the otic capsule, a subtotal temporal bone resection is indicated. Parotidectomy and neck dissection may also be appropriate, and radiation therapy is recommended for patients with advanced-stage carcinoma to improve survival (19). Chemotherapy is sometimes offered as adjuvant or palliative therapy but has not yet been shown to increase survival.

Melanoma

Malignant melanoma of the external ear is a cutaneous neoplasm that originates from melanocytes in the epidermis or dermis of the pinna. Melanomas account for only 3% of malignant cutaneous neoplasms, yet approximately 75% of deaths from cutaneous malignancies are caused by melanoma. The external ear is the site of origin for approximately 10% of all primary melanomas of the head and neck and 1% of all melanomas, with the helix or antihelix being the most common location of the original lesion. Primary melanoma of the external auditory canal is extremely rare, and melanoma of the middle ear is most likely to be metastatic disease or the result of regional extension. The average age at diagnosis of melanoma of the pinna is 50 years, but this disease affects all age groups except for young children. Men are affected by melanoma at least three times more often than women, and fair-skinned individuals with blonde or red hair, blue eyes, and freckled skin are predisposed to the disease. Sun exposure, specifically repeated intense exposure causing severe solar injury, has a role in the pathogenesis of this neoplasm. Melanoma is five times more common in the southwestern United States when compared with the northeast. The incidence of melanoma in all areas of the world appears to be increasing annually. Atmospheric ozone depletion may be responsible for some of this increase, but heightened awareness of skin malignancy by patients and by medical professionals enhances the likelihood of detection. Patients may also be genetically predisposed to melanoma. First-degree relatives of patients with melanoma have twice the risk of developing this malignancy, and inherited disorders, such as familial dysplastic nevus syndrome, also increase the risk of developing melanoma.

Melanomas of the ear are divided into five subtypes based on appearance and potential for dermal invasion. *Superficial spreading melanoma* is the most common type. It starts as a regular dark pigmented macule that first grows radially throughout the epidermis and dermal–epidermal junction, becoming nodular and ulcerated with transition into its vertical growth phase. Round, pigmented epithelioid melanocytes grow in nests that invade the epidermis during the radial growth phase and the dermis during the vertical growth phase. The radial growth phase is intermediate in length and is estimated to last anywhere from 1 to 6 years. Many of these lesions will incite an inflammatory response. *Nodular melanoma* is the most aggressive of the three types. These darkly pigmented nodules invade the dermis and subcutis with minimal, if any, radial spread. On histologic examination, atypical melanocytes are both spindle shaped and epithelioid in nature, and the surrounding inflammatory response is minimal (Fig. 147.5). On immunohistochemical studies, malignant melanoma demonstrates reactivity for vimentin, S-100 protein, HMB-45, and Melan-A. *Lentigo maligna*, the third type of melanoma, is a macular lesion with variable pigmentation that tends to have a prolonged radial growth phase before dermal invasion occurs. A lentigo consists of pigmented spindle cells that are usually confined to the epidermis, and there may be a surrounding inflammatory response. *Desmoplastic melanomas* are associated with preexisting melanocytic lesions but can be amelanotic. They have a high local recurrence rate and frequent perineural involvement, but they rarely metastasize. *Mucosal melanomas* may be associated with the eustachian tube or, rarely, arise primarily from the middle ear mucosa. They are associated with a poor prognosis secondary to late stage at presentation and difficulty in obtaining adequate surgical margins.

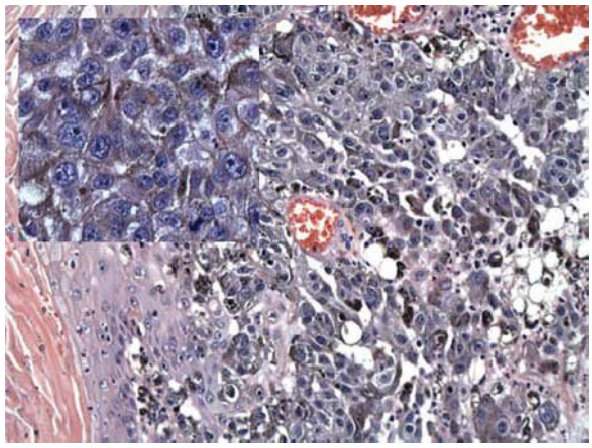

Figure 147.5 Melanoma: Histologic section showing remarkable pigmentation of malignant melanoma cells, even on standard H&E preparation. Characteristic prominent nucleoli with multiple mitotic figures are demonstrated (**inset**).

The diagnosis of melanoma is suspected when pigmented lesions change color or texture, increase rapidly in size, or ulcerate. Prompt excisional biopsy is recommended for all suspicious pigmented lesions because early melanoma is curable. Tumor thickness is critical to establish the prognosis, but nodular configuration, ulceration, and regional or distant metastases all indicate a poor prognosis. Once the dermis is invaded, the probability of regional or distant metastases increases. Unfortunately, one-third of patients have cervical node involvement at presentation. The precise location of the tumor does not appear to correlate well with metastatic patterns, but melanomas of the ear have been found to metastasize to preauricular, postauricular, anterior and posterior cervical chains, and into the parotid nodes. Elective lymph node dissection has been shown to overtreat 80% of patients without providing a survival benefit. However, waiting to perform a therapeutic lymph node dissection when metastatic disease is present may be responsible for unacceptable treatment delays. As a solution to this dilemma, sentinel node mapping using preoperative lymphoscintigraphy and intraoperative intradermal injection of marker dye and radioactive isotope has become the primary method for identification of lymph-draining nodal basins (20). Problems unique to sentinel lymph node biopsy (SLNB) in the head and neck include proximity of the sentinel node to the injection site, inaccessibility of the node (intraparotid lymph nodes), and potential for sentinel nodes that may exist in more than one region. One series demonstrated sentinel lymph nodes from primary melanomas of the auricular helix that were located in levels I to V of the neck and the parotid gland, with an average of three nodes per patient and a range of 1 to 7. Almost 90% had at least one node in level IIA (21).

The treatment of choice for malignant melanoma is complete surgical excision with at least a 1-cm margin for lesions less than 2.0 mm in depth and a 2 cm or greater margin for deeper lesions as satellite clusters can occur. The goal of treatment is negative margins on permanent pathology. In the presence of ulceration, cartilage invasion, or recurrence, full thickness wedge resections are recommended. Sleeve resections of the external canal may be indicated for involvement, progressing to lateral temporal bone resections with more extensive disease. Reconstructions should not be performed until margins are clear. Lymphoscintigraphy with sentinel node biopsy has been recommended in appropriate surgical candidates with Breslow depth ≥0.76 mm and is becoming established as the standard of care. In the past, information about histologic features and immunohistochemical staining of lesions has been used to guide the decision regarding neck dissection for patients with clinically negative necks. However, this strategy for surgical treatment has failed to increase overall survival or influence 5-year disease-free survival (22). Completion lymphadenectomy after positive SLNB yields a superior 5-year survival rate when compared with lymphadenectomy undertaken after disease is clinically evident. In addition to its influence over the decision to proceed with lymphadenectomy, SLNB provides prognostic information, and that may determine whether adjuvant therapy is recommended (23). Though its efficacy remains controversial, interferon-alpha-2b has been shown to increase disease-free survival and may even provide overall survival benefit in subgroups of patients with high-risk melanoma. Other adjuvant therapies including immunomodulation therapy, vaccination, high-dose fractionated radiation therapy, and chemotherapy have not been shown to improve survival, but continue to be investigated (24).

Glandular Tumors

Glandular tumors of the external auditory canal are rare neoplasms that are thought to arise from the ceruminous glands of the canal. Nearly all glandular tumors of the external auditory canal arise in the lateral membranous portion of the canal where ceruminous and sebaceous glands predominate. Both ceruminous and sebaceous glands are categorized as apocrine glands, meaning that glandular cells release secretions by pinching off and liberating the secretion-rich portion of the cell. Some glandular tumors of the external ear canal, however, seem to arise from eccrine glands. These are glands that secrete by releasing secretory granules. Ceruminous glands might give rise to eccrine gland tumors if they also had some eccrine function. Electron microscopy suggests that ceruminous glands do indeed release secretory granules and may have eccrine function. They might then be better classified as apoeccrine glands and thus might be the origin of all glandular tumors of the external auditory canal.

It is possible to distinguish at least four different histologic types of glandular tumors of the external auditory canal. *Ceruminous adenoma* clearly arises from ceruminous glands. Histologically, it consists of well-differentiated proliferating ceruminous glands that form solid, cystic, and

papillary patterns. The glands have a cuboidal or columnar cell layer of apocrine origin and an outer spindle-cell layer of myoepithelial origin. These tumors may be more common in males, and the average age of patients at presentation is 60 years. These nonencapsulated benign neoplasms do not invade surrounding structures. *Ceruminous adenocarcinoma*, on the other hand, is an invasive neoplasm that can metastasize to regional lymph nodes. Histologically, this tumor is nearly identical to a benign adenoma, and it may be difficult to distinguish benign and malignant forms based on microscopic anatomy. However, in some cases, microscopic examination of malignant lesions shows anaplasia, nuclear pleomorphism, mitotic figures, and perivascular or perineural invasion. The primary distinguishing features are regional metastases and invasion into surrounding tissues. Like adenomas, adenocarcinomas are more common in males, but they are diagnosed at an earlier age, averaging 48 years. *Pleomorphic adenoma* of the external auditory canal is similar to neoplasms of the salivary glands, which are eccrine glands, and consists of both epithelial and mesenchymal elements. These benign tumors affect males and females equally, and the average age at diagnosis is 51 years. *Adenoid cystic carcinoma* is the most common glandular neoplasm of the external auditory canal. The cell type that gives rise to these tumors when they occur in the external auditory canal is uncertain. Histologically, these tumors are similar to malignant salivary gland tumors. They lack a capsule and consist of small hyperchromatic cells arranged in cribriform, tubular, or solid patterns. Perineural invasion and invasion along deep tissue planes are prominent features. Regional lymph node metastases are not uncommon, and distant metastases can occur in any vascularized organ, but the lung is the most common site of distant disease. Adenoid cystic carcinoma is more common in females and is diagnosed on average at 43 years of age.

Glandular tumors usually present as asymptomatic soft tissue masses in the membranous external auditory canal. Once the canal is occluded, conductive hearing loss or secondary otitis externa may result. Malignant lesions are more likely to ulcerate or to cause otalgia. Both benign and malignant tumors grow along the path of least resistance, extending laterally out the meatus or medially through the tympanic membrane and into the middle ear. Invasive malignant tumors also extend radially through auricular cartilage and the fissures of Santorini into the parotid gland or into surrounding periauricular tissue. Medial extension with erosion of tympanic membrane or temporal bone is also indicative of malignancy. Diagnosis is made on the basis of microscopic examination of biopsy specimens. To distinguish between benign and malignant ceruminous tumors, biopsy specimens should be large enough to identify deep tissue invasion. HRCT of the temporal bone and MRI of soft tissue around the lateral skull base can be helpful in this respect also. Benign tumors are treated with wide local excision and reconstruction of the external auditory canal. Because of high recurrence rates, especially in cases of adenoid cystic carcinoma, treatment of malignant lesions should be aggressive (25). Lateral temporal bone resection and postoperative radiation therapy are appropriate for early lesions. Larger malignant tumors require a more extensive temporal bone resection, parotidectomy, and cervical lymph node dissection in addition to postoperative radiation therapy.

Osteomata and Exostoses

Osteomata and exostoses are benign bony growths that involve the external auditory canal. Some controversy exists about whether these are separate entities or actually variations of the same pathologic process, but most sources suggest that osteoma and exostosis are clinically and histologically distinct. *Osteomata* are solitary pedunculated osseous lesions that are smooth and round and originate on the tympanosquamous and tympanomastoid suture lines inside the bony external auditory canal. Patients in almost any age group may present with these neoplasms, but most are middle-aged adults at presentation, and women appear to be affected more often than men. The etiology of osteomata is unknown. Clinically, most patients are unaware of the neoplasm until it is incidentally discovered during otologic examination. When the tumor is sufficiently large, patients may experience conductive hearing loss or recurrent bouts of otitis externa. Histologically, osteomata consist of lamellar bone around trabeculated cancellous bone that contains marrow spaces or fibrovascular tissue. The bone is lined with periosteum and keratinizing stratified squamous cell epithelium. The diagnosis is made during otologic examination when palpation reveals a pearly white or erythematous tender bony growth fixed within the bony canal. Surgical removal of symptomatic tumors requires either a transcanal or a postauricular approach for exposure. Osteomata are removed with a drill while preserving as much skin as possible. Split-thickness skin grafts are used to cover exposed tympanic bone when necessary.

Exostoses are broad-based osseous lesions that occur around the circumference of the medial aspect of the bony external auditory canal. They occur as multiple lesions and are often bilateral. Most patients are diagnosed in their teens or as young adults, and exostoses are far more common in males. The occurrence of exostoses is strongly correlated with exposure to cold water and is therefore thought to result from cold-induced periostitis. Like patients with osteomata, most are asymptomatic until the external auditory canal is occluded or nearly occluded and the diagnosis is made during otologic examination. Histologically, exostoses differ from osteomata. Exostoses consist of parallel layers of subperiosteal bone containing no or only poorly developed trabeculated fibrovascular channels. Surgical removal of exostoses is usually more challenging than removal of osteomata. Generally, a postauricular approach is required, and facial nerve monitoring is recommended

because the distal mastoid portion of the facial nerve is at risk during drilling of the posteroinferior aspect of the bony canal. Skin flaps are developed to expose the bony lesions, and they are removed with a drill while preserving the skin. Split-thickness skin grafts may be necessary to prevent postoperative cicatrix formation.

Miscellaneous Neoplasms of the Pinna and External Auditory Canal

Merkel cell carcinoma is a rare but highly malignant cutaneous neuroendocrine tumor that has many characteristics in common with small cell carcinoma of the lung. Fifty percent of these tumors are found in the head and neck, and most that involve the external ear are found in the external auditory canal instead of the pinna. Lesions seem to occur on sun-exposed areas of skin or in patients who are immunosuppressed. The average patient is 65 years old and presents with a rapidly growing, firm, painless nodule that is red, pink, or blue in color. Metastases to regional lymph nodes are present in more than half of patients, and distant pulmonary, hepatic, skeletal, and neurologic metastases occur in approximately 30%. Biopsies specimens show cords, strands, and clusters of round cells in the dermis. Like small cell carcinoma of the lung, these cells have uniform basophilic oval nuclei and stain positively with labeled antibodies to vasoactive intestinal peptide and neuron-specific enolase. Merkel cell carcinoma may be distinguished from amelanotic malignant melanoma, lymphoma, or metastatic carcinoma on the basis of these immunohistochemical staining characteristics. Aggressive therapy is indicated because local recurrence rates approach 50%, metastatic potential is high, and nearly half of patients fail to survive more than 5 years (26). Wide local excision with a 2- to 3-cm margin or Mohs micrographic surgery is recommended, along with SLNB and/or therapeutic lymph node dissection, to address drainage basins in the parotid gland and in the neck. The efficacy of adjuvant therapy is uncertain, but radiation therapy is advisable in all cases. Chemotherapy, like that used for small cell carcinoma of the lung, may offer additional therapeutic benefit for patients with extensive or widely metastatic disease.

Squamous cell papilloma is a benign epithelial neoplasm that occurs in the external auditory canal and is thought to result from infection by human papillomavirus type 6 and 11 (27). Most squamous cell papillomas are fungiform lesions with narrow stalks. Microscopic examination shows well-differentiated squamous cells proliferating on the periphery of a fibrous tissue core. Papillomas are treated by complete excision or laser ablation. *Pilomatrixoma*, also termed calcifying epithelioma of Malherbe, is another benign tumor that may be found in the membranous portion of the external auditory canal or on any hair-bearing skin of the ear such as the lobule. These are solitary cystic lesions that originate from primitive hair matrix cells and are most commonly found in children. Histologically, the wall of the tumor consists of basaloid cells interposed with connective tissue septa surrounding a central region of degenerative debris containing ghost or shadow cells, keratin, and calcified material. These lesions are easily removed and usually do not recur. *Auricular endochondral pseudocysts* are cyst-like degenerations of auricular cartilage that are thought to result from recurrent minor trauma. These are tumor-like lesions that occur in young adults and are often confused with auricular hematomas. Pathogenesis is thought to be related to minor trauma when small amounts of serous fluid collect between auricular cartilage and the perichondrium. In time, the internal surface of the perichondrium generates a layer of cartilage that encloses the serous fluid. There is no epithelial or endothelial lining and no associated inflammation. Auricular endochondral pseudocysts can be difficult to eliminate. They may require aspiration and injection of a sclerosing agent or incision and drainage with curettage and obliteration with a sclerosing agent. *Chondrodermatitis nodularis chronica helicis (Winkler disease)* is an inflammatory condition of unknown etiology. Caucasian adult males are most commonly afflicted, and the problem manifests as painful papules or nodules on the free border of the helix or on the antihelix. Within the lesions, there is a chronic inflammatory infiltration of the perichondrium, often with focal degeneration or deformity of the underlying cartilage. The lesions can be successfully treated with pressure relief strategies, wide excision with deep shave of the underlying cartilage, or intralesional injections with steroid.

NEOPLASMS OF THE MIDDLE EAR, MASTOID, AND TEMPORAL BONE

Adenomatous Tumors

Since they were first described over a century ago, classification of adenomatous tumors of the middle ear and mastoid has been the subject of controversy. The clinical course of these rare tumors is highly variable, and attempts have been made to identify tumor subtypes so that neoplastic behavior can be predicted and appropriate treatment implemented. Much of the debate about tumor classification focuses on whether the varied microscopic anatomy can be correlated with the tissue of origin (mucosal vs. neuroendocrine) and tumor growth potential. It has been suggested, based on immunohistochemical analysis, that all adenomatous tumors of the temporal bone arise from pluripotential undifferentiated neural crest cells that have migrated to the middle ear (27). This would not explain why some adenomatous lesions develop into malignant tumors, whereas others remain benign. Currently, most evidence suggests two distinct types of primary adenomatous neoplasms of the temporal bone, *benign adenoma*, which arises from the mucosa of the middle ear, and *aggressive papillary tumor*, which arises from the endolymphatic sac. Carcinoid tumors of the middle ear, which are primarily

neuroendocrine derived, are either a separate clinical entity or a variant of a benign adenoma.

Benign adenomas of the middle ear are rare nonaggressive neoplasms that are most commonly found in adolescents and young adults, affecting males and females equally. As discussed above, middle ear adenomas seem to arise from the glandular elements of the middle ear mucosa, but what initiates their histogenesis is unknown. Histology of these tumors often reveals benign glandular proliferation, and it has been suggested that benign adenomas represent reactive hyperplasia and not true neoplasm. However, in most reports, there is no history of otitis media or any other source of inflammation. Adenomas are rubbery fibrous tumors that are white, gray, or reddish brown in color. Microscopic examination shows cuboidal or columnar endothelial cells arranged in single-layered glandular structures. Some tumors have trabecular or ribbon-like architecture with sheets of endothelial cells lying adjacent to one another. Nuclei are round or oval and lack mitotic figures or other features of dysplasia. Immunohistochemical staining shows positive staining for synaptophysin, chromogranin, and serotonin, suggesting a neuroectodermal origin for the tumor. Neurosecretory tumor cells predominate in carcinoid variants. Patients most often present with a middle ear mass and an intact tympanic membrane, but tumors can extend through the tympanic membrane or into the mastoid. Generally, there is no bony erosion and no other sign of malignant aggressive growth. Excisional biopsy is recommended, and recurrence is unlikely.

Endolymphatic sac tumors are rare aggressive papillary tumors of the middle ear and mastoid. Just over 100 cases have been reported since they were first described by Heffner in 1989 (28). The age of the patient at the time of diagnosis ranges from 15 to 80 years, with a mean of approximately 40 years. There appears to be no predilection for right- versus left-sided tumors, and a review of the literature suggests that they occur more frequently in females. The time between the onset of symptoms and diagnosis of the tumor is variable and ranges from 1 month to 23 years, with an average of approximately 9 years.

The association between aggressive papillary tumor of the middle ear and von Hippel-Lindau disease was first suggested by Eby et al. in 1988 (29). von Hippel-Lindau disease is an autosomal dominant disorder associated with a defect on chromosome 3p25-26 (30). The disease manifests itself as multiple hemangioblastomas of the retina and central nervous system accompanied by renal cysts, clear cell renal cell carcinoma, pheochromocytoma, and endolymphatic sac tumor. The prevalence of this disease is estimated to be 1 in 35,000 to 1 in 40,000, and the diagnosis is readily confirmed with genetic testing. Endolymphatic sac tumors associated with von Hippel-Lindau disease are clinically and histologically identical to endolymphatic sac tumors in patients without this disease. While the incidence of endolymphatic sac tumor is higher in patients with von Hippel-Lindau disease, these patients are also more likely to have bilateral tumors. Approximately 10% of patients with von Hippel-Lindau disease have endolymphatic sac tumor (31). Additionally, as many as 60% of patients with von Hippel-Lindau disease who also have hearing loss will eventually develop an endolymphatic sac tumor. Therefore, it is prudent to screen for endolymphatic sac tumor in patients with von Hippel-Lindau disease because early diagnosis allows prompt therapy.

Endolymphatic sac tumors are highly vascular friable polypoid masses. Bony invasion is characteristic of these tumors, and infiltrated bone appears to be completely replaced by fibrotic portions of the invasive tumor. On microscopic examination, endolymphatic sac tumors contain both papillary and cystic components. The cellular structure of the papillary component resembles the rugose portion of normal endolymphatic sac epithelium. The epithelial lining of an endolymphatic sac tumor consists of a single cell layer of either low cuboidal or low columnar cells. The nuclei of endolymphatic sac tumor cells are typically aligned in a uniform fashion. Nuclear pleomorphism and mitotic activity are uncommon histologic findings in these tumors. The lumen of the cystic component of the tumor contains a proteinaceous material. This material may be indistinguishable from thyroid colloid. Consequently, it is important to use thyroglobulin staining to distinguish metastatic papillary thyroid carcinoma from endolymphatic sac tumor. The underlying stroma in endolymphatic sac tumors contains an abundant capillary vascular supply that may have the appearance of a second epithelial layer. Immunohistochemical analysis of normal endolymphatic sac tissue provides additional support for the theory that adenomatous tumors of the temporal bone arise from the endolymphatic sac. Normal endolymphatic sac tissue and tissue from endolymphatic sac tumors both stain positively for S-100, a neuron-specific protein; for vimentin, an intermediate filament protein; and for neuron-specific enolase.

The clinical manifestations of endolymphatic sac tumors are best understood on the basis of tumor origin and potential routes of spread. The endolymphatic sac is located in the posteromedial plate of the petrous bone approximately midway between the sigmoid sinus and the internal auditory canal. The sac consists of both a proximal and distal segment. The proximal or rugose portion of the sac is contiguous with the endolymphatic duct and lies within the posterior portion of the petrous bone. This portion of the sac is covered in part by the bony operculum. The distal portion of the sac is located between the dura mater proper and the periosteal portion of the dura mater within the posterior cranial fossa. Both histologic and radiologic studies suggest that the proximal portion of the sac gives rise to tumors.

Endolymphatic sac tumors extend along the endolymphatic duct in the direction of the bony labyrinth. Destruction of the labyrinth results in unilateral sensorineural hearing loss, tinnitus, and vertigo. From the endolymphatic duct, an endolymphatic sac tumor may erode

into the vestibule, the posterior semicircular canal, and the mastoid cavity. Once in the mastoid cavity, these tumors follow the retrofacial air cell tract to encompass the facial nerve or to involve the jugular bulb. The middle ear may become involved when tumor enveloping the facial nerve extends anteriorly. From the middle ear cavity, tumor may erode superiorly through the tegmen tympani into the middle fossa, medially to involve the otic capsule, or laterally through the tympanic membrane to involve the external auditory canal. Because of these routes of spread, involvement of the facial nerve and the middle ear space is a common clinical finding. On rare occasion, anterior extension of an endolymphatic sac tumor along the petrous ridge into the petrous apex and cavernous sinus has been reported. Anterior extension into Meckel cave and the internal auditory canal may lead to involvement of cranial nerves V, VII, and VIII. Extension into the cerebellum and into the posterior cranial fossa accounts for the high incidence of ataxia and headaches in patients with advanced lesions. Finally, inferior extension to the region of the jugular foramen accounts for the clinical findings of hoarseness, weakness of the sternocleidomastoid muscle, and palatal dysfunction.

The diagnosis of an endolymphatic sac tumor is usually made by screening audiometry in conjunction with temporal bone imaging studies. Audiograms from patients with endolymphatic sac tumors usually reveal a sensorineural hearing loss. On occasion, a conductive hearing loss may be caused by extension of the tumor into the middle ear cavity. CT shows a soft tissue mass on the posterior petrous face with erosion of adjacent regions of the temporal bone (Fig. 147.6). On bone windows, these tumors commonly contain stippled, reticular, or spiculated areas of calcification. Endolymphatic sac tumors have an "expansile" appearance that helps to differentiate them from other aggressive neoplasms of the temporal bone such as metastatic tumors and high-grade chondrosarcomas that have a less regular pattern of bony destruction. Unenhanced T1-weighted images on MRI studies reveal a pattern of signal intensity that varies with tumor size. In general, endolymphatic sac tumors show increased signal intensity on T1-weighted images, but tumors greater than 3 cm in diameter display multiple intratumoral foci of increased intensity and have a "speckled" appearance. In contrast, tumors less than 3 cm in diameter often have a circumferential rim of increased signal intensity. This rim of high signal intensity is probably generated by breakdown products of subacute hemorrhage found at the periphery of tumors. This characteristic finding on unenhanced T1-weighted imaging is dissimilar to other more common tumors of the petrous apex. Endolymphatic sac tumors enhance with intravenous contrast, but the degree and type of enhancement obtained with this technique varies from tumor to tumor. On T2-weighted imaging, endolymphatic sac tumors contain scattered areas of increased signal intensity. Flow voids are found in 80% of endolymphatic sac tumors and appear to be related to tumor size.

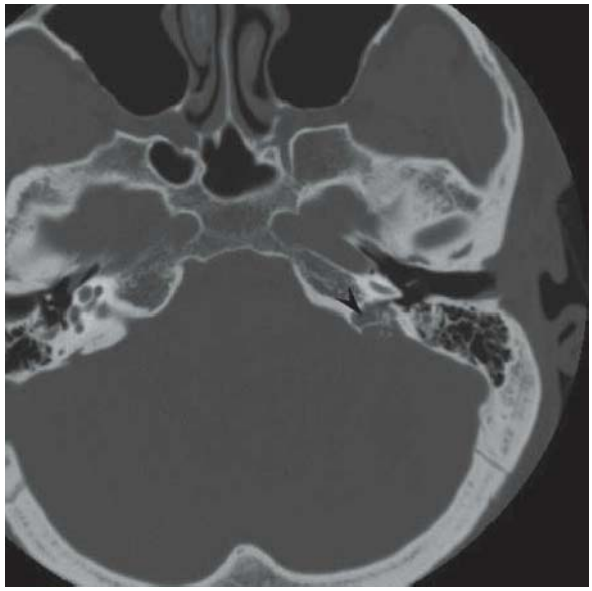

Figure 147.6 Aggressive papillary tumor of the temporal bone (endolymphatic sac tumor). Axial CT showing a left-sided tumor eroding through the posterior face of the petrous bone with invasion (*black arrowhead*) of the petrous apex adjacent to the basal turn of the cochlea. This tumor originated in the endolymphatic sac and extended inferiorly before invading the temporal bone.

Surgical excision of endolymphatic sac tumors is the treatment of choice, and cure may be achieved with complete resection. Most endolymphatic sac tumors, however, are quite large at the time of diagnosis and may involve the entire lateral skull base. Subtotal resection combined with regularly scheduled radiologic follow-up examinations and revision surgery for significant tumor progression is an alternate treatment option for these indolent neoplasms. However, because most patients with endolymphatic sac tumors are young adults, complete tumor resection using modern techniques in skull base surgery should be the goal. Because these tumors are quite vascular, preoperative embolization plays a role in all but the smallest tumors. Conventional radiotherapy and gamma knife radiosurgery do appear to play a role in the treatment of recurrent or unresectable disease.

Langerhans Cell Histiocytoses

Langerhans cell histiocytoses, also called Langerhans cell tumors, are a group of neoplasms characterized by idiopathic histiocytic and eosinophilic proliferation. Until recently, these tumors were discussed as three separate disease entities: Letterer-Siwe disease, Hand-Schüller-Christian disease, and eosinophilic granuloma. These disorders are now considered to represent three different manifestations of the same disease. However, the use of these names persists mainly as an aid in categorizing the location and extent of disease. In the case of eosinophilic granuloma, the mass is usually localized, whereas in Hand-Schüller-Christian disease and Letterer-Siwe disease,

the disease tends to be disseminated. All forms of this disorder are characterized by proliferation of Langerhans histiocytes. These are cells that are derived from monocytes in the bone marrow, but are normally found in the epidermis. Langerhans cell histiocytes proliferation is an aggressive and sometimes malignant disease process that seems to occupy a continuum between the two extremes: histiocytic malignant lymphoma and benign reactive lymph node hyperplasia. Thus, these lesions are more accurately described as tumor-like proliferations, and the lesions may merely be the result of imbalanced immunoregulation. Eosinophils associated with histiocytosis, in cases of eosinophilic granuloma, are believed to be incidental and may be a secondary reaction that accompanies abnormal proliferation of Langerhans cells. All forms of this disease may involve the temporal bone and lateral skull base.

Eosinophilic granuloma presents as a unifocal bony lesion, usually involving the flat bones of the skull, specifically the frontal and temporal bones and the mandible. Patients are generally children and young adults with complaints of chronic or recurrent middle and external ear infection. White males are affected more frequently than other groups. The tumor is characterized by a localized collection of histiocytes, in polygonal and sheet formation, and eosinophils that cause resorption of bone, producing a radiolucent lesion. Diagnosis is confirmed by bone scan and open biopsy showing characteristic histopathology and positive immunohistochemical staining for S-100 and CD1 antigens. This disease process is considered to be the localized form of Langerhans cell histiocytosis. Treatment of eosinophilic granuloma is surgical excision, with radiation therapy for recurrent lesions.

Otologic manifestations of *Hand-Schüller-Christian disease* include chronic purulent middle and external ear disease and hearing impairment. This is also a disease of children and young adults. Typically, there are numerous bony lesions of the skull and axial skeleton. Multifocal involvement of the abdominal viscera and cutaneous lesions indicates a particularly poor prognosis. In CT images, the osteolytic lesions are described as punched-out defects or moth-eaten holes. In addition, there is triad that exists in approximately 10% of the patients, consisting of bone lesions, diabetes insipidus, and exophthalmos. Invasion of the temporal bone occurs frequently and is often bilateral. Biopsy helps establish the diagnosis, showing sheets of polygonal histiocytes admixed with eosinophils, plasma cells, and lymphocytes as the characteristic microscopic finding in these lesions. This is considered to be a chronic disseminated form of Langerhans cell histiocytosis. Treatment includes medical therapy with vinblastine and corticosteroids. Despite treatment, the mortality rate approximates 30%.

Letterer-Siwe disease affects infants and manifests as hepatosplenomegaly, lymphadenopathy, bleeding diathesis, anemia, cutaneous lesions, and multiorgan dysfunction secondary to histiocyte proliferation and infiltration. This is the acute disseminated form of Langerhans cell histiocytosis. The temporal bone may be involved, and patients may present with ear pain and/or otorrhea. Treatment consists of chemotherapeutic agents, but the disease is almost uniformly fatal in 1 to 2 years.

Sarcoma and Chordoma

Sarcomas of the lateral skull base are exceptionally rare neoplasms; however, in children, they are the most common primary malignancy of the temporal bone. Rhabdomyosarcoma is the most common of these neoplasms, accounting for 30% of sarcomatous temporal bone tumors and 4% to 7% of all temporal bone malignancies. Ninety percent of patients with rhabdomyosarcoma are less than 10 years of age, with the average age at presentation of 4.5 years. Pluripotential mesenchymal cells in the middle ear and eustachian tube give rise to this neoplasm. Most patients present with chronic otorrhea and otalgia that fails to respond to appropriate medical therapy. Otologic examination reveals a friable aural polyp, hemorrhagic aural discharge, and/or mastoid swelling. Facial weakness or paralysis is not uncommon early in the disease process and may indicate a malignant process. Regional lymph node metastases are unusual, but distant metastases to lungs, liver, brain, and bone are present in 14% of patients at the time of presentation. Rhabdomyosarcoma is divided into several histologic types: embryonal, botryoid, alveolar, and pleomorphic. The *embryonal type* is the most common. Microscopic features of embryonal rhabdomyosarcoma are small round and spindle-shaped primitive mesenchymal cells in a loose myxoid or compact pattern. Longitudinal or cross-striations characteristic of rhabdomyosarcoma may or may not be evident in the embryonal subtype. *Alveolar rhabdomyosarcoma*, which has a poorer prognosis, consists of sheets of round, oval, or strap-like cells arranged in a trabecular pattern surrounding empty alveolar compartments. *Pleomorphic rhabdomyosarcoma* is composed of anaplastic multinucleated spindle cells that form whorls and fascicles with longitudinal striations. Most *botryoid tumors* are histologically classified as embryonal, and the term botryoid refers to their gross appearance resembling a grape cluster. Radiologic imaging of the temporal bone shows a soft tissue in the middle ear and mastoid with surrounding bony destruction. With this type of clinical presentation, the diagnosis is confirmed with biopsy specimens. Attempts at radical surgical excision rarely offer survival advantage for this highly malignant neoplasm, and therefore, current treatment includes limited surgical intervention, external beam radiation therapy, and chemotherapy. Survival has improved with the use of contemporary adjuvant therapy, and 5-year failure-free survival exceeds 60% (32).

Chondrosarcoma of the skull base is thought to arise from persistent islands of embryonal cartilage rests that occur near cranial base synchondroses. Patients in nearly all age groups can be afflicted by this relatively low-grade

sarcoma, but it is most common in young adults in their fourth and fifth decades of life. Males and females are affected equally. The petroclival region near foramen lacerum and the petrous apex is perhaps the most common location of origin. Patients present with headache and symptoms suggesting cranial nerve compromise such as diplopia, hoarseness, dysphagia, facial dysesthesia, and hearing loss. Cranial nerve examination often confirms the neurologic deficits in symptomatic patients. Histologic diagnosis of sarcoma can be difficult without clinical features or radiologic findings that suggest malignancy because benign cartilage shows varying patterns of cellularity and heterogeneity that may be interpreted as anaplastic. Like rhabdomyosarcoma, there are a number of histologic subtypes of chondrosarcoma, and prognosis varies depending on histologic subtype and grade of differentiation. Imaging studies show bony destruction of the skull base lateral to the midline (Fig. 147.7) and enhancement of the tumor mass when contrast is injected. Surgical excision is the primary therapeutic modality for chondrosarcoma, but complete excision is often not possible, and recurrences are common (33). Both radiation therapy and chemotherapy are of unproven benefit.

Ewing sarcoma, osteogenic sarcoma, and fibrosarcoma are rarely reported to occur in the temporal bone. *Ewing sarcoma* of the temporal bone is an aggressive but rare malignancy that occurs in patient less than 20 years old. Patients present with signs and symptoms much like those of other temporal bone sarcomas, and imaging studies show a well-circumscribed soft tissue lesion eroding into the surrounding bone. Ewing sarcoma is a cellular tumor that is readily diagnosed during microscopic examination of biopsy specimens. Because no more than 20 cases of Ewing sarcoma of the temporal bone have been recorded in the world literature, the prognosis is uncertain. Limited experience, however, shows that metastatic disease does not occur, and favorable outcomes can be obtained with combined temporal bone resection, radiation therapy, and chemotherapy. *Osteogenic sarcoma* of the temporal bone is highly malignant but fortunately exceedingly rare. Most patients are between the ages of 10 and 30 years, and males are affected more often than females by a ratio of 3:2. Few cases of radiation-induced osteogenic sarcoma have been reported, but in most instances, there is no clear etiology. Patients present with rapidly progressive painful swelling in the periauricular area. Temporal bone resection along with radiation therapy and chemotherapy is advocated, but this disease appears to be uniformly fatal. *Fibrosarcoma* of the temporal bone can occur in infants, and nearly one-third of infants with this neoplasm present at birth. Lymph node metastases may occur in 10% of pediatric patients, but 5-year survival rates are above 80% after surgical treatment. The prognosis for adults is not as favorable. Regional lymph node metastases occur in 50%, and radiation-induced fibrosarcoma in adults is a lethal neoplasm (34).

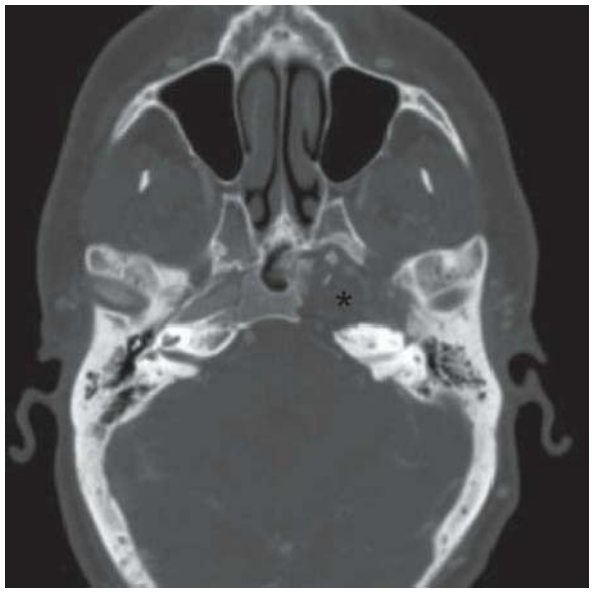

Figure 147.7 Chondrosarcoma. Axial CT showing an aggressive neoplasm eroding the left petrous apex and adjacent sphenoid bone (*asterisk*), centered at the petroclival synchondrosis.

Skull base chordomas are low- to intermediate-grade malignancies that result from defective embryonic remnants of the notochord. During embryonic development, the cranial aspect of the notochord begins in the sphenoid bone just posterior to the sella turcica. As the notochord is followed inferiorly, it exits the bone traveling along the clivus in the soft tissue adjacent to the nasopharyngeal mucosa and reenters the basiocciput skull base before coursing inferiorly into the odontoid process and vertebral bodies. The cranial aspect of the notochord gives rise to stalks that project into the subendothelial tissue of the nasopharynx and intracranially along the ventral aspect of the brainstem. Therefore, chordoma not only occurs in the clivus but also as a primary intracranial or nasopharyngeal soft tissue tumor. Patients of all age categories may have chordomas, but they are most likely to occur in males between the ages of 35 and 45 years. On gross examination, tumors are covered with a pseudocapsule and have a characteristic lobular configuration. They are gray and semitranslucent and contain gelatinous material. Chordomas are divided into histologic subtypes, but the main microscopic features are stellate, intermediate, and vacuolated physaliphorous or soap-bubble cells in a mucoid matrix growing in nests, cords, or trabeculae. Immunohistochemical staining is positive for cytokeratin and epithelial membrane antigen, which helps to distinguish chordoma from chondrosarcoma. Metastases are unusual, and most chordomas grow slowly and insidiously, eroding the skull base and compromising regional neurovascular structures. Headache, diplopia, and visual deficits are the most common presenting complaints, and physical examination usually reveals oculomotor function abnormalities, especially abducens nerve palsy. When chordoma originates or extends into the nasopharynx, patients can present with upper airway

obstruction and a nasopharyngeal mass. In many cases, the diagnosis can be obtained from imaging studies and cytologic evaluation of a transnasal fine-needle aspirate. CT images show bony erosion of the clivus or basiocciput in the midline instead of lateral erosion that is more characteristic of chondrosarcoma. The soft tissue component of the tumor is heterogeneous on MRI, usually demonstrating low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. CT and MR images both show signal enhancement after injection of contrast material. The primary mode of therapy is surgical excision via transoral–transpalatal, transcondylar, or infratemporal fossa approach, but complete resection is often not feasible, and recurrence is common. Postoperative proton beam radiation therapy or stereotactic radiosurgery may improve survival and prolong disease-free intervals.

Dermoid, Teratoma, and Choristoma

Dermoids, teratomas, and choristomas are mass lesions that result from errors in fetal development. These tumors are distinguished on the basis of the embryologic germ layer from which they are derived. *Dermoids* of the temporal bone are cystic lesions derived from the ectoderm that are more correctly classified as congenital inclusions and not true neoplasms. When they occur in the middle ear, the mastoid, or the eustachian tube, they are thought to originate at a point where the first branchial cleft, the anlage of the external auditory canal, lies adjacent to the first branchial pouch, the anlage of the middle ear, and the eustachian tube. This location may be significant because it suggests that the histogenesis of dermoids is related to incomplete closure at the lines of fusion between branchial elements or to traumatic introduction of inappropriate germinal layers into the middle ear. However, dermoids may also occur in the petrous apex.

Dermoid cysts are pink or white pedunculated tumors. They have both ectodermal and mesodermal components. They are lined by keratinizing stratified squamous epithelium that contains hair follicles, sebaceous glands, smooth muscle, and adipose tissue. Most patients present as infants or children with hearing loss, otorrhea, dizziness, or upper airway obstruction, and examination reveals a middle ear mass that may extend through the eustachian tube and into the nasopharynx. The growth rate of these cysts is variable, but they eventually become symptomatic and require removal.

Teratomas of the temporal bone are extremely rare and differ significantly from dermoid cysts. They are considered to be true neoplasms that arise from pluripotential stem cells that originate near the notochord. These pluripotential cells may differentiate into types of tissue derived from any of the three embryonic germinal layers. The type of tissue into which they differentiate is generally not native to the site where they occur. Tumors are firm polypoid or cystic lesions that may contain stratified squamous epithelium, respiratory and gastrointestinal endothelium, cartilage, skeletal muscle, glandular tissue, neural tissue, and, surprisingly, even mature teeth. Tumors are graded in relation to tissue differentiation. Malignant undifferentiated forms exist, but they have never been reported in the temporal bone. Patients present at birth or in early childhood, often with large rapidly growing tumors, and their symptoms include facial paralysis, hearing loss, and airway obstruction. Imaging studies show a heterogeneous tumor that may contain calcifications. Teratomas can be cured with complete resection, but this may require radical transtemporal or infratemporal fossa approaches to achieve adequate surgical exposure for curative resection.

Choristoma is a term that is used to describe normal tissue that occurs in a nonnative location. When choristoma occurs in the middle ear, this generally refers to salivary tissue, although sebaceous glands and neural tissue have been reported. Choristomas are probably derived from rests of salivary tissue trapped in the middle ear during development. These rests mature into small masses but have no neoplastic potential. Choristomas are pink or tan lobular masses located lateral to the long process of the incus and medial to the manubrium, and some have been associated with anomalies of the ossicles or the intratemporal portion of the facial nerve. Histologic examination reveals mature ectopic salivary gland tissue. Patients may have conductive hearing loss, but most are asymptomatic. They usually present with a middle ear mass that was incidentally discovered during routine otoscopic examination. Choristomas have little if any growth potential and only require incisional or excisional biopsy to confirm diagnosis.

Cholesterol Granuloma

Cholesterol granuloma of the petrous apex is not a true neoplasm but rather a mass lesion that results from a reactive process within the temporal bone. It can be diagnosed from imaging studies and should be included in the differential diagnosis when evaluating temporal bone masses. Cholesterol granuloma was first described more than 100 years ago as dark blue discoloration of the tympanic membrane and was called an "idiopathic hematotympanum." This condition occurred in patients with eustachian tube dysfunction and was often accompanied by chronic otitis media or cholesteatoma. It was hypothesized that cholesterol granuloma occurs as a consequence of four factors: interference with drainage of the middle ear, hemorrhage, obstruction of ventilation, and foreign body reaction to cholesterol crystals derived from hemoglobin catabolism. Evidence in support of this hypothesis has been provided by animal experiments. Cholesterol granuloma can be produced by injecting cholesterol into the middle ear or by occluding the eustachian tube (35). Cholesterol granuloma of the petrous apex, whereas not necessarily associated with otitis media or cholesteatoma, probably results from a similar pathophysiologic process. It is found in

pneumatized petrous bones that occur in 30% of patients. The process starts when ventilation of petrous air cells is disrupted secondary to temporal bone trauma, eustachian tube dysfunction, or mucosal edema. Inflammation or trauma of the petrous bone may cause hemorrhage into the air cells of the petrous apex, and because there is no effective drainage pathway, detritus from the hemorrhage accumulates in the air cells. The membranes of degenerating red blood cells appear to be the primary source of cholesterol crystals, which subsequently initiate a foreign body reaction. Inflammation from the foreign body reaction increases hemorrhage and mucosal edema, promoting the inflammatory cycle and allowing the granuloma to enlarge. An alternative theory for cholesterol granuloma pathogenesis proposes these lesions result when expanding air cell tracts lined with mucosa interface with marrow spaces in the petrous apex. Coaptation between the mucosal lining and the exposed marrow results in a progressive sustained hemorrhage from the marrow spaces, and this leads to cyst formation and expansion (36). It is not surprising that histologic examination of cholesterol granuloma shows cholesterol crystals surrounded by multinucleated giant cells, round cell infiltration, and hemosiderin-laden macrophages. Cholesterol granuloma may be confined to the petrous bone and may be asymptomatic. Alternatively, it may extend into the posterior cranial fossa and cause an abducens nerve palsy, diplopia, facial pain, facial weakness or twitching, headache, dizziness, tinnitus, and hearing loss. The diagnosis of cholesterol granuloma may be made by MRI, which shows a smooth-walled, nonenhancing, expansive lesion that has high signal intensity on both T1-weighted and T2-weighted images (Fig. 147.8). The mainstay of surgical therapy is simple drainage, allowing permanent aeration of the cavity. However, some controversy exists about whether the fibrous wall of the cyst requires removal to achieve long-term cure.

NEOPLASMS OF THE INTERNAL AUDITORY CANAL AND CEREBELLOPONTINE ANGLE

Schwannoma

Schwannomas of the temporal bone and the skull base are benign neoplasms that arise from the sheaths of cranial nerves. Available evidence suggests that these tumors arise from Schwann cells alone and not other nerve components. Therefore, terms such as acoustic neuroma are not appropriate. The etiology of schwannoma is unclear, but it has been suggested that neoplastic growth occurs preferentially at the junction between the central and peripheral components of the cranial nerves. Myelin is formed by oligodendrocytes in the intracranial portion of a cranial nerve, and as the nerve enters the skull base, there is a transition to a Schwann cell sheath. This transition occurs in a region called the Obersteiner-Redlich zone, and this zone is variable in location in different cranial nerves. It has also been proposed that schwannomas may arise in locations with the greatest concentration of Schwann cells. For vestibular schwannomas, this would be Scarpa ganglion, whereas for jugular foramen schwannomas, this would be the superior and inferior ganglia of the glossopharyngeal nerve, the jugular and nodose ganglia of the vagus nerve, or the junction of cranial and spinal components of the spinal accessory

nerve. What causes the proliferation of Schwann cells is not known, but genetic aberrations, such as those associated with neurofibromatosis type 2 (NF2), are likely associated with this neoplastic transformation. Schwannomas in NF2 patients appear to be the result of a defect on the long arm of chromosome 22, which is responsible for the production of a tumor suppressor protein called merlin. Exactly what this protein does to inhibit Schwann cell proliferation is uncertain, but merlin interacts with many cellular proteins that regulate cell function (37). One such group of cellular proteins includes tyrosine kinase growth factor receptors, specifically a family called ErbB. NF2 is an autosomal dominant disorder, and patients may have a functioning copy of the tumor suppressor gene on their intact chromosome. However, production of merlin is terminated when a mutation occurs on the intact chromosome 22, and merlin depletion results in deregulation of ErbB receptors, which may be the event that causes NF2 patients to develop schwannomas. For the same sequence of events to occur in a patient without NF2, mutations must occur on the long arm of both chromosomes. Thus, neoplastic transformation in cases of sporadic schwannoma is a much less likely event. Other factors that may lead to neoplastic transformation of Schwann cells are under investigation. Increased genetic expression of neurotrophic factors such as brain-derived neurotrophic factor has also been observed in vestibular schwannomas when compared to peripheral nerve tissue suggesting a role in the modulation of tumor growth (38). Additionally, small RNA molecules called microRNA can regulate gene expression by inhibiting production of certain target proteins. When comparing vestibular schwannoma cells with vestibular nerve tissue, microRNA is overexpressed, which can lead to downregulation of tumor suppressor pathways (39). Genetic research looking at these pathways and others continues, but it appears likely that schwannoma growth is the result of demodulation of Schwann cell proliferation resulting in tumorigenesis.

Schwannomas of the temporal bone can be categorized as vestibular, facial, trigeminal, and jugular foramen tumors. Vestibular schwannomas are by far the most common, comprising approximately 10% of all intracranial tumors and 80% of cerebellopontine angle tumors. They occur in about 1 of 100,000 patients per year. Because they usually arise in the vicinity of the vestibular ganglion, most vestibular schwannomas begin inside the internal auditory canal. Isolated intralabyrinthine schwannomas do occur, as do cochlear schwannomas, but they are extremely rare. Vestibular schwannomas expand centrally from the internal auditory canal into the cerebellopontine angle and may compress the pontine brainstem and the cerebellum. Therefore, the most common symptoms with which patients present are unilateral hearing loss, tinnitus, and dysequilibrium. Vestibular schwannomas may also extend anteriorly within the cerebellopontine angle, compressing the trigeminal nerve and causing facial hypesthesia or paresthesia, but neuralgia is infrequent. Large tumors will eventually result in hydrocephalus with headache, visual impairment, and alterations of mental status if the tumor is left untreated.

Facial nerve schwannomas differ from vestibular schwannomas in that they can arise anywhere along the nerve from the oligodendrocyte–Schwann cell junction to the most distal aspect of the extratemporal facial nerve. Most commonly, however, they arise from the perigeniculate, tympanic, or mastoid segments of the nerve. Multiple nerve segments are usually involved by the time these lesions are diagnosed. Facial weakness or paralysis that progresses gradually over weeks or months is the most common presentation. Twenty percent of patients with facial nerve schwannoma may present with acute facial paralysis suggesting Bell palsy. Conductive hearing loss, tinnitus, or otalgia occur when neoplasms extend into the middle ear.

Trigeminal schwannomas are rare lesions that usually originate from the gasserian ganglion and may expand into posterior and/or middle cranial fossae. Patients present with facial neuralgia, paresthesia, or hypesthesia in one or more divisions of the trigeminal nerve. Retroorbital pain may be another complaint. When motor function is affected, patients describe difficulty when chewing.

Jugular foramen schwannomas arise within the jugular fossa from the sheaths of cranial nerves IX, X, and XI. Because they grow vertically along the path of least resistance, intracranial and extracranial extension of the tumor is variable. Vagus nerve origin seems most frequent, followed by glossopharyngeal origin, but it is often difficult to identify the nerve from which the tumor is derived. Patients present with dysphagia, hoarseness, or shoulder weakness. If there is significant intracranial extension, patients may note hearing loss, tinnitus, imbalance, or headache.

On gross and microscopic examination, all temporal bone schwannomas are generally the same. They are tan, yellow, or pale gray rubbery masses with varying amounts of surface vascularity. As they enlarge, schwannomas displace adjacent soft tissue structures and may become tightly adherent to these structures. They appear to have a fibrous capsule, but histologic examination shows that the capsule may be so thin that tumor cells oppose surrounding tissue directly. Tumor cells are spindle shaped and are arranged in both Antoni type A and type B patterns (Fig. 147.9). The type A pattern consists of densely packed spindle cells with aligned or palisading nuclei, termed Verocay bodies. The type B pattern, on the other hand, is characterized by spindle cells that are loosely arranged in a myxoid stroma. Cystic degeneration, necrosis, and hemorrhage are often noted, especially in larger tumors. Nuclear pleomorphism and hypercellularity might appear consistent with malignancy, but malignant degeneration of schwannomas is highly unusual.

Radiographic imaging studies may provide the diagnosis, but physical examination reveals functional deficits caused by the tumor. Otologic exam is generally normal unless a facial nerve schwannoma presents as a retrotympanic

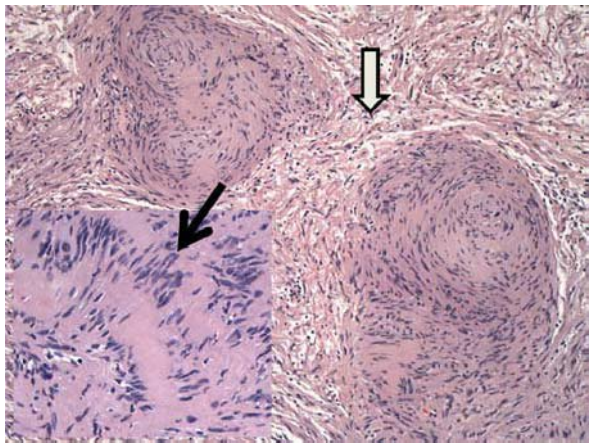

Figure 147.9 Schwannoma: Histologic section showing delicate, tightly organized wavy nuclear palisades known as Verocay bodies within the hypercellular or Antoni A regions (*solid arrow*). The characteristic pale, eosinophilic cytoplasm is more apparent in relatively hypocellular Antoni B regions (*hollow arrow*).

mass. In patients with cervical extension of jugular fossa schwannomas, head and neck examination may show an anterosuperior neck mass, sternocleidomastoid muscle weakness, or bulge of the lateral pharyngeal wall, suggesting a mass in the parapharyngeal space. Cranial nerve examination showing palatal weakness and vocal cord paralysis is also indicative of a jugular fossa lesion. When decreased corneal reflexes, facial hypesthesia, and masseter muscle weakness are apparent, trigeminal schwannoma or other cerebellopontine schwannomas that compress the trigeminal nerve may be the cause. Facial nerve dysfunction suggests facial nerve schwannoma rather than vestibular schwannoma, but audiometric evaluation helps to differentiate the two lesions. Sensorineural hearing loss is more common in patients with vestibular schwannoma, whereas conductive hearing loss is more common in patients with facial nerve schwannoma. The preliminary diagnosis of schwannoma is made when the deficits discovered on physical exam correlate with findings from imaging studies. MRI shows a lesion with low signal intensity on T1-weighted images that enhances during injection with intravenous contrast (Fig. 147.10). HRCT of the temporal bone shows expansion or erosion of the fallopian canal and extension into the middle ear in patients with facial nerve schwannomas. HRCT also helps to define skull base anatomy preoperatively in patients with jugular foramen schwannomas.

Details regarding the management of temporal bone schwannomas are beyond the scope of this chapter. Suffice it to say that patients generally have three therapeutic options: surgical excision, stereotactic radiation therapy, or observation. Complete surgical excision is the only curative therapy available at this time. The major disadvantage is morbidity associated with cranial nerve injury, cerebrospinal fluid leak, and central nervous system damage. Advanced technology for treating patients with schwannomas using stereotactic radiosurgery has now been available for more than 20 years. Long-term follow-up in patients treated marginal radiation dosages of 12 to 13 Gy using highly accurate tumor targeting technology shows that complications can be minimized while tumor growth is controlled in approximately 95% (40,41). It is generally not recommended for patients with tumors greater than 3 cm in diameter or in patients who are symptomatic with significant brainstem compression. Observation as a management option is based on data suggesting that more than 60% of vestibular schwannomas, especially sporadic and intracanalicular tumors, grow very slowly, remain stable in size, or involute during an average of 4 years of follow-up (42). All three therapeutic options play a role in the management of patients with temporal bone schwannomas.

Meningioma

Meningiomas are neoplasms that arise from the arachnoid layer of the meninges. More specifically, temporal bone meningiomas arise from arachnoid cell granulations that cluster at the tips of arachnoid villi inside dural venous sinuses and at foramina, such as the internal auditory canal, the jugular fossa, the geniculate ganglion, and the bony sulci near the greater and lesser superficial petrosal nerves. Meningiomas are common neoplasms and constitute between 13% and 20% of all intracranial tumors and approximately 10% of all cerebellopontine angle tumors. The incidence of meningioma increases with age, with the highest incidence rate (40 per 100,000) in individuals older than 65 years. Children and even infants can have meningiomas, but fortunately this is rare. In children, boys are affected as often as girls, and their tumors are generally

more aggressive, growing rapidly and becoming relatively large before they are diagnosed. In adults, women with meningioma outnumber men by at least 2 to 1, especially in the older age groups. The most frequent location for meningioma of the lateral skull base is on the posterior aspect of the petrous bone between the superior and inferior petrosal sinuses. Less commonly, meningioma presents as a tumor that is confined to the internal auditory canal, and in rare cases, meningioma presents as an extracranial neoplasm in the middle ear, the external auditory canal, or the infratemporal fossa.

The etiology of meningioma is the subject of controversy. The relationship between severe head injuries and subsequent development of meningioma a number of years later was first suggested by Cushing in the 1920s when he observed that meningiomas occur directly beneath a previous skull fracture. In most patients, however, there was no history of trauma, or the injury may have occurred at a site distant from the tumor. Subsequent epidemiologic studies have failed to show a causal relationship between trauma and the occurrence of meningioma. Genetic factors have some role in the pathogenesis of meningioma because inherited tumors occur in patients with NF2. In fact, aberrations involving chromosome 22 occur in almost 50% of patients with sporadic meningiomas, and abnormalities have also been identified on chromosomes 1 and 14 (43). Radiation exposure seems to be clearly linked to the occurrence of meningioma. The most convincing evidence of this is the discovery that children who were treated with low-dose radiation for tinea capitis in the 1950s were almost 10 times more likely to develop meningioma. As the radiation dose increases, the risk of developing a tumor seems to rise. Hormonal stimulation, specifically from progesterone and possibly from estrogen, is thought to have a role in the genesis and progression of meningioma. This has been suggested because meningioma is more common in women, there are estrogen and progesterone receptors in meningioma, meningiomas seem to change size during pregnancy and during the menstrual cycle, and there may be a link between meningioma and breast cancer, which also has estrogen and progesterone receptors. The details relating estrogen or progesterone release and meningioma growth are unclear, but such an association could have consequences related to prevention, detection, and treatment of this tumor.

Meningiomas are well-circumscribed, firm, rubbery, nodular masses that invade dural lining, dural sinuses, and neurovascular channels. One-fourth of these tumors are flat, so-called en plaque tumors, that invade adjacent bone and incite an osteoblastic reaction referred to as hyperostosis. Most meningiomas are benign, but approximately 5% have malignant characteristics. These tumors show anaplastic histologic features and may invade the adjacent brain. Metastatic disease is highly unusual. The clinical presentation of meningioma is variable and depends on where the tumor is located within the temporal bone or skull base. Meningioma of the internal auditory canal is difficult to distinguish from vestibular schwannoma, which is more common. Both neoplasms present with unilateral sensorineural hearing loss and tinnitus, but auditory complaints occur more frequently in patients with vestibular schwannoma. Conversely, meningioma is more likely to cause facial twitching, weakness, or paralysis. Meningioma that originates on the posterior petrous face expands into the posterior cranial fossa, compressing the cerebellum and brainstem. These patients present with imbalance or vertigo and difficulty with fine motor movements. When these tumors become very large, they may cause hydrocephalus and elevated intracranial pressure resulting in headaches, nausea, vomiting, lethargy, and somnolence. Petrous apex lesions may extend onto the clivus, into the cavernous sinus, or through Meckel cave and into the middle cranial fossa. Extensive tumors in these locations can cause trigeminal neuralgia, facial hypesthesia, visual disturbance, and headache. Jugular fossa meningiomas may cause dysphonia, aspiration, and dysphagia, whereas physical examination shows palatal weakness, pooling of hypopharyngeal secretions, and vocal cord paresis. Geniculate ganglion and petrosal nerve tumors result in facial weakness or paralysis, and conductive hearing loss may occur when tumor extends to fill the middle ear.

The diagnosis is based on histopathologic findings and imaging characteristics that are consistent with meningioma. Histologic features that mark meningioma include polygonal- and spindle-shaped cells arranged in nests, vascular spaces, and psammoma bodies, which are spherical concretions consisting of calcium salts (Fig. 147.11). However, the microscopic appearance of meningioma is highly variable. Consequently, meningiomas are classified as endotheliomatous, fibrous, transitional, angiomatous, and sarcomatous depending on predominant cell shape, stromal content, tumor vascularity, and nuclear

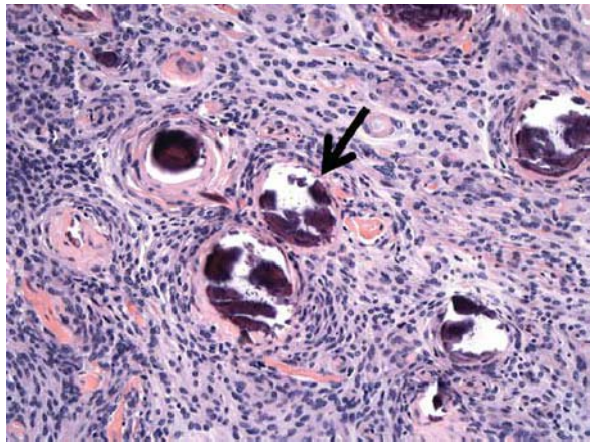

Figure 147.11 Meningioma: Histologic section demonstrating laminated calcific spheres known as psammoma bodies (*arrow*). The presence of numerous psammoma bodies indicates slow growth and a relatively favorable prognosis.

anaplasia. Further, the World Health Organization classifies meningiomas based on histologic characteristics, cellular atypia, and evidence of brain invasion. Both methods to classify meningiomas may provide prognostic information. In many cases, imaging characteristics on CT and MRI are diagnostic. Meningiomas are hyperdense or isodense compared with surrounding brain on CT images, and they exhibit homogeneous enhancement after contrast injection. Calcification within the tumor or associated hyperostosis supports the diagnosis of meningioma. Vestibular schwannomas are, on the other hand, isodense or hypodense to brain, and they exhibit inhomogeneous enhancement and lack of calcification or hyperostosis. MR images reveal the broad-based eccentric nature of meningioma and may sometimes show obvious dural or dural sinus origin (Fig. 147.12). MRI of vestibular schwannoma is more likely to show erosion of the internal auditory canal where the tumor originates and pronounced enhancement with injection of intravenous contrast. Intracanalicular lesions are difficult to distinguish on any imaging study.

Meningioma of the skull base and temporal bone can be observed with serial imaging, surgically resected, treated with radiation, or treated with a combination of subtotal resection and postoperative SRS or IMRT. Complete surgical removal is the only curative treatment available at this time. Resection is recommended for most patients with accessible tumors, especially if the patient has symptoms and there are no medical contraindications to surgery. Under ideal conditions, a Simpson grade I resection is achieved when tumor is removed with a wide margin of meninges and adjacent. Less complete resections, Simpson grades II to VI, are associated with higher recurrence rates. Preoperative angiography helps to identify the major feeding vessels of the tumor and may be combined with embolization to reduce operative blood loss. Despite efforts at total resection, recurrence rates for meningioma are relatively high. Even with a Simpson grade I resection, meningiomas recur in almost 10% of patients. The most important features to consider when estimating the probability of surgical cure are tumor location, which may allow complete resection, and lack of malignant characteristics. For patients who are not candidates for surgery, who have residual disease after surgery, who have recurrent or unresectable disease, who have meningiomas that show malignant characteristics, or who elect for nonsurgical therapy, radiation therapy should be considered. Recent clinical studies examining the efficacy of radiosurgical treatment of skull base meningiomas are encouraging. Long-term follow-up data, excluding atypical and malignant schwannomas, show local tumor control in more than 85% of patients (44). Local control in radiosurgery patients may be better when meningiomas are treated with radiosurgery alone compared to patients treated with radiosurgery postoperatively. Current research focuses on hormonal treatment, targeted chemotherapy, gene therapy using adenovirus vectors, and other forms of medical therapy that might help to arrest tumor growth and prevent recurrences.

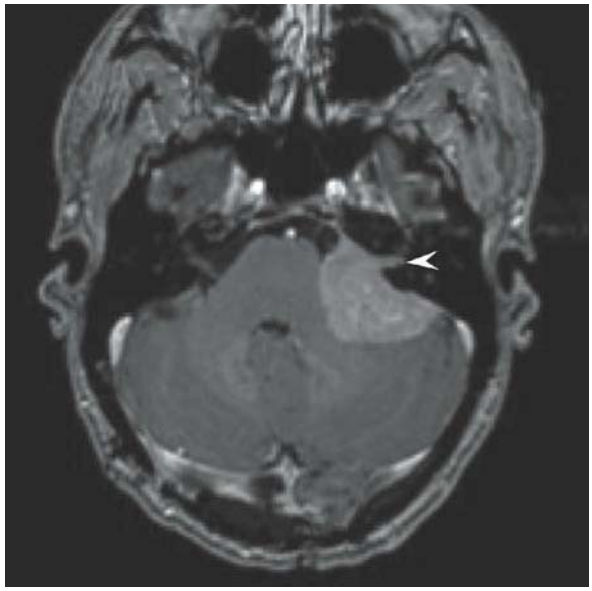

Figure 147.12 Meningioma. Axial T1-weighted image with contrast showing a left-sided tumor with its wide dural base on the posterior petrous face. There is enhancing tumor that extends laterally into the internal auditory canal (*arrowhead*), which usually indicates schwannoma, but can sometimes be seen with meningioma.

Lipoma

Lipomas of the internal auditory canal and the cerebellopontine angle are rare but potentially problematic tumors that may originate from the aberrant differentiation of neural crest cells into adipocytes. Bigelow et al. (45) provide the most comprehensive review of this subject in their multiinstitutional study and review of the world literature. They recorded 84 documented cases of lipoma of the internal auditory canal and cerebellopontine angle and studied the clinical findings in each case. Patients ranged in age from 7 months to 82 years with an average age of 40 years. Tumors predominated in males by a ratio of 2:1. Lipomas measured from 1 to 26 mm in diameter with a mean of 11 mm. Three patients presented with bilateral tumors. Ninety-two percent of patients were symptomatic. They most often presented with hearing loss, dizziness, tinnitus, and headache. Lipomas are fatty masses that may envelop the neurovascular structures of the internal auditory canal and cerebellopontine angle. Large lipomas may be adherent to the lateral aspect of the brainstem. Some lipomas have highly vascularized outer surfaces and are more accurately classified as angiolipomas. Biopsy specimens show benign mature adipocytes and varying amounts of fibrous tissue. Lipomas may infiltrate cranial nerves and surround component fascicles of nerve fibers.

Lipomas have unique imaging characteristics. Therefore, a definitive diagnosis can be obtained from an MRI. On MRI, lipomas are similar to subcutaneous fat with high signal intensity on T1-weighted images and diminished signal intensity on T2-weighted images. T1-weighted images do not enhance with injection of intravenous contrast because the tumor signal is near saturation. MRI with fat suppression further confirms the diagnosis. Follow-up for most patients with unresected tumors has been short, and thus, the rate of growth of lipoma, thought to be very slow, is unknown. The only documented instance of the growth of a lipoma involves a patient with a 2-cm tumor that was biopsied but not removed. The tumor enlarged 15% over an 8-year period. Review of surgical outcomes shows that complete tumor resection is possible in only one-third of patients and 68% suffer postoperative neurologic deficits. Forty-three percent of postoperative patients have improvements in symptoms, but only 19% have improvement with no new neurologic deficits. From this experience, it is clear that expectant management is advisable in most cases. Surgical therapy should be reserved for patients with progressive or disabling symptoms.

METASTATIC DISEASE OF THE TEMPORAL BONE AND LATERAL SKULL BASE

Temporal bone metastases resulting from distant malignancies are an infrequent but not insignificant occurrence. In the largest series of patients with temporal bone metastases studied to date, 47 metastases to the temporal bone were documented at autopsy in a population of 212 individuals with primary nondisseminated malignant neoplasms (46). The most common sites of origin of temporal bone metastases in order of decreasing frequency are breast, lung, kidney, gastrointestinal tract, larynx, prostate gland, and thyroid gland. The incidence of bilateral involvement may exceed 50%. Metastatic involvement of the temporal bone may occur as the first evidence of distant malignant disease, first presenting as hearing loss and later as facial paralysis or dysequilibrium. There is usually a conductive hearing loss that may be accompanied by pain. More frequently, temporal bone involvement is occult and occurs late in the course of disease. Tumor cells may accumulate preferentially in area of bone with sluggish blood flow, including the marrow and aerated regions. Areas of the temporal bone that show a predilection for metastatic disease include the petrous apex, the mastoid, and the internal auditory canal. The bony labyrinth appears to resist neoplastic invasion because inner ear involvement is uncommon.

Metastatic disease should be considered as a possible cause of hearing loss in a patient with a clinical history of malignant neoplasm, especially in patients with rapidly growing temporal bone lesions associated with progressive neurological symptoms.

HIGHLIGHTS

- Paragangliomas of the temporal bone arise from nonchromaffin paraganglia, or glomus bodies, which originate from the neuroendocrine system. Glomus jugulare tumors arise within the jugular fossa, and glomus tympanicum tumors arise along the course of the tympanic branch of cranial nerve IX (Jacobson nerve) and along the course of the auricular branch of cranial nerve X (Arnold nerve).
- Temporal bone and cerebellopontine angle epidermoids are aberrant collections of keratin debris within a sac of squamous epithelium. They result from entrapment of ectodermal rests during embryogenesis and therefore are categorized as congenital lesions. Epidermoids expand to fill empty spaces and incite a localized inflammatory reaction. Thus, they are usually large and very adherent to surrounding structures by the time they are treated with surgery.
- Patients with cutaneous carcinomas of the external auditory canal may present with symptoms similar to those of patients with chronic otitis externa. Chronic bloody drainage and sudden onset of deep ear pain are indicators of a possible malignancy and indicate the need for biopsy.
- Melanoma accounts for more than 75% of deaths from cutaneous malignancies. Excisional biopsy for early diagnosis is the key first step to optimize therapeutic outcomes. Sentinel node mapping using lymphoscintigraphy is the primary method of identifying nodal drainage patterns for these neoplasms, and high-dose interferon-alpha-2b may benefit patients with high-risk disease.
- Aggressive papillary tumors of the middle ear appear to be derived from the pars rugosa portion of the endolymphatic sac. They are slow growing but aggressive tumors that erode and spread extensively throughout the temporal bone and often recur after surgical treatment. Endolymphatic sac tumors occur in more than 10% of patients with von Hippel-Lindau disease, and therefore, these patients require screening.
- Embryonal rhabdomyosarcoma accounts for 30% of sarcomatous temporal bone neoplasms and is the most common sarcoma of this region. It is derived from pluripotential mesenchymal cells that differentiate into primitive skeletal muscle cells. Most patients are less than 12 years old and present with hemorrhagic aural drainage, a friable aural polyp, mastoid swelling, and facial nerve dysfunction. Current therapy includes limited surgical intervention, external beam radiation therapy, and chemotherapy.

- Chordomas result from defective embryonic remnants of the notochord. They are semitranslucent neoplasms that contain gelatinous material and are histologically characterized by clusters of physaliphorous (soap-bubble) cells in a mucoid matrix. Most chordomas occur in the clivus, but some originate or extend laterally into the petrous apex.
- Schwannomas of the lateral skull base are neoplasms that arise from Schwann cells at the transition zone between central myelin-producing oligodendrocytes and peripheral myelin-producing Schwann cells. What initiates the growth of these neoplasms is unknown, but aberrations or mutations on the long arm of chromosome 22, such as those that occur in NF2, reduce or eliminate merlin production, and this leads to demodulation of ErbB receptors in Schwann cells.
- Microscopic examination of schwannomas is characterized by spindle-shaped cells arranged in Antoni type A and type B patterns. The type A pattern consists of densely packed cells with palisading nuclei, termed Verocay bodies. The type B pattern consists of loosely arranged spindle cells in a myxoid stroma.
- Meningiomas are neoplasms that arise from the arachnoid layer of the meninges. Imaging studies of cerebellopontine angle meningiomas show homogeneous enhancement of a broad-based eccentric neoplasm that may contain speckled calcifications and may initiate a local hyperostotic reaction. Vestibular schwannomas, conversely, often exhibit heterogeneous enhancement and are "mushroom shaped," showing internal auditory canal origin and erosion.

148 Congenital Malformation of the Ear

Paul R. Lambert

Atresia of the ear canal with middle ear anomalies can occur in isolation or in association with microtia or craniofacial dysplasia. The reported incidence is 1 in 10,000 to 20,000 births. Genetic transmission occurs in many of the syndromes that include aural atresia (e.g., Treacher Collins syndrome), but it is rarely found in cases of isolated atresia. Aural atresia is bilateral in approximately one-third of the cases, and each side can vary in complexity (1).

The evaluation and treatment of aural atresia present a number of challenges to the otologic surgeon. First, overall hearing must be assessed and the need for immediate amplification determined. The second challenge is to formulate a long-term rehabilitation strategy. The key component of this challenge is to determine if surgical correction of the atresia is appropriate. This decision process requires the integration of results from audiometric and radiographic studies with a qualitative assessment of the patient's functional hearing status and the probability of restoring serviceable hearing. If surgery is recommended, the last challenge becomes the operative procedure itself, which is made complex by abnormal development of the temporal bone. This fact places the facial nerve and labyrinth at a greater risk than that encountered in routine temporal bone surgery and complicates the healing process, particularly for canal patency. This chapter reviews the concepts and protocols necessary to meet these challenges successfully.

EMBRYOLOGY

Placed in the context of congenital aural atresia, a general knowledge of the embryologic development of the ear is fascinating and essential for understanding the altered surgical anatomy. Development of the first pharyngeal pouch, the first and second branchial arches, the first branchial cleft, and the otic capsule must all be considered in this discussion.

External Auditory Canal

The external ear canal is derived from the first branchial groove (cleft), between the mandibular and hyoid arches. It is initially represented by a solid core of epithelial cells that extends down to the area of the tympanic ring and first pharyngeal pouch. This core of cells remains in place until the middle trimester of fetal life, a time when most structures of the inner, middle, and outer ear are well differentiated. At this point, absorption of the epithelial cells begins, progressing in a medial to lateral direction. If this canalization process is arrested prematurely, it is possible to have a more normally developed tympanic membrane and bony external ear canal associated with an atretic or very stenotic membranous canal, a situation that predisposes to canal cholesteatoma formation as the trapped squamous epithelium continues to desquamate.

The medial portion of the external ear canal is formed by the tympanic bone. This structure begins to ossify in the third embryonic month, eventually forming the tympanic ring and osseous ear canal; the latter structure continues its lateral growth during the first and second postnatal years. Malformation of the tympanic bone produces atretic bone at the level of the tympanic membrane and results in atresia of the ear canal (2). The mandibular condyle articulates with this rudimentary tympanic bone.

Mastoid and Middle Ear

The eustachian tube, middle ear, and mastoid air cells are derived from the first pharyngeal pouch. Although the middle ear cavity and mastoid air cells are smaller than normal in patients with aural atresia, no anatomic or clinical studies show impaired eustachian tube function in these ears. Pneumatization of the mastoid is a late embryologic event, starting at the seventh or eighth month and continuing into postnatal life. A well-pneumatized mastoid usually

indicates good middle ear development, including size of the tympanum and formation of the ossicles. The relationship between middle ear development and degree of differentiation of the pinna is disputed (3).

The ossicles, except for the vestibular portion of the stapes footplate, are formed from the first and second branchial arches. The external ear canal and tympanic membrane are derived from the first branchial cleft. Isolated branchial arch (ossicular) or branchial cleft (external ear canal) deformities are possible, but usually these malformations occur in combination (2). Other branchial arch defects may occur, especially mandibular hypoplasia. The stapes footplate is formed in part from the otic capsule, and in most cases it is normally developed in ears with congenital atresia. It is uncommon to encounter a fixed stapes footplate in the usual major congenital ear malformation, although the superstructure is frequently deformed. This information is important, because the stapes is often partially obscured by the lateral ossicular mass or the facial nerve in atretic ears, and its normal mobility may be difficult to determine with certainty.

Absence of the stapes footplate and oval window can occur, but this is usually encountered in a patient with a patent external ear canal and normal-appearing tympanic membrane rather than in a patient with aural atresia (4). It has been suggested that this condition is caused by abnormal development of the facial nerve (5,6). By the fifth to sixth week of gestation, the horizontal and vertical segments of the facial nerve are evident (6). If anterior displacement of the facial nerve occurred at this time, the nerve could become interposed between the otic capsule and the stapes blastema, which is beginning to grow toward the otic capsule. This would interfere with further stapes development, resulting in a rudimentary ossicle attached to the incus. Continued growth of the stapes toward the otic capsule could result in the rudimentary crura becoming embedded in the displaced facial nerve (4). Because the stapes never contacts the otic capsule, an oval window does not form. With further anterior displacement of the facial nerve, it is possible for that structure to course across the promontory, inferior to the region of the oval window (4). It has been hypothesized that displacement of the facial nerve occurs because of underdevelopment of the first branchial arch (5). This results in a compensatory overshifting of the second branchial arch, and its nerve follows this shift, assuming a more anterior position.

Inner Ear

The membranous labyrinth is derived from the ectodermal otocyst. In most cases of isolated aural atresia, sensorineural and vestibular functions are normal. A comprehensive review of inner ear abnormalities in aural atresia was recently reported by Vrabec and Lin (7). Their study included aural atresia within a broad spectrum of conditions termed "craniofacial microsomia" (e.g., CHARGE, branchiootorenal syndrome, Treacher Collins syndrome). They noted an inner ear anomaly by computed tomography (CT) in 22% of 105 patients, with an abnormality of the horizontal semicircular canal and/or vestibule accounting for over half (Fig. 148.1). A sensorineural hearing loss, usually mild and defined as a bone-conduction threshold greater than 20 dB involving two or more frequencies, was found in 15% of patients; the sensorineural hearing loss was usually mild.

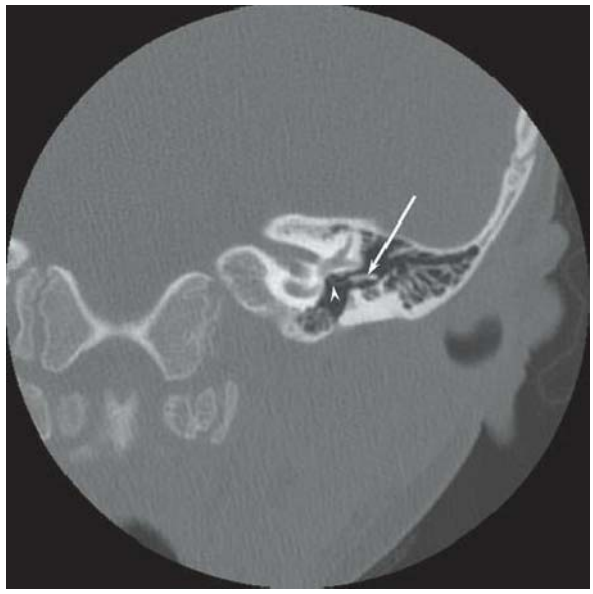

Figure 148.1 Aural atresia with inner ear dysplasia. Axial CT shows absence of the external auditory canal, incomplete partition of the upper turns of the cochlea (*arrow*), and an enlarged lateral semicircular canal (*arrowhead*).

Facial Nerve

Preoperative facial nerve weakness is uncommon in isolated aural atresia, but can be seen in 10% to 15% of patients with aural atresia in association with other craniofacial anomalies (7). Facial nerve abnormalities are common in cases of aural atresia (8,9). Bony dehiscence of the fallopian canal frequently occurs, and the facial nerve may also take an anomalous course. Typically, the facial nerve makes an acute angle at the second genu, crossing the middle ear in a more anterior and lateral direction to exit into the glenoid fossa. This abnormal position of the mastoid segment of the facial nerve places it at jeopardy when drilling the posterior inferior portion of the new external ear canal. As the facial nerve exits the skull, it may lie just deep to the area of the tragus. Inadvertent injury to the nerve can occur if undermining of the auricle is necessary to better align the meatus and newly created external ear canal. A correlation between the degree of microtia and the extent of facial nerve abnormality has been observed (3,10). An association between preoperative facial nerve dysfunction and inner ear abnormality by CT has also been noted (7).

CLASSIFICATION

Patients with congenital aural atresia are classified on the basis of auricular development and external canal/middle ear development. Deformity of the auricle is straightforward and is divided into three grades (11). Grade I microtia represents a minor malformation, with the auricle being smaller than normal but with all parts discernible. In grade II microtia, the auricle is represented by a curving or vertical ridge of tissue. In grade III microtia, any resemblance to an auricle is lost, and only a small rudimentary soft tissue structure is present.

Classification of the external canal/middle ear deformity has been more problematic because of the various parameters that have been used, including clinical examination, radiographic findings, surgical observations, or histopathologic studies. Ombredanne (12) proposed dividing congenital aural atresia into two groups only, major and minor malformations. This classification scheme is attractive because of its simplicity and clinical utility. With minor modifications, the following descriptions reflect Ombredanne's criteria.

Major Malformation

In the major malformation group, the external ear canal and tympanic membrane are usually absent, although cases of severe canal stenosis are also included. A small rudimentary tympanic membrane attached to a bony septum is occasionally seen in the canal stenosis patients, but typically the stenosis prevents visualization of the medial aspect of the ear canal. The size of the middle ear space is reduced, and the malleus and incus are deformed, fused, and fixed to the atretic bone. In severe cases, the middle ear space is very hypoplastic, and ossicles are rudimentary or absent. Dehiscence or displacement of the facial nerve can be expected in most major malformations. Grade II or III microtia is common, and inner ear function is usually normal.

Minor Malformation

The significant defect in the minor malformation group involves the middle ear. A conductive hearing loss exists because of absence or deformity of one or more ossicles or fixation of the ossicular chain. Abnormalities of the stapes may be more severe in the minor malformation group than in the major group. The middle ear space and tympanic membrane are normal or only slightly smaller. The external ear canal is patent but may be mildly stenotic. Dehiscence or displacement of the facial nerve can occur, and the pinna is normally developed or only slightly deformed.

PATIENT EVALUATION

Most cases of major congenital ear malformations are evident at birth because of microtia or other craniofacial anomalies. Patients with a normal or only slightly deformed pinna and a stenotic or blindly ending external auditory canal, however, may escape diagnosis for years. Unilateral minor congenital ear malformations with a patent ear canal and normal tympanic membrane can be more difficult to diagnose and may be discovered only with routine hearing screening in school.

The evaluation of an infant or young child with congenital aural atresia must involve both the functional and cosmetic aspects of this condition. First, one must assess the overall hearing status and need for immediate amplification. Second, one must formulate a treatment plan that usually includes consultation with other specialists (e.g., plastic surgery, genetics, developmental pediatrics.)

PHYSICAL EXAMINATION

The initial focus of the physical examination is on overall craniofacial development, because abnormalities or syndromes involving the first or second branchial arch may be associated with the aural atresia. Careful palpation of the mandible may reveal a mild hemifacial microsomia not immediately obvious on inspection. Development of the palate and other intraoral structures should be assessed. The degree of microtia is observed, as is mastoid development. The caliber of the external auditory canal should be graded as normal, stenotic (i.e., mild or severe), blindly ending, or completely atretic. If possible, the tympanic membrane is examined otoscopically. Displacement of the malleus handle (usually anteriorly) or a bony shelf extending from the posterior canal wall may exist. Mobility of the tympanic membrane and malleus handle is determined. Any abnormalities of the digits, limbs, or cervical vertebra are noted.

In the case of a child, achievement of neurologic milestones, such as speech and ambulation, is assessed by history and direct observation. This information can provide insight into auditory and vestibular development. Each major division of the facial nerve is carefully examined and any weakness observed. It is rare to encounter a paresis or paralysis involving the entire hemiface, although there is occasionally involvement of the lower face or lip area. The most common anomaly of facial function is a congenital absence of the depressor anguli oris muscle.

Audiometric Evaluation

Auditory assessment in patients with unilateral atresia is usually straightforward. Behavioral audiometry can be used in most cases, although auditory brainstem response testing may be necessary in young infants or children who are difficult to test. Patients with bilateral atresia present more of a challenge because of the masking dilemma. In such cases, it is essential to determine the level of cochlear function in each ear to prevent operating on an only-hearing ear or on an ear with little or no potential for hearing improvement. It is unsafe to assume that cochlear

function is normal bilaterally, even if inner ear development appears normal by CT. Objective data are needed, and bone-conduction auditory brainstem response testing can provide this (13). This testing involves placing recording electrodes near both ears to measure the responses to a bone-conduction stimulus.

Wave I of the auditory brainstem response is generated by the distal portion of the auditory nerve. There is minimal crossover of this small potential to the contralateral ear, and it is thus best measured by a recording electrode ipsilateral to the stimulated side. When recording simultaneously from both ears with surface electrodes, the presence of a wave I should represent the response from the ear being stimulated only. Although stimulation of each ear independently is not possible with a bone-conducted signal, the wave I response is ear specific, thereby allowing differential assessment of cochlear function.

If the ear canals are patent, electrocochleography can be used in a similar way to obtain ear-specific information. Instead of surface electrodes, a transtympanic, tympanic membrane, or canal electrode are possible, providing a more robust wave I response.

Computed Tomography

CT of the temporal bone is necessary in all patients being considered for surgery. It is also recommended in patients with stenosis of the external auditory canal to examine for possible cholesteatoma formation. To completely assess middle ear development, images in the axial (i.e., parallel to the line from the infraorbital rim to the external meatus) and coronal (i.e., parallel to the ramus of the mandible) planes are necessary. For example, the body of the malleus and incus, the incudostapedial joint, and the round window are best seen on axial images, but the stapes, the oval window, and the vestibule are best delineated on coronal images; both planes are necessary to follow the course of the facial nerve. Modern CT scanners can provide images in both planes without having to irradiate the patient twice. A 64-slice CT scanner (or better) is preferred to create diagnostic reformatted coronal images.

Assuming normal sensorineural function has been confirmed audiometrically, the decision to operate depends primarily on the degree of middle ear development, as reflected by the size of the tympanum and status of the ossicles. CT is also important for assessing the development of the cochlear and vestibular labyrinths because their appearance can influence middle ear surgery. For example, an enlarged vestibule and horizontal semicircular canal suggest the possibility of an abnormal communication between the perilymph and cerebrospinal fluid. In such cases, manipulation of the stapes should be avoided.

The course of the facial nerve usually can be delineated by CT. The inability to define this structure precisely, however, is not a contraindication to surgery, assuming that the other criteria for middle ear development are met.

Cholesteatoma can occur in association with congenital aural atresia. Occasionally, sufficient canalization of the external canal occurs such that a space develops in the medial end of the bony canal. Because the lateral end of the canal remains atretic or stenotic, the potential for cholesteatoma formation exists. Early in the development of this problem, symptoms such as pain or drainage from the ear canal or a fistulous track may be absent, and the diagnosis can only be made by CT.

Temporal bone CT is performed near the time of operation. Radiographic studies on infants are usually not recommended because the information is rarely applicable to immediate rehabilitative plans. In very young children, poor patient cooperation often necessitates anesthesia or results in a suboptimal study that must be repeated later. Almost all patients with cholesteatoma formation are older than 3 years, which is another reason to delay the CT evaluation until the patient is beyond that age (14).

MEDICAL MANAGEMENT

Unilateral Atresia

No immediate medical intervention is necessary in the infant discovered to have unilateral atresia, assuming there is normal hearing in the contralateral ear by ABR and OAE testing. The parents can be reassured that speech, language, and intellectual development will proceed normally. Preferential seating in school and possibly an FM system are advised, but a hearing aid is not recommended because of poor acceptance by most children. Many adults, however, find the consequences of unilateral hearing loss from atresia to be a significant aggravation at work and in social settings, and they more readily accept hearing aids. In patients with atresia of the ear canal, a bone-conduction hearing aid must be used. If the canal is only stenotic, an air-conduction aid is preferred because of cosmesis, improved sound localization (i.e., stimulation of one cochlea only), broader frequency response, less sound distortion, and comfort.

Bilateral Atresia

Early amplification within the first 3 to 4 months of life is essential in infants with bilateral atresia. Initial medical and audiologic evaluations can be completed within the first few months of life and a bone-conduction hearing aid or soft band BAHA can be fitted soon thereafter.

SURGICAL MANAGEMENT

Unilateral and Bilateral Atresia Repair

Although most otologic surgeons would consider atresia repair in bilateral cases, many are reluctant to operate on unilateral atresias. The issue is not the unilateral aspect of the hearing loss because most otologic surgeons will

explore the middle ear of a child with a large unilateral conductive hearing loss due to other causes (e.g., trauma, infection). The concern is the degree and predictability of hearing improvement that can be achieved, potential lifetime care of a mastoid cavity, and the risk to the facial nerve in atresia surgery. These concerns have prompted many surgeons to recommend delaying surgery in unilateral cases until adulthood, when patients can make their own decision based on the risks and benefits.

An improvement in the hearing threshold to 25 dB or better eliminates the handicap of unilateral hearing loss. This degree of hearing improvement is not possible in all atresia patients, but it can be achieved in at least 50% of carefully selected patients. A mastoid cavity is not created if the "anterior" surgical approach is used, and risk to the facial nerve is minimized by understanding the abnormal development of this structure and by using intraoperative facial nerve monitoring. I and others contend that the benefits of binaural hearing and the possibility of achieving that goal are sufficiently great to offer corrective surgery to carefully selected children with unilateral atresia (10,15).

Patients with bilateral atresia present less of a surgical dilemma. The goal in these cases is to restore sufficient hearing so that amplification is no longer needed. In contradistinction to ear selection for other otologic disorders, the "best" (as determined by CT evaluation) ear is selected for the initial surgical procedure. Most surgeons recommend operating as the child approaches school age and, depending on the hearing result, on the second ear within the next several years. As with many conductive hearing losses (e.g., otosclerosis), the possible use of amplification with a BAHA should be discussed. The probable need for yearly or semiannual cleaning of the reconstructed ear canal should also be acknowledged.

Selection Criteria

Most patients undergoing atresia repair have a residual conductive deficit of at least 10 dB. Sensorineural function should be normal to achieve binaural hearing in unilateral cases or to obviate the need for a hearing aid in bilateral cases. Normal or near-normal sensorineural function in the contralateral ears is also important to avoid operating on the better hearing ear.

Although audiometric criteria can be defined quantitatively, the real art of patient selection is centered on the CT evaluation of the middle ear. Hypoplasia of the middle ear space, ranging from mild to severe, occurs in most cases of congenital atresia, and ossicular development can be expected to correlate directly with middle ear size. The risk of surgical complications will be minimized and the chances for a successful hearing result are increased if the middle ear and mastoid size are at least two-thirds of the normal size and if all three ossicles, although deformed, can be identified (Figs. 148.1 and 148.2). CT demonstration of the oval and round windows and a near-normal course of the facial nerve further define the ideal surgical candidate. The relationship of the facial nerve to the oval window (i.e., normally positioned or overhanging) and the position of the vertical segment are noted. Severe anterior displacement of

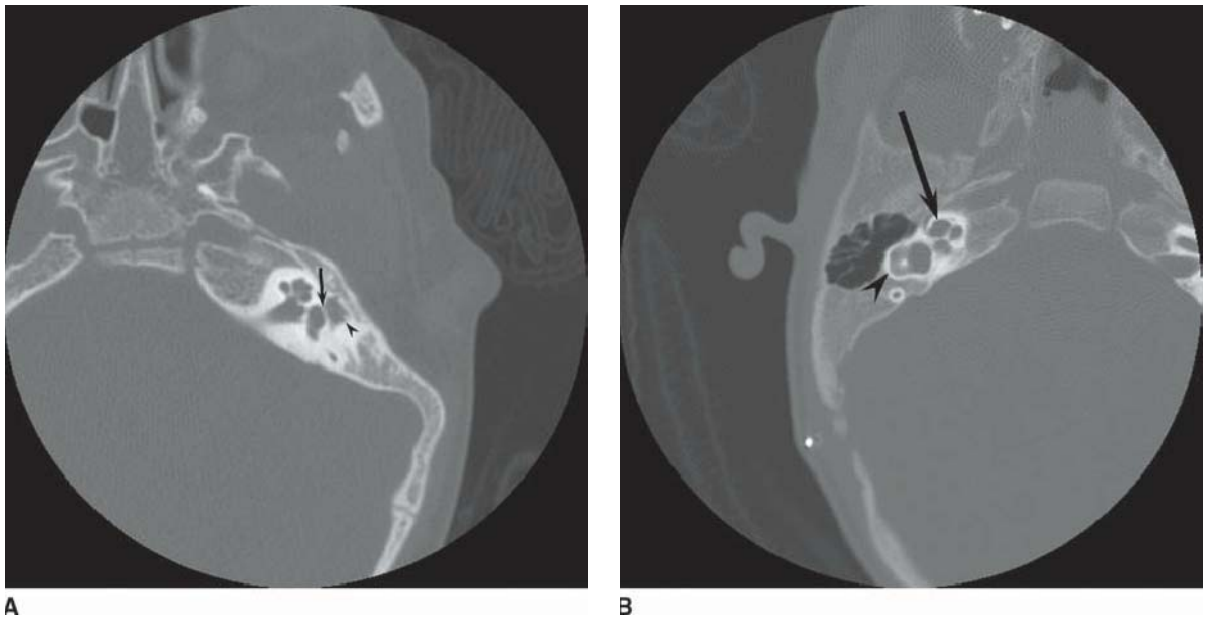

Figure 148.2 **A:** Aural atresia with mild middle ear dysplasia. Coronal CT shows an intact stapes with an intact incudostapedial joint (*arrowhead*), but the malleoincudal complex (*arrow*) is not properly formed. The tympanic segment of the facial nerve has a normal course. This patient would be a candidate for surgery. **B:** Aural atresia with severe middle ear dysplasia. Axial CT shows a diminutive middle ear cavity with no visible ossicles. The oval window is sclerosed (*arrow*), and the tympanic segment of the facial nerve is displaced laterally (*arrowhead*). This patient is not a candidate for surgery.

the vertical segment of the nerve restricts access to the middle ear space, reducing the chance for a successful hearing result and increasing the chance of facial nerve injury.

The Jahrsdoerfer grading system that quantifies the developmental status of the ear has been shown to predict postoperative hearing results (Table 148.1) (16). Specific dimensions of the mesotympanum can also be analyzed to further refine the CT analysis of atretic ears. Oliver et al. defined mesotympanic height, length, and weight measurement landmarks and showed a strong correlation with postoperative speech reception threshold (SRT) (17). Height of the mesotympanum was measured on the coronal scan from the horizontal facial nerve to the first bony prominence inferiorly (in normal ears, this would be the bony annulus). On the same coronal cut, width of the mesotympanum was measured as the distance between the oval window and the atretic bone (scutum in normal ears). Length of the mesotympanum was measured on the axial CT as the distance from the promontory to the nearest posterior lateral bone (usually the bone overlying the vertical facial nerve). If the area (height × width of the mesotympanum) was ≥20 mm^2, patients were six times more likely to have an SRT ≤ 25 dB. If the mesotympanum volume was ≥42 mm^3, patients were 24 times more likely to have an SRT ≤ 25 dB. Clearly, volume of the middle ear is a critical determinant of success in atresia surgery. This calculation will be facilitated as more sophisticated radiographic software programs designed to measure volumes of irregular shapes and contours, such as characterize the middle ear, become available.

In unilateral atresia cases, only the ideal candidates are selected; in bilateral cases, the minimal criteria are a middle ear of at least one half normal size and the presence of an ossicular mass. Overall, only about 60% of patients with aural atresia are surgical candidates.

Often the CT findings can be anticipated by the physical examination. For example, poor middle ear development is more frequently seen in patients with craniofacial deformities than in patients with isolated aural atresia. Patients with Treacher Collins syndrome often have truly bizarre middle ear findings. In general, the better developed the auricle, the larger and better developed the middle ear.

Timing of Surgery

If elected, surgery can be performed as early as 6 to 7 years of age. By this time, accurate audiometric tests have been obtained, pneumatization of the temporal bone is well advanced, and most children are able to cooperate with postoperative care. This timing also permits microtia repair to be well under way.

In microtia patients requiring major external ear reconstruction, it is reasonable for the reconstructive surgeon to operate first. This ensures a virgin field without scars or compromised blood supply, optimizing survival of the implanted auricular framework. The overall cosmetic result should also be better without the restriction of having to reconstruct the auricle around a bony canal drilled in the temporal bone. Typically, the otologic surgery is performed midway through the multistaged microtia repair, after the auricular framework has been implanted and the lobule transposed but before the tragus is reconstructed and the auricle is elevated from the side of the head. Although the reconstructed auricle may not be centered exactly over the created bony canal, it can be repositioned with appropriate undermining so that the meatus and external canal are aligned.

Cholesteatoma

Cholesteatoma in congenital aural atresia results from squamous epithelium, which has been trapped within the medial ear canal after an arrest of the canalization process. The membranous canal may appear completely closed in these cases, but usually shows either a pinhole opening or severe stenosis. There is one reported case of a cholesteatoma appearing medial to the atretic bone in a patient with complete canal atresia (18). In this patient, an epidermoid rest in the middle ear was hypothesized as the origin of the lesion.

Cole and Jahrsdoerfer (14) reviewed a series of 50 patients (54 ears) with an average canal diameter of 4 mm or less and found that 50% of them developed a cholesteatoma. Patient age and exact canal size were important variables in predicting disease. For example, no cholesteatomas were found in patients younger than 3 years, and bone erosion and middle ear involvement from a canal cholesteatoma were not encountered in patients younger than age 12. The preponderance of cholesteatomas developed in canals 2 mm or less in diameter. Beginning in young adolescence, individuals with severe canal stenosis are at a particular risk for cholesteatoma formation (i.e., 10 of 11 ears in the series reported by Cole and Jahrsdoerfer (14)). The usual presenting symptom in these patients is drainage from the ear canal or from a fistula track postauricularly.

Patients with cholesteatoma, regardless of CT or audiometric findings, should undergo surgery to eradicate the disease process and, if possible, improve hearing. Patients with stenosis of the external canal who are at risk for cholesteatoma formation should also be considered for surgery. Given these data on the risk of canal cholesteatomas, management protocols can be set forth. Patients with stenosis extensive enough to prevent adequate cleaning of the canal and examination of the tympanic membrane should have CTs by age 4 or 5, even if there is no aural drainage. Assuming a cholesteatoma is not found, several options are available, depending on middle ear development. If the CT findings are favorable with regard to hearing improvement, canal and middle ear surgery is advised at this time. Canaloplasty alone is offered to patients with unfavorable middle ear findings. If the parents are uncomfortable with surgery, a CT should be obtained every few years to rule out cholesteatoma development. Periodic CTs are not necessary in patients with a completely atretic ear canal, given the rarity of cholesteatoma formation in that setting.

SURGICAL TECHNIQUE

There are two basic surgical approaches for repair of aural atresia: the mastoid approach and the anterior approach. In the mastoid approach, the sinodural angle is first identified and followed to the antrum (19–21). The facial recess is opened and the incudostapedial joint separated. The atretic bone is then removed. In the anterior approach, as popularized in this country by Jahrsdoerfer (3), exposure of the mastoid air cells is limited. Drilling is confined to an area defined by the temporomandibular joint (TMJ) anteriorly, the middle cranial fossa dura superiorly, and the mastoid air cells posteriorly. An advantage of the anterior approach is that a large mastoid cavity with its attendant problems of debris accumulation and infection is avoided. There is also less surgical manipulation in the area of the mastoid segment of the facial nerve, and the more cylindrical contours of the new canal with limited mastoid exposure facilitate placement of the split-thickness skin graft. For these reasons, the anterior approach is preferred and is the technique described here. Facial nerve monitoring is used.

Incision

A postauricular incision is used to expose the mastoid bone. The soft tissues are elevated anteriorly until a depression is encountered. In most major malformations, this depression is the TMJ, although occasionally a stenotic bony ear canal may be encountered. Dissection within this area may be necessary to differentiate between the two, but the manipulation should be limited because the facial nerve frequently exits the skull into the glenoid fossa.

Drilling a Canal

In most atretic ears, a tympanic bone remnant is not identified, but occasionally it is present and clearly demarcated from the surrounding cortex (Fig. 148.3). In such instances, the atretic bone serves to direct the drilling for

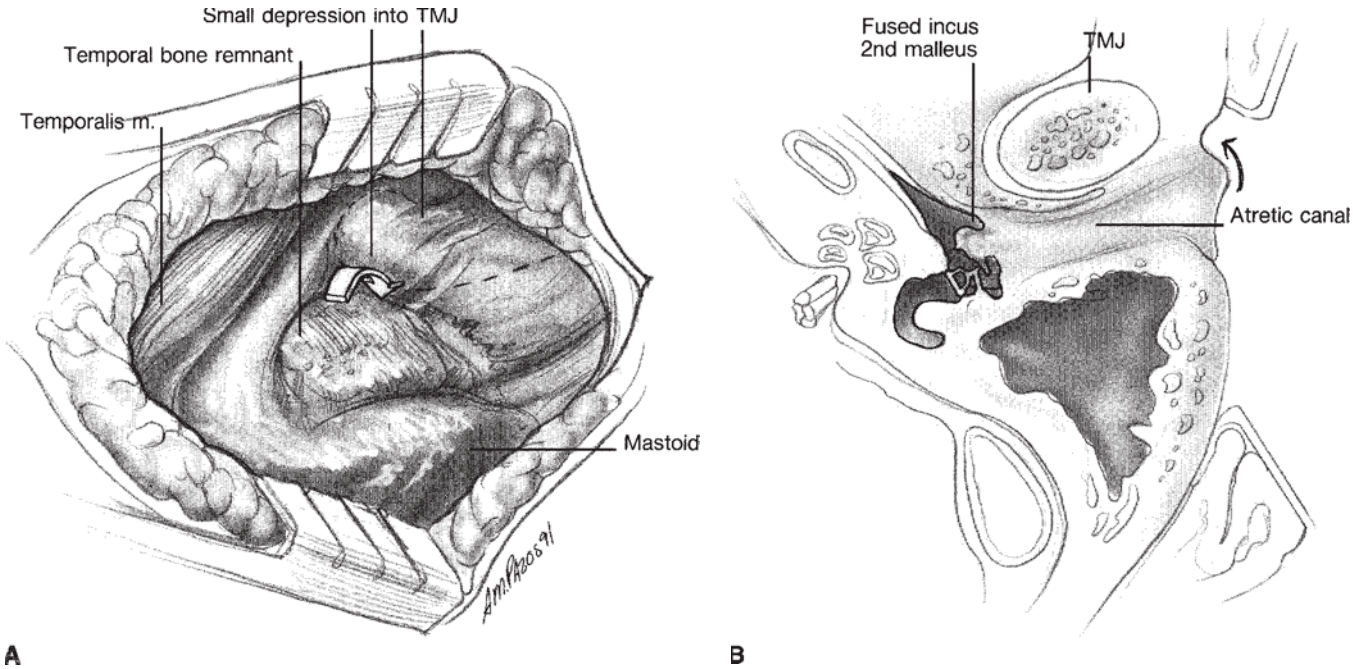

Figure 148.3 **A:** Through a postauricular incision, the soft tissues have been elevated to reveal the mastoid cortex and the atretic bone (tympanic bone remnant). Notice the depression anterior to the atretic bone, which represents the temporomandibular joint (TMJ). **B:** Axial section.

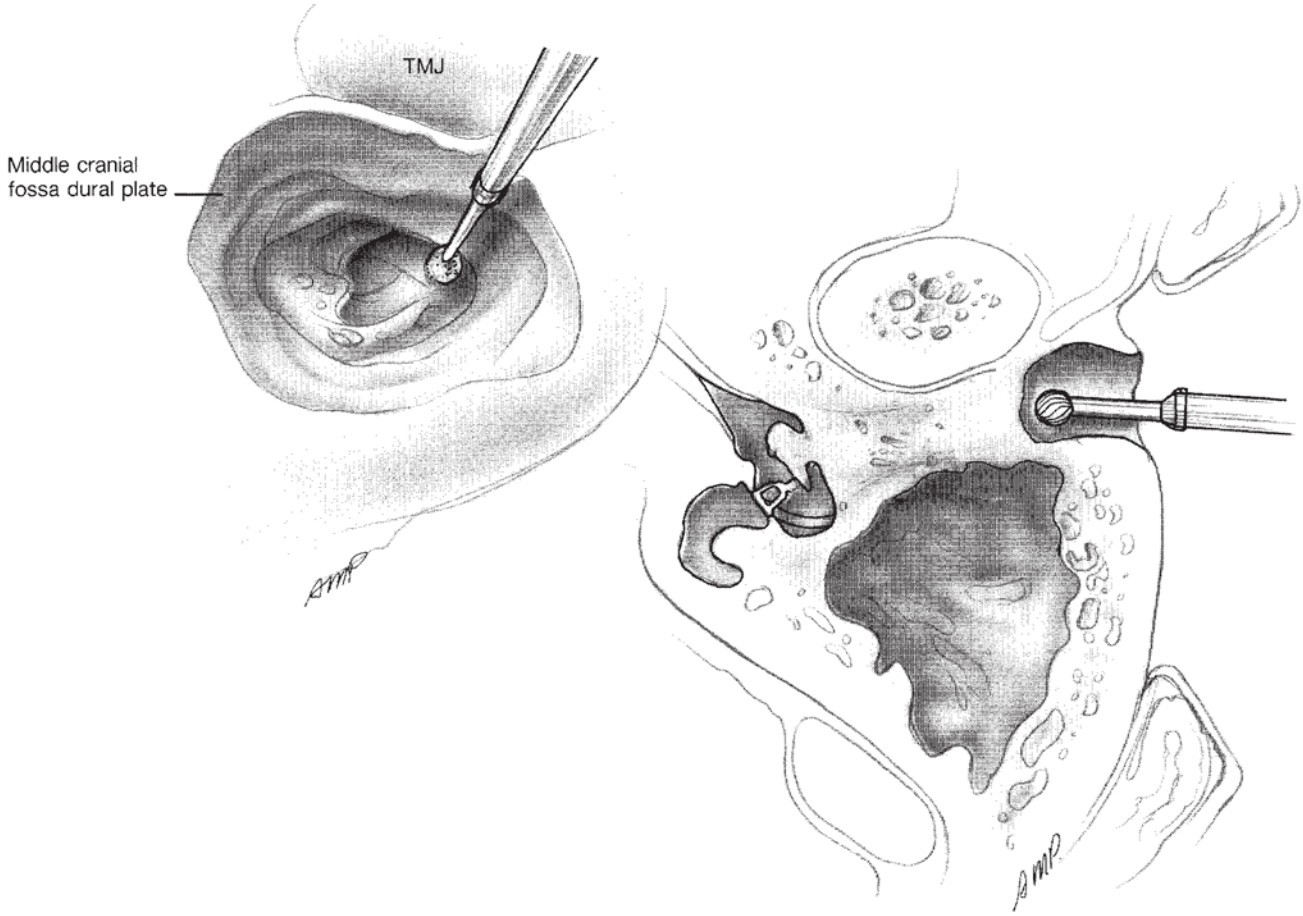

Figure 148.4 The initial stage of drilling an external auditory canal is shown. Landmarks for the canal include the middle cranial fossa dura superiorly, the temporomandibular joint (TMJ) anteriorly, and the mastoid air cells posteriorly.

the external canal. Even when not identified, there is sufficient space between the glenoid fossa anteriorly and the mastoid air cells posteriorly for a canal. Drilling is begun just slightly posterior and superior to the glenoid fossa. The tegmen is the critical landmark to define initially. Drilling toward the middle ear is accomplished by using the middle cranial fossa dura as the superior landmark and the TMJ as the anterior landmark. The bone removed is usually solid but may be cellular in areas (Fig. 148.4). The posterior wall of the glenoid fossa should be very thin to maximize anterior exposure and to limit opening into the mastoid air cells. If air cells are uncovered, they can be filled with cartilage pieces from the meatoplasty later in the procedure. As the middle cranial fossa dura plate is followed medially, the epitympanum will be entered and the fused heads of the malleus and incus identified (Fig. 148.5). Concentrating the drilling superiorly along the middle cranial fossa has the advantage of protecting the facial nerve because that structure always lies medial to the ossicular mass in the epitympanum. Because of the more acute angle the facial nerve may take at the second genu, it is vulnerable to injury as the external canal is enlarged in the posteroinferior direction. In this area, the nerve may lie lateral to the middle ear cavity in addition to being anteriorly displaced.

Exposure of the Ossicular Chain

The malleus neck or deformed manubrium is typically fused to the atretic bone. To free the ossicular chain, this overlying bone is thinned carefully with a diamond burr and then completely removed with an incudostapedial joint knife or small hook. Periosteum underlying the atretic bone is still attached to the malleus and should be sharply excised with a microknife or microscissors, or vaporized with the laser. Care is taken to limit trauma to the inner ear by drilling or excessive manipulation of the ossicular chain. The incudostapedial joint is not routinely separated.

Except for the fossa incudis, which may be left intact, bone should be completely removed around the ossicles, leaving at least a 2- to 3-mm space between these structures and the adjacent canal wall. The atretic bone should be removed so that the ossicular mass is centered

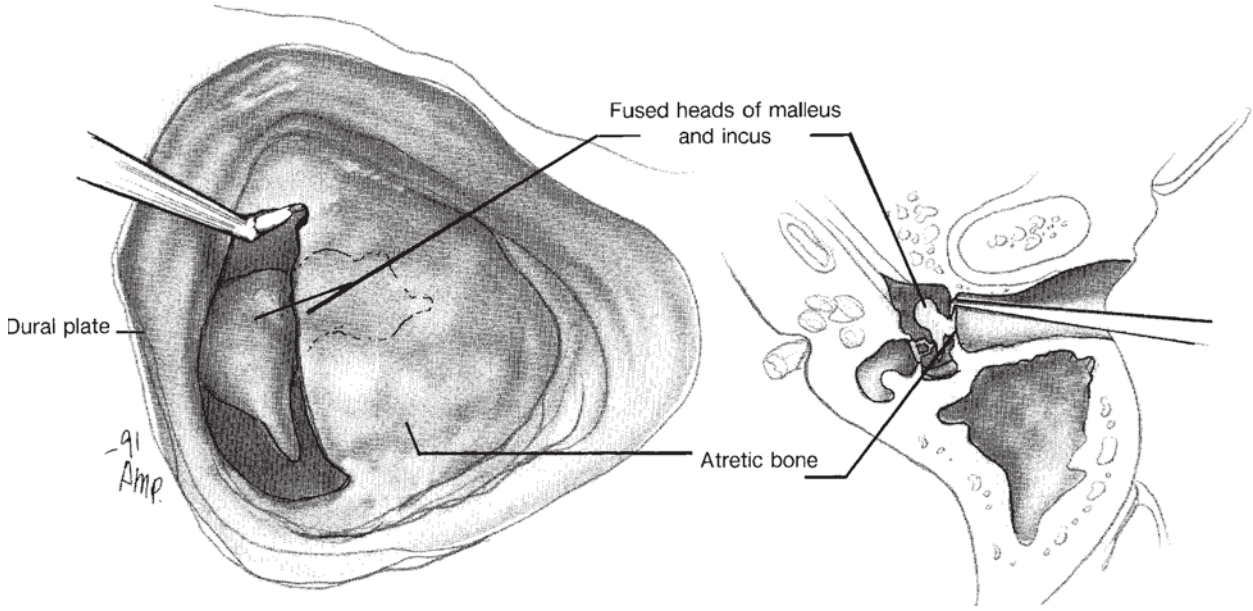

Figure 148.5 The epitympanum is entered by following the middle cranial fossa dura medially. The atretic bone over the fused malleus–incus complex is thinned with a diamond burr and removed with a right-angle hook.

in the new canal (Fig. 148.6). To ensure proper draping of the fascia and split-thickness skin graft, the canal walls should be smooth and without ledges lateral to the ossicular mass.

Middle Ear Surgery

The stapes may be partially obscured because of the contracted middle ear cavity, the malformed lateral ossicular mass, or the overlying facial nerve. Usually, enough of that ossicle can be seen to assess its mobility and the integrity of the incudostapedial joint. Although the stapes is often small, with delicate misshapen crura, a normal oval window and stapes footplate are anticipated. The lateral ossicular mass is maintained in position and not removed to obtain a better view of the stapes. In most cases, the ossicular chain, although deformed, is mobile, and hearing results may be better when the chain is left intact instead of interpositioning a prosthesis or autograft material (10,22).

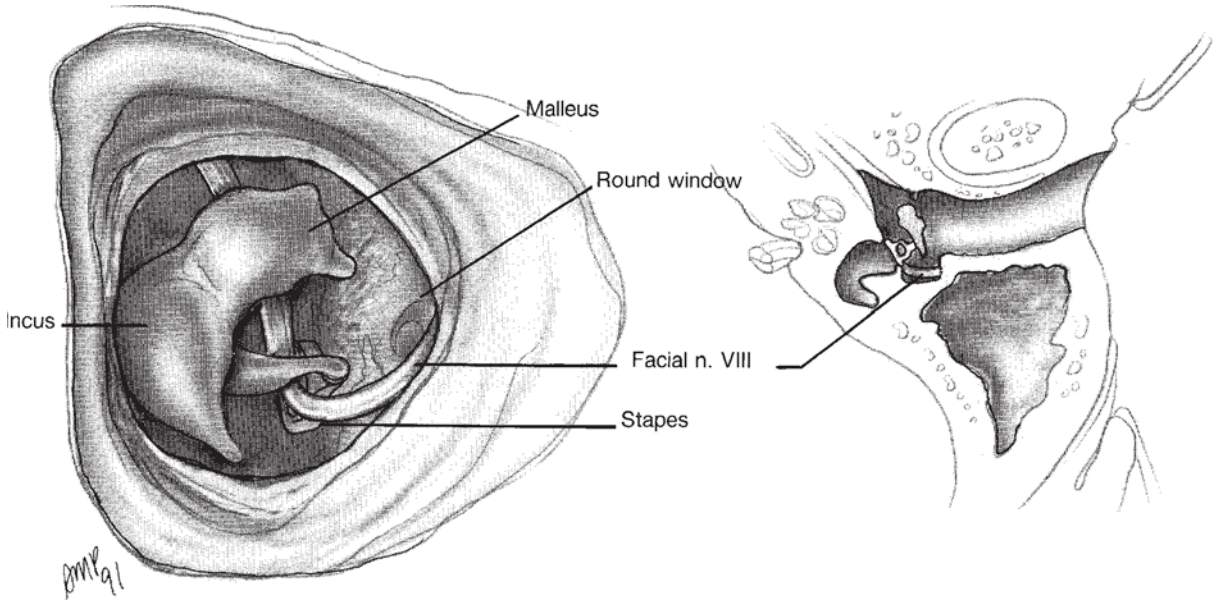

Figure 148.6 The ossicular mass is fully exposed. Notice the more acute angle of the facial nerve at its genu.

Tympanic Membrane Grafting

A thin fascia graft is placed over the mobilized ossicular chain. Because the manubrium of the malleus is either absent or very deformed, it is difficult to anchor the graft beneath the ossicular chain. Absence of a tympanic membrane remnant or annulus further predisposes to lateralization. Several techniques can be used to prevent this potential complication. First, the graft can be tucked beneath the anterior and superior bony ledges of the canal wall. If the ledges are too shallow to stabilize the graft, a sulcus several millimeters deep can be drilled in the anterior canal wall medial to the level of the ossicles. A second technique to avoid lateralization involves covering the fascia graft with the split-thickness skin graft (STSG) of the canal and then placing a silastic button that has been contoured to the circumference of the canal on top of the covered ossicles (23).

Meatoplasty

A large meatus, approximately twice normal size is created. The auricle is undermined and the deep soft tissue debulked from the approximate area of the meatus. Leaving only a small amount of subcutaneous tissue around the meatus limits the length of the membranous canal and helps prevent stenosis. When possible, an anteriorly based thin skin flap is raised over the planned meatal opening. This skin flap is subsequently noted medially into the new ear canal to cover a portion of the anterior membranous canal. The auricle is returned to its normal anatomic position to check for alignment of the meatus and the bony canal. It is secured in place by suturing its distal edge to a cuff of periosteal tissue at the bony edge of the drilled canal.

Frequently, the meatus appears to be offset anteriorly or inferiorly. In such cases, further undermining of the auricle is necessary so that it can be positioned without tension more posteriorly and superiorly. The facial nerve is vulnerable to injury if extensive soft tissue undermining is necessary because prior auricular reconstruction may have caused scarring and tethering of the extratemporal facial nerve in a more superficial position. A strip of skin can be excised from the postauricular incision to help maintain the auricle in its new location. In some cases, the framework of the auricle may need to be anchored to the periosteum to maintain proper alignment.

Skin Grafting

A skin graft 0.008 inch thick is taken from the upper thigh or upper arm and used to line the canal. To determine the proper configuration of the split-thickness skin graft, several measurements of the canal are made with a 2-0 silk suture. Typically, the resulting skin graft is shaped like a hexagon and is approximately 4 × 6 cm^2. To facilitate graft placement at the level of tympanic membrane and to ensure eversion of the skin edges, multiple small wedges are excised from the medial portion of the graft; the graft is also pie crusted.

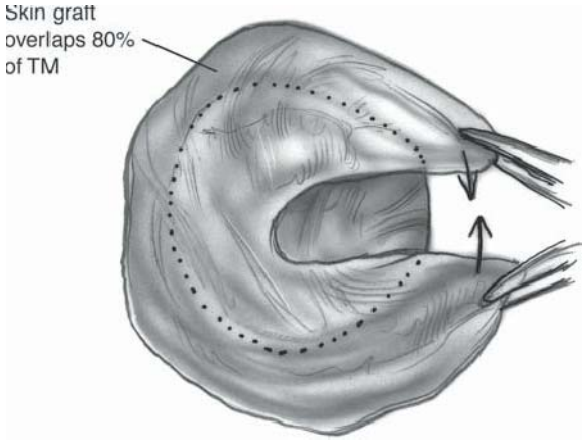

Figure 148.7 The fascia graft for the tympanic membrane has been placed and the STSG is positioned within the ear canal, overlapping the fascia.

With the ear retracted forward, the STSG is positioned in the bony canal so that it overlaps the fascia graft (Fig. 148.7). The seam of the graft is placed anteriorly, away from any open mastoid air cells posteriorly. Partial or substantial covering the fascia graft with the skin graft is acceptable and may facilitate epithelialization of the new tympanic membrane. A silastic disc (0.04 inches thick), approximating the diameter of the bony canal, is placed over the covered ossicles to help prevent lateralization. Stabilization of the STSG within the canal is achieved by placing Merocel wicks which are then hydrated with an antibiotic-steroid solution (Fig. 148.8). After the bony

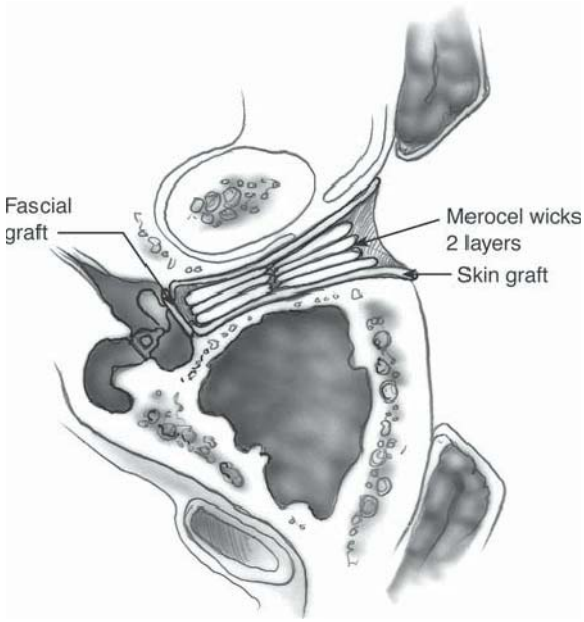

Figure 148.8 The fascia graft and split-thickness skin grafts are stabilized by layered packing (axial view).

canal has been fully packed, the ear is returned to its normal anatomic position, and the postauricular incision is closed with subcuticular sutures. Working through the meatus, the lateral end of the STSG is grasped and pulled through the meatal opening. It is trimmed as necessary and sutured in place. Additional packing with Merocel is used to fill the lateral soft tissue portion of the canal. The initial packing of the STSG in the bony canal prevents it from being dislodged during the final step of suturing the graft to the meatal skin. The placement of the graft in the bony canal while the ear is reflected forward provides maximal exposure, ensuring that the entire canal is covered and that the STSG has been positioned accurately relative to the fascia graft. The previously elevated skin flap from the area of the meatus is sutured to a cuff of periosteal tissue near the TMJ to cover a portion of the anterior membranous canal.

Postoperative Care

Postoperative antibiotics are not prescribed. The patient is instructed to place 10 drops of the antibiotic-steroid solution in the ear twice daily to keep the Merocel wicks moist. Approximately 10 days postoperatively, the ear canal packing and silastic disc are removed. Complete take of the STSG is anticipated at this time. If any granulation tissue is seen, antibiotic-soaked pieces of Gelfoam are placed within the canal and the patient is instructed to keep these moist for the next 7 to 10 days.

SURGICAL FINDINGS

Ossicles

In major atresia cases, the expected finding is a fused and deformed malleus–incus complex. The malleus is typically more deformed than the incus and has a short manubrium (Fig. 148.9). The site of ossicular fixation is most commonly between the malleus neck or shortened manubrium and the atretic bone. In minor malformations, the incus and malleus are less deformed and may be completely normal. If abnormal, ossicular fixation in the epitympanum and/or a deformed manubrium or incus long process is common.

In atretic ears, the stapes is usually small and delicate with misshapen crura. Stapes fixation is uncommon. The incudostapedial joint may also appear fragile and occasionally may exist as only a fibrous connection. The facial nerve may encroach on the stapes, partially obscuring the footplate. Complete visualization of the stapes may also be impaired by the overlying ossicular mass.

Fixation of the stapes, severe deformity of the stapes, or even absence of the stapes and oval window may be encountered in minor malformation cases. These abnormalities, although rare, are more common in patients with a patent external auditory canal and normal tympanic membrane than in patients with major atresia of the ear.

Facial Nerve

Facial nerve abnormalities are common in major atresia patients. The anticipated abnormalities include complete dehiscence of the tympanic segment, inferior displacement of the tympanic segment, and anterior and lateral displacement of the mastoid segment. The last abnormality frequently obscures the round window. Although the course of the facial nerve is often aberrant, predictable abnormalities are the rule and help guide the surgeon. The degree of external ear deformity provides some indication of facial nerve development, with a higher incidence of facial nerve anomalies occurring in patients with more severe microtia (3,4).

Aberrant facial nerves are frequently encountered in ears with minor malformations, and the abnormalities

Figure 148.9 The typical appearance of a fused malleus–incus complex is shown (**left**). Notice that this complex is smaller than the normal malleus and incus (**right**) and that the malleus is more deformed than the incus.

may even be more severe than those seen in atresia cases. The most common findings include dehiscence or inferior displacement of the tympanic segment. In several cases, a facial nerve coursing across the middle portion of the promontory, well inferior to the oval window, has been observed. In all patients with a congenital conductive hearing loss, even if the pinna, external auditory canal, and tympanic membrane are normal, an abnormal facial nerve should be anticipated and appropriate facial nerve monitoring and surgical care exercised.

HEARING RESULTS

It is difficult to compare hearing results from various series because of differences in classifying congenital ears, in selection criteria, in reporting hearing results, and in the length of follow-up. In general, an initial postoperative hearing level of 30 dB or better can be achieved in approximately 50% to 75% of major congenital atresia patients; a hearing level of 20 dB or better is possible in 15% to 50% of these patients. Bellucci (2) reported a hearing level of at least 30 dB in 55% of 71 patients followed for at least 2 years. Schuknecht (24) reported similar success in 30 patients with a mean follow-up of 1.3 years. Thirty percent of Schuknecht's patients had a hearing level of 20 dB or better. Nager and Levin (19) reported that 70% of 23 patients treated over a 17-year period had a hearing level of at least 30 dB. Mattox and Fisch (25) found at least a 30-dB improvement in air-conduction thresholds in 45% of 11 patients followed a minimum of 2 years. De la Cruz and colleagues (21,26) reported 56 patients with a 6-month follow-up and observed that 53% had a conductive deficit of 20 dB or less and 73% had a deficit of 30 dB or less. In a follow-up series involving 77 ears, air-bone gap closure to less than 30 dB was achieved in 60% of cases (27). In 2003, De la Cruz and Teufert (28) reported a 30-dB or less conductive hearing loss in 58.5% of 116 ears with short-term follow-up, which decreased to 50.8% with longer-term (3.5 years) observation. Lambert (10) reported that 67% of 15 patients followed for at least 1 year had an SRT of 30 dB or better; the mean improvement in the hearing level was 30 dB. Jahrsdoerfer (3) found that 65% of 17 patients followed for 2 months to 8 years had a pure-tone average of 30 dB or less. In a more recent series of 86 patients, Jahrsdoerfer (16) reported a postoperative hearing level at 1 month of 25 dB or better in 71%.

Lambert (29) reported data comparing early (less than 1 year) and longer term (1.0 to 7.5 years, mean follow-up 2.8 years) hearing results after surgery for congenital aural atresia. This study involved 59 consecutively operated ears. In the early postoperative period, an SRT of less than 25 dB was achieved in 60% and an SRT of less than 30 dB in 70%. With longer-term follow-up, 46% of patients maintained an SRT of less than 25 dB. Digoy and Cueva reviewed less than 1 year and greater than 1 year hearing outcomes in 54 ears (30). The short-term mean SRT was 33, with 53% of patients at 30 dB or less. For follow-ups greater than 1 year ($n = 16$), 56% of patients had an SRT of 30 dB or less (mean 32 dB).

Chang et al. reported on 100 ears (some requiring revision surgery) with a minimum follow-up of 3 years (31). The mean air-bone gap at 3 years was 30 dB, which was not statistically different from the mean value of 27 dB at 6 months postoperatively.

COMPLICATIONS

Given the fact that near-normal hearing is not universally achieved even in carefully selected atresia patients, the surgical complications must be carefully compared with the merits of atresia surgery. The two potential serious complications are sensorineural hearing loss and facial nerve paralysis. Other complications that can occur include canal stenosis, chronic infection, and recurrent conductive hearing loss.

It should be recognized that revision surgery is often required after congenital aural atresia repair (29–34). In the series by Lambert in which patients were followed for an average of 2.8 years, one-third of the patients did require revision surgery. Stenosis of the ear canal and lateralization of the tympanic membrane were the most common problems encountered. After revision surgery, approximately half of these patients did achieve an SRT of 25 dB or better with at least 1 year of follow-up.

Labyrinthine Injury

The anterior surgical approach limits exposure of mastoid air cells, thus minimizing potential injury to the horizontal semicircular canal. High-frequency sensorineural hearing loss has been noted in some patients postoperatively, although a loss in the speech frequencies is rare (10,20,24,26,35). Because the ossicular mass is connected to the atretic bone, energy from drilling will be transmitted to the inner ear in all atresia cases regardless of the approach. This may be of less consequence, however, than direct manipulation of the ossicular chain by instruments or the drill. Care in removing the final portion of atretic bone from the ossicular chain is particularly important in the anterior approach, because the incudostapedial joint is not disarticulated.

Facial Nerve Injury

The abnormal development of the temporal bone in cases of aural atresia places the facial nerve at increased vulnerability. Understanding the anomalies of the facial nerve likely to be encountered and the use of facial nerve monitoring, however, enable the surgeon to proceed with confidence. Temporary facial paralysis has occurred rarely. This complication has usually resulted from transposition of the facial nerve to gain access to the oval window (24,36).

In my series of over 200 aural atresia surgeries, facial paresis or paralysis has occurred in less than 1%. A similar incidence has been reported by Jahrsdoerfer and Lambert (37).

Potential damage to the facial nerve can be minimized by adhering to several surgical guidelines. First, as the atretic bone is removed, the drilling should be concentrated superiorly along the middle cranial fossa dural plate, entering the middle ear first in the epitympanum. The facial nerve is protected in this approach because it will always lie medial to the ossicular heads. Second, care should be exercised as the canal is enlarged in the posterior-inferior direction because of the more anterior and lateral course of the mastoid segment. Injury to the facial nerve can also occur in its extratemporal segment, as the postauricular incision is made, or as the auricle is undermined to align the soft tissue meatus and the created bony canal.

Canal Stenosis

In the reviews by Lambert (29) and Oliver et al. (32), stenosis of the membranous canal was the most common reason for revision surgery. Some degree of narrowing of the membranous canal requiring local care in the office (e.g., cauterization for granulation tissue, Kenalog injections, wick with steroid—antibiotic drops) or surgery occurs in as many as 25% of patients. If a large meatus (i.e., approximately twice normal size) has been made, this narrowing can be managed conservatively in the office. Occasionally, a significant stenosis occurs, trapping squamous epithelium and causing infection. In such cases, attempts to dilate the canal with soft or hard stents are usually ineffective, and a secondary meatoplasty with skin grafting is necessary. This potential problem can be minimized by generously debulking soft tissue from the auricle before the meatoplasty, thus decreasing the length of the membranous canal. Coverage of all exposed bone and soft tissue by the STSG is also essential to prevent granulation tissue formation and subsequent stricture. The use of the anteriorly based meatal skin flap to cover a portion of the anterior—lateral membranous canal obviates a circumferential STSG at the meatal opening and helps prevent stenosis. In addition to Kenalog injections, the application of mitomycin C has been suggested as a method to prevent or reduce excess fibrosis within the ear canal (38–40). Early results have been mixed. In a study from our laboratory, brief application of mitomycin C (0.5 mg/mL) to the middle ear of gerbils caused acute, adverse electrophysiologic changes and chronic hair cell, stria vascularis, and spiral ganglion cells damaged (41).

In some patients, the lateral canal may be narrowed by displacement of the pinna rather than by fibrous proliferation. Because the reconstructed auricle has more mass and less muscular and soft tissue support than the normal pinna, it can shift, usually anteriorly or inferiorly, after surgery. This shift causes a malalignment of the meatus and bony canal. If there is concern about proper alignment of the membranous and bony canals during the atresia surgery, a permanent suspension suture from the framework of the auricle to the mastoid periosteum or to a hole drilled in the mastoid cortex is placed.

Chronic Infection

Normal migration of keratin debris is lacking in the skin-grafted ear canal. Protective secretions from sebaceous and apocrine glands are also absent. As a consequence, the incidence of canal infections is higher than in the normal ear. A widely patent meatus and membranous canal are important for aeration and cleaning, which may be required once or twice annually. Most patients are not restricted with regard to water activities, although use of an alcohol- or acetic acid–based ear drop after swimming is often recommended.

Conductive Hearing Loss

Persistent or recurrent conductive hearing loss is the most common negative outcome in aural atresia surgery. The causes of the former are varied and include inadequate mobilization of the ossicular mass from the atretic bone, an unrecognized incudostapedial joint discontinuity, or a fixed stapes footplate. Wide exposure of the ossicular mass at surgery is necessary to ensure chain mobility and to facilitate assessment of chain integrity. Recurrence of a conductive hearing loss after an initial satisfactory improvement in air-conduction thresholds is usually secondary to refixation of the ossicular chain or to tympanic membrane lateralization. At least a 2- to 3-mm wide area of bone removal around the ossicular mass (except at the fossa incudis) is desirable, because bony regrowth can occur, especially as children enter puberty. In several male patients with initial excellent hearing results for 8 to 10 years, complete closure of the bony canal has been observed during their rapid growth spurt of adolescence. At revision surgery in these cases, the canal resembled a virgin atresia. Anchoring the fascia graft beneath a bony ledge and/or the use of a Silastic disc help minimize graft lateralization. The incidence of tympanic membrane perforation or middle ear adhesions approximates that encountered in routine tympanoplastic procedures.

Bone-Anchored Hearing Implant

A bone-anchored hearing aid is an alternative rehabilitative strategy for patients with unilateral or bilateral aural atresia, and especially for those patients who are marginal or poor surgical candidates. This approach uses an osseointegrated titanium fixture, placed in the mastoid area, to which a sound processor is attached. The osseointegration allows more efficient transfer of sound than can be achieved with a traditional bone-conduction hearing aid (42). As in patients with otosclerosis, this hearing aid option should be discussed in tandem with surgical

intervention. It is also important to acknowledge that the BAHA is often associated with soft tissue infection around the titanium post. Less commonly, skin overgrowth necessitating surgical revision of the implant site and failure to osseointegrate can occur (43).

Currently, the minimum age for BAHA implantation is 5 years per FDA guidelines. A "soft band" that holds an external BAHA sound processor firmly against the skull can be worn by infants. This device provides an alternative to the traditional bone-conduction hearing aid and should be considered in children born with bilateral aural atresia.

CONCLUSIONS

The objective in congenital ear surgery is to create a functional pathway by which sound can reach the cochlear fluids. Although simple in concept, this type of surgery presents a true challenge to the otologic surgeon. A thorough knowledge of the anatomic variations that can occur with abnormal development of the temporal bone is essential, and the nuances of audiometric and radiographic interpretation must be mastered.

Hearing results that are consistently excellent cannot yet be achieved in atresia surgery, but with adherence to strict selection criteria and with further refinements in surgical technique, this goal is realistic.

HIGHLIGHTS

- During the fifth to seventh month of embryogenesis, the solid core of epithelial cells representing the external auditory canal canalizes, beginning medially and progressing laterally. If incomplete, this process can result in a stenotic membranous canal laterally, with a more normal caliber bony canal and tympanic membrane medially. This condition predisposes to cholesteatoma formation within the ear canal.
- Congenital ear malformations can be classified as major or minor. The significant defect in the minor malformation group involves the middle ear, especially the ossicular chain. In most cases of microtia and atresia of the ear canal, the cochlear and vestibular labyrinths are normally formed.
- In major atresia cases, the stapes is usually small with misshapen crura. The footplate is usually intact and mobile.
- The facial nerve is often aberrant in major congenital ear malformations. Dehiscence of the tympanic segment with or without inferior displacement is often seen. The mastoid segment of the facial nerve often makes a more acute angle at the second genu, resulting in anterior and lateral displacement; it may obscure the round window.
- Bilateral congenital atresias can present a masking dilemma during audiometric testing. Bone-conduction auditory brainstem response can provide objective data on ear-specific cochlear function in these cases and help with operative selection.
- In cases of major atresia, the middle ear space should be greater than 50% of normal size, and all three ossicles, although deformed, should be visible.
- The principal landmarks in the anterior approach for aural atresia are the middle fossa dura superiorly, the TMJ anteriorly, and the mastoid air cells posteriorly.
- With proper patient selection in cases of major atresia, it is possible to achieve a hearing level of 25 dB or better in approximately 50% to 70% of patients.
- The most frequent complications in congenital atresia surgery are canal stenosis and failure to achieve an adequate hearing level. The latter can occur because of inadequate mobilization of the ossicular mass from the atretic bone, lateralization of the tympanic membrane graft, or refixation of the ossicular chain by bony regrowth or fibrous tissue.

Intratemporal and Intracranial Complications of Otitis Media

149

H. Alexander Arts *Meredith E. Adams*

Otitis media (OM) is a heterogeneous disease with a wide spectrum of presentations and natural histories. The etiology, presentation, natural history, and management of acute and chronic otitis media (AOM and COM) are discussed in detail in other chapters. In this chapter, we discuss the complications, both intratemporal and intracranial, of AOM and COM and cholesteatoma, and their management. These complications are summarized in Table 149.1.

AOM is a common infection, estimated to represent up to 5.8% of all patient visits to physicians (1,2). In the vast majority of cases, the pathologic process is self-limited, or resolves with antibiotic therapy. Indeed, although not universally agreed upon, some have recently considered observation alone for straightforward cases of AOM, with antibiotics reserved for refractory cases, or for prevention of complications in higher risk patients (3). AOM may resolve completely, resolve and recur, or evolve into one of many manifestations of COM. Complications of OM can occur directly from AOM or arise from COM. Although these complications are rare today, they occur in developed countries at approximately the same frequency as in underdeveloped countries, and are associated with high rates of serious morbidity and mortality (4). Prompt diagnosis and rapid, effective therapy are critical to minimizing these sequelae.

PATHOPHYSIOLOGY

Pathophysiology of OM

Both AOM and COM are bacterial infections involving the middle ear cleft. Risk factors can be complex and interrelated, but are primarily associated with (a) exposure to pathogens, (b) local anatomy, and (c) host response.

Exposure to pathogens can be increased or altered by exposure to day care environments, or crowded or unhygienic living situations. The specific microbiologic flora is strongly influenced by prior individual and community antibiotic treatment (5). Exposure to nasopharyngeal flora may be enhanced with patent eustachian tubes. In the case of COM, contamination by pathogens can occur via the external auditory canal via a tympanic membrane perforation or by direct contamination of debris within a cholesteatoma. The latter can be enhanced by exposure to water from swimming or bathing. Different pathogens have varying degrees of pathogenicity and disease progression. The bacteriology of OM is summarized in Table 149.2.

The primary anatomic variable affecting the development of OM is eustachian tube function. Eustachian tube function varies widely in otherwise normal individuals, but is reduced in patients with cleft palate, exposure to smoke (smokers and passive exposure), allergic rhinitis, neoplastic processes involving the cranial base, acromegaly, and many other conditions. Abnormally patent eustachian tubes result in reflux of nasopharyngeal contents into the middle ear. Mucosal disease such as nasal polyposis, ciliary dyskinesia, or cystic fibrosis results in reduced eustachian tube function. If a patient develops cholesteatoma, the local anatomy has a direct effect on how the cholesteatoma grows and what bony destruction it causes. The cholesteatoma and associated inflammation can then, in turn, directly or indirectly impact eustachian tube function.

Host response factors such as immunodeficiency, immunization status, ciliary dyskinesia, and history of bottle-feeding also play important roles in the development of OM.

Pathophysiology of Complications of OM

Similar factors influence the development of complications of OM, with the addition of many other variables. It is important to understand the anatomy in which these infections exist, their routes of spread, and the characteristic patterns of disease. Infection can spread via direct extension, via venous structures, or hematogenously. However, the primary pathogenesis seems to be a complex interaction between the specific organisms and the host (8).

TABLE 149.1 COMPLICATIONS OTITIS MEDIA

Intratemporal (extracranial)
- **Mastoiditis**
  - Acute
  - Coalescent
  - Chronic
  - "Masked"
  - Associated with subperiosteal abscess
  - Associated with deep neck abscess (Bezold abscess)
- **Petrositis**
- **Labyrinthitis**
  - Serous or toxic
  - Suppurative
    - Otogenic
    - Meningogenic
- **Facial paralysis**
- **Labyrinthine fistula**

Intracranial
- **Extradural granulation tissue or abscess**
- **Sigmoid sinus thrombophlebitis**
  - Occluding
  - Nonoccluding
- **Brain abscess**
- **Otitic hydrocephalus**
- **Meningitis**
- **Subdural abscess**

TABLE 149.2 BACTERIOLOGY OF OM (PATHOGENS LISTED IN ORDER OF PREVALENCE) (6,7)

Acute suppurative OM
- *Streptococcus pneumoniae*
- *Haemophilus influenza* (nontypeable)
- *Moraxella catarrhalis*
- Others (far less common)
  - Group A Streptoccoci
  - *Staphylococcus aureus* (infrequent)
  - Gram-negative bacilli (infrequent)

Acute mastoiditis
- *Streptococcus pneumonia*
- *Pseudomonas aeruginosa*
- Group A beta-hemolytic *Streptoccoci* (e.g., *Streptococcus pyogenes*)
- Coagulase-negative *Staphylococcus* sp.
- Others (far less common)
  - *Staphylococcus aureus*
  - *Proteus* sp.
  - *Bacteroides* sp.

Chronic otorrhea with or without cholesteatoma
- Mixed aerobic (also occasionally including *S. pneumonia*) and anaerobic organisms
  - Foul-smelling ears (especially with cholesteatoma) may grow 5–11 organisms, always mixed aerobic and anaerobic
- *Pseudomonas aeruginosa* (most common aerobe)
- *Staphylococcus aureus* and *Staphylococcus epidermidis*
- Other aerobic organisms including *Proteus* sp., *Klebsiella* sp., *Escherichia coli*
- Various anaerobic organisms including *Bacteroides fragilis*

Intracranial abscesses (brain and subdural) of otogenic origin (mixed cultures)
- *Streptococcus* sp.
- *Staphylococcus* sp.
- *Proteus* sp.
- Anaerobic organisms (*Peptococcus*, *Peptostreptococcus*, *Bacteroides fragilis*)

Bacterial meningitis in children
- *Streptococcus pneumonia*
- *Haemophilus influenzae*, type B
- *Neisseria meningitidis*

An important host response leading to complication is the production of tissue edema and granulation tissue that subsequently becomes obstructive to drainage and aeration. This creates an environment conducive to the growth of anaerobic organisms and the destruction of bone. Important microbiologic factors seem to pivot about the synergistic pathogenicity of anaerobic organisms (9).

The epidemiology and microbiologic behavior of the organisms found in complications offer some insight into the pathogenesis and pathophysiology of these complications (Table 149.2). For example, infections with *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis* are the most common causes of acute suppurative OM (3,10). Only about 4% of OM is caused by infection with *H. influenzae* type B; however, pediatric patients with OM occurring simultaneously with meningitis or other central nervous system infections were found to have an unusually high incidence of *H. influenzae* type B (10).

Uncomplicated chronic otorrhea characteristically cultures *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and a variety of other Gram-negative organisms, such as *Proteus* sp., *Klebsiella* sp., and *Escherichia coli*. In contrast, mastoiditis associated with chronic suppurative otitis media (CSOM) frequently has a fetid odor and often cultures positive for *Bacteroides fragilis* (6). Multiple organisms are found in 57% of chronically draining ears with cholesteatoma, with an average of three different organisms. However, if these ears have a fetid discharge, characteristically 5 to 11 organisms are found, always including both anaerobes and aerobes. Malodorous discharge is a significant early sign of complication. Anaerobic organisms are a major cause of foul-smelling discharge.

β-Lactamase-producing organisms, such as *S. aureus*, *H. influenzae*, *B. catarrhalis*, and *Bacteroides* sp., not only survive β-lactam antibiotics but may also protect other potentially penicillin-susceptible pathogens from penicillin and other β-lactam antibiotics. Anaerobic organisms have recently been shown to play major roles in pathogenic synergism by protecting against host defenses, creating suitable environments for other organisms, and inactivating antibiotics (8,9).

Anatomic variables are tremendously important in the development of complications. Eustachian tube function plays a critical role in not only the development of the original infection and its resolution but also the development of complications. The mucosal edema resulting from OM itself impairs eustachian tube function and inhibits resolution of the infection. Highly variable factors, such as the integrity of bone over the facial nerve or dura, influence access of the infection and its products to neurovascular structures and the intracranial space. Numerous venous channels traverse the bone between the mastoid and middle ear and the dural venous sinuses, sometimes associated with arachnoid granulations. Inflammation adjacent to these veins and venules can promote thrombosis. Thrombi and infection can then propagate to the dural venous sinuses and subarachnoid space. Cholesteatoma often results in patterns of bone destruction exposing the dura or facial nerve to the infectious process. Finally, prior surgery can result in areas of entrapped squamous epithelium or deficient areas of bone that act as sources of infection and routes for the infection to spread.

GENERAL PATTERNS OF PRESENTATION

Complications of OM tend to present in predictable patterns (Table 149.3). With the exception of meningitis in children and some cases of facial paralysis, which are usually associated with AOM, most complications tend to be associated with COM. Typically, mastoiditis is the initial complication, with more severe complications developing secondarily. Petrositis (petrous apicitis), for example, almost never occurs without preceding mastoiditis. Labyrinthine fistulae virtually always develop secondary to cholesteatoma. Granulation tissue in air cells adjacent to the sigmoid sinus can result in erosion of the bone overlying the sinus, with resultant sigmoid sinus exposure and possible sigmoid sinus thrombophlebitis. If the sigmoid becomes obstructed with thrombus, intracranial hypertension, that is, otitic hydrocephalus, can result (11). Retrograde thrombophlebitis may extend intracerebrally, resulting in a brain abscess. Subdural empyema rarely occurs due to COM, but is a more typical complication of meningitis in infants.

Without a high index of suspicion, early evidence of an impending complication will be missed. Early symptoms and signs of complication are summarized in Table 149.4. Because antibiotic therapy may have a masking effect on the significant signs and symptoms of complications, a high level of clinical awareness is important for early diagnosis. Persistence of acute symptoms for 2 weeks or more or recurrence of symptoms or infection within 2 weeks is often the first sign of a potential complication. In chronically draining ears, acute exacerbation of pain or the new development of fetid drainage should be evaluated. Foul-smelling drainage that fails to respond to conservative treatment (debridement and topical antibiotics) portends an impending complication.

Once a complication has begun, signs and symptoms typically progress rapidly. Fever associated with COM

TABLE 149.3 PATTERNS OF PRESENTATION OF COMPLICATIONS OF OM

Origin of complication
- Acute infection
  - Meningitis—infants and young children
  - Meningitis—adults or children with occult CSF leaks
  - Facial paralysis—children more commonly
  - Labyrinthitis
- Subdural abscess—infants more commonly
- Subacute or chronic infection
  - Mastoiditis
  - Petrositis
  - Facial paralysis
  - Labyrinthitis
  - Extradural abscess and granulations
  - Sigmoid sinus thrombophlebitis
  - Brain abscess
  - Otitic hydrocephalus
  - Meningitis
  - Subdural abscess

Patterns of associated diseases and usual sequence
- Mastoiditis or petrositis
  - Extradural granulation tissue and/or abscess
  - Sigmoid sinus thrombophlebitis
  - Brain abscess or otitic hydrocephalus
- Meningitis
  - Subdural abscess—infants more commonly

TABLE 149.4 EARLY SIGNS AND SYMPTOMS OF COMPLICATIONS

Impending complication
- Persistence of acute infection for 2 weeks or more
- Recurrence of symptoms within 2 weeks after initial resolution
- Acute exacerbation of chronic infection, especially if foul-smelling
- Foul-smelling discharge during treatment
- *Haemophilus influenza* type B or anaerobes

Complication (associated complication)
- Fever associated with a chronic perforation (intracranial infection or extracranial cellulitis)
- Pinna displaced inferolaterally and/or edema of the posterosuperior ear canal wall skin (subperiosteal abscess)
- Retro-orbital pain (petrositis)
- Vertigo in a patient with an infected ear (labyrinthitis or labyrinthine fistula)
- Facial paralysis ipsilateral to an infected ear (facial paralysis)
- Headache and lethargy (intracranial complication of any sort)
- Meningismus (meningitis or subdural abscess)
- Focal neurologic signs or seizure (brain abscess)
- Global neurologic signs (subdural abscess or meningitis)

implies some degree of extracranial cellulitis or intracranial infection. Postauricular edema/erythema, edema of the posterior-superior external auditory canal (EAC) wall, or anterolateral displacement of the pinna indicates mastoiditis associated with subperiosteal abscess. Retro-orbital pain in an infected ear is highly suggestive of petrositis (petrous apicitis). Vertigo and nystagmus in a patient with OM may indicate serous or suppurative labyrinthitis, or possibly a labyrinthine fistula. Facial paralysis ipsilateral to an infected ear may complicate AOM, or COM with cholesteatoma. Papilledema is an obvious sign of elevated intracranial pressure, but will go undetected without a fundoscopic examination. Headache and lethargy usually accompany an intracranial infectious complication. Meningismus is associated with meningitis, and focal neurologic signs or seizures are seen in brain abscess.

SPECIFIC COMPLICATIONS

Intratemporal (Extracranial) Complications

Mastoiditis

As commonly used clinically, the term "mastoiditis" is nonspecific and often misleading. Since the mastoid air cell system is confluent with the middle ear space, any inflammatory process within the middle ear will also involve the mastoid. Although it may be pathologically correct to refer to purulent fluid within the mastoid secondary to OM as "mastoiditis," it is not clinically meaningful or helpful, and does not represent a complication of OM. An example of this clinically misleading use of the term "mastoiditis" is the radiologic diagnosis of "mastoiditis" based on the presence of opacification or increased T2 signal intensity alone. This does not imply a complication and does not require additional therapy beyond that indicated for the primary middle ear process. True mastoiditis as a complication of OM implies an invasive or persistent infection involving the mastoid bone and/or surrounding structures, distinct from AOM or OM with effusion. With this in mind, mastoiditis can be subdivided into (a) acute mastoiditis, (b) coalescent mastoiditis, (c) chronic mastoiditis, and (d) masked mastoiditis. Clinically, there is often some overlap between these diagnostic categories.

Acute Mastoiditis

Acute mastoiditis is diagnosed in the presence of postauricular pain, tenderness, erythema, swelling, and/or auricular protrusion, with or without evidence of AOM. Acute mastoiditis is most commonly seen in young children 2 to 6 days following the onset of AOM. Due to partial treatment with antibiotics, signs and symptoms may be much less obvious: antibiotic therapy obscuring the presentation but not the complication. Some authors insist on the presence of AOM for a diagnosis of acute mastoiditis; however, attic blockage may preclude otoscopic visualization (12). Most authors recommend treatment with parenteral antibiotics, with or without simple mastoidectomy. When treated with parenteral antibiotics alone, up to one-third of patients will require mastoidectomy for failure to improve or complications (13). The most common complication is subperiosteal abscess. Other complications of acute mastoiditis include coalescent mastoiditis, facial paralysis, meningitis, and Bezold abscess. Antibiotic treatment of routine AOM has been shown to be associated with a lower incidence of acute mastoiditis (14).

Coalescent Mastoiditis

Coalescent mastoiditis implies breakdown and decalcification of the bony septa within the mastoid, progressing to bony destruction of the cortex or other aspects of the mastoid bone. Coalescent mastoiditis is what is commonly and classically referred to as "mastoiditis." This infection typically affects boys, 4 years or younger, who have previously well-aerated mastoids and little or no prior history of OM. Coalescence rarely, if ever, occurs in the setting of COM. Patients typically present with fever, otalgia, purulent otorrhea, and mastoid pain, tenderness, erythema, and/or edema. Typically, it occurs in patients who have had persistent otorrhea or otalgia for 2 weeks or more following AOM, or when these symptoms recur 10 to 14 days following AOM. Up to 25% of patients presenting with coalescent mastoiditis will have a concomitant intracranial complication. *S. pneumoniae* is the most common offending organism (15). Of those with a simultaneous intracranial complication, nearly 30% will culture positive for anaerobic organisms as well.

Diagnosis. The diagnosis is confirmed by CT imaging, demonstrating breakdown of bony septa, loss of cortical bone, and opacification of the air cell system. MR imaging should be obtained if there is any suspicion of intracranial complication.

Treatment. Treatment of coalescent mastoiditis consists of myringotomy and intravenous antibiotics, with or without simple mastoidectomy. If mastoidectomy is not performed, intravenous antibiotics should be continued for a minimum of 3 to 6 weeks. Mastoidectomy almost always results in prompt resolution of the infection and its symptoms, and is the safest and most conservative approach.

Chronic Mastoiditis

As used clinically, chronic mastoiditis is a broad term and implies chronic inflammation within the mastoid air cell system. It can occur in typical COM with tympanic membrane perforation, and results in mucosal disease and/or granulation tissue that causes otorrhea to persist in spite of antibiotic therapy. Likewise, persistent mastoid mucosal disease or granulation tissue can be a cause of tympanostomy tube otorrhea refractory to antibiotics. Mastoidectomy in either of these settings can be helpful in eradicating otorrhea. Long-term chronic mastoiditis usually results in

sclerosis of the mastoid air cell system, commonly seen in CSOM. A key element in the differential diagnosis of chronic mastoiditis can be skull base osteomyelitis, otherwise known as malignant otitis externa. Malignant otitis externa is classically seen in diabetics or renal failure patients. It usually presents with a several month history of otalgia with or without otorrhea or chronic otitis externa. Focal osteomyelitis is seen adjacent to granulation tissue in the external auditory canal. CT imaging demonstrates bone destruction in the area of osteomyelitis. This topic is discussed more fully elsewhere in this text.

"Masked" Mastoiditis

This term is sometimes applied to the rare situation where granulation or mucosal disease involves some mastoid air cells when there is a normal tympanic membrane and an otherwise aerated middle ear and mastoid air cell system. Other areas of infection and inflammation respond to topical and systemic antibiotics; however, this localized area does not. Osteitis and bone erosion can occur locally at the site of the disease. Patients with masked mastoiditis have chronic mild or moderate postauricular pain and mild postauricular tenderness.

Bezold Abscess

A neck abscess secondary to mastoiditis is called a Bezold abscess. These are, typically in the upper neck, just deep to the sternocleidomastoid muscle. They occur by extension of an infection in the mastoid tip, by osteitis, bone destruction, and direct extension, or without bone erosion by venous propagation. A neck abscess can also occur by suppurated lymph nodes related to mastoid pathology, which is not a true Bezold abscess. Treatment involves surgical drainage of the neck abscess, appropriate surgical management of the temporal bone pathology, and parenteral antibiotics.

Petrositis (Petrous Apicitis)

Petrositis or petrous apicitis is, as the name implies, an infection of the apex of the petrous portion of the temporal bone and is exceptionally rare. The petrous apex is contiguous with the middle ear space, and may be aerated, sclerotic, or consist of diploic bone. Infection occurs in the petrous apex by direct extension from the middle ear and, like in the mastoid, can consist of mucosal disease, granulation tissue, purulence, or coalescence. Petrous apicitis may be associated with any of the other complications of OM. Due to its location, extension of infection from the apex may also result in cavernous sinus thrombophlebitis.

Petrous apicitis typically presents with deep, retro-orbital pain in the setting of COM. The classic triad originally described by Gradenigo consists of retro-orbital pain, otorrhea, and abducens palsy, although abducens palsy is rarely seen (16). Other manifestations can include facial paralysis, and sensory hearing loss and vertigo due to labyrinthitis.

CT imaging, with or without MR imaging, defines the nature and location of the disease (17). Treatment consists of parenteral antibiotics and surgical drainage (18). Surgical access to the petrous apex is difficult, and the route taken depends on the highly variable nature of temporal bone anatomy. Depending on the specific anatomy, access to the petrous apex may be obtained via the retrolabyrinthine, infracochlear, or subarcuate air cell tracts. In some cases, it may be necessary to perform a canal wall down mastoidectomy or possibly a middle cranial fossa approach to access this area (19).

Labyrinthine Fistula

Labyrinthine fistula consists of the erosive loss of otic capsule bone with exposure of the interior of the labyrinth (20). These fistulae occur almost exclusively secondary to cholesteatoma. The matrix of the cholesteatoma covers the exposed perilymphatic space; therefore, there is no leakage of perilymph as seen in perilymphatic fistulae. Labyrinthine fistulae from cholesteatoma most commonly involve the horizontal semicircular canal, but can involve any of the canals, the vestibule, the cochlea, or even the internal auditory canal (21). In addition to the bone of the labyrinth, cholesteatoma can erode any bone to which it comes in contact, commonly including the fallopian canal and the tegmen tympani. The mechanism of bone erosion due to cholesteatoma is the subject of considerable investigation and is discussed in other chapters of this text.

Labyrinthine fistula is frequently asymptomatic and only discovered on CT imaging or at surgery. Whenever CT demonstrates a labyrinthine fistula preoperatively, erosion of the fallopian canal or tegmen tympani should also be considered. If symptoms are present, they consist of vertigo with Valsalva or straining, motion- or position-provoked vertigo, Tullio phenomenon (vertigo secondary to auditory stimuli), vertigo with manipulation of the auricle or EAC, and varying degrees of hearing loss. Fistulae are usually clearly delineated on CT, which should always be obtained preoperatively when fistula is a consideration.

Proper management of the underlying cholesteatoma is the basis of treatment of labyrinthine fistula and is discussed elsewhere in this text (20,22,23). In brief, the matrix of the cholesteatoma can be left over the fistula when the cholesteatoma is being exteriorized. If the cholesteatoma is being removed, the matrix must be very carefully dissected from the fistula and the fistula covered with a soft tissue graft. Risks of vestibular dysfunction and hearing loss in this setting are significant. Successful management of labyrinthine fistula usually improves vestibular symptoms.

Facial Nerve Paralysis

After mastoiditis, facial nerve paralysis is the second most common complication of AOM. Less commonly, facial paralysis presents as a complication of COM—virtually always due to cholesteatoma. In either of these settings, the facial paralysis is secondary to neurapraxia. In AOM,

this is due to inflammation and edema from the adjacent infection. In COM with cholesteatoma, this is usually due to compression by the cholesteatoma, with or without local inflammation. Facial paralysis can also be associated with coalescent mastoiditis, "masked" mastoiditis, or petrous apicitis.

AOM typically involves the facial nerve in its tympanic segment. Although there is no study clearly demonstrating this, it is thought that most cases of facial paralysis with AOM have dehiscent fallopian canals in the tympanic segment, which is a common finding in otherwise normal temporal bones. When facial paralysis occurs due to cholesteatoma, the site of lesion depends on the anatomy of the cholesteatoma. Most commonly, the nerve is compressed in the tympanic segment, due to bone erosion by the cholesteatoma. Other sites of injury include the geniculate ganglion region (anterior epitympanic cholesteatoma), the mastoid segment (facial recess/sinus tympani/retrofacial cholesteatoma), or the internal auditory canal (superior perilabyrinthine cholesteatoma). Cholesteatoma may not be immediately recognized as the cause of cholesteatoma in these more unusual locations.

Evaluation of facial paralysis associated with OM usually involves directed imaging. Except perhaps in very straightforward cases of facial weakness associated with AOM, dedicated temporal bone CT imaging is very useful and will likely demonstrate the pathology and site of lesion. MR imaging is helpful if lesions other than cholesteatoma are considered. Electrophysiologic facial nerve testing is sometimes useful. Electromyography (EMG), either evoked (electroneuronography) or spontaneous (standard EMG), can be helpful in predicting prognosis for recovery in some cases. This topic is fully discussed elsewhere in this text.

Management of facial paralysis associated with OM consists of aggressive treatment of the underlying OM (24). In AOM, myringotomy with cultures of the aspirate, and parenteral antibiotics are indicated. For facial paralysis due to COM with cholesteatoma, topical and systemic antibiotics followed by surgical management of the cholesteatoma are appropriate. Systemic steroid therapy is probably helpful to reduce inflammation and edema in the acute phases of facial paralysis for any type of OM. Surgical decompression of the fallopian canal, proximal and distal to the site of injury is advocated by some, and may be helpful in selected cases.

Labyrinthitis

Serous or Toxic

Serous labyrinthitis is thought to be due to alteration of the inner ear tissue fluid environment due to bacterial toxins (25). Bacterial toxins are presumed to enter the inner ear via the round or oval window, or via a labyrinthine fistula. Variable degrees of vertigo and sensory hearing loss can result. Treatment with appropriate antibiotics and steroids is probably helpful. Recovery of hearing and vestibular function is possible in serous labyrinthitis. Endolymphatic hydrops can be seen pathologically associated with serous labyrinthitis.

Suppurative

Otogenic suppurative labyrinthitis consists of bacterial invasion of the inner ear from a suppurative process within the middle ear (25). This acute suppurative process results in rapid destruction of inner ear contents, with associated severe vertigo and sensory hearing loss. In the early phases, it is not possible to discern serous from suppurative labyrinthitis—subsequent recovery of hearing and/or vestibular function indicates that the process was serous in nature. Treatment consists of parenteral antibiotics (choose drugs with good cerebrospinal fluid penetration) and timely surgical intervention aimed at preventing additional extracranial or intracranial complications.

A particular concern with suppurative labyrinthitis is the development of meningitis. A suppurative process within the labyrinth can gain access to the subarachnoid space via the fundus of the cochlea or the cochlear aqueduct. Indeed, otogenic sources are thought to be a common etiology of bacterial meningitis in childhood. Conversely, suppurative meningitis may extend into the labyrinth and result in a secondary suppurative (meningogenic) labyrinthitis. In either direction, this phenomenon underlies the frequent association between meningitis and hearing loss. Ossification of the labyrinth (labyrinthitis ossificans) is frequently seen following suppurative labyrinthitis, particularly due to *S. pneumoniae*, and can complicate cochlear implantation (26). Early evaluation of hearing following meningitis and early cochlear implantation when appropriate can result in substantially better outcomes for patients with postmeningitic deafness.

Intracranial Complications

Meningitis

Bacterial meningitis presents with severe generalized headache, fever, nausea/vomiting, photophobia, and varying levels of altered mental status (ranging from irritability to unconsciousness). Patients may develop nuchal rigidity, characterized by pain and limitation of neck flexion. With progression of disease, papilledema and abnormal reflexes may develop, including Kernig sign (inability to completely extend the knee when the leg is flexed at the hip) and Brudzinski sign (passive neck forward flexion leads to active flexion of the hip and knee).

The clinician evaluating a patient with meningitis should attempt to identify the route of spread to the meninges and the organism involved. All patients with meningeal signs should undergo otoscopic examination to rule out AOM and CSOM. Most cases of otogenic meningitis in children result from hematogenous dissemination of invasive organisms during AOM (most commonly *S. pneumoniae*) (27). Of note, the introduction of routine vaccination against

S. pneumoniae and *H. influenzae* type B has decreased the rate of meningitis secondary to these common causative agents—recent reports suggest that brain abscess may supplant meningitis as the most common intracranial complication of OM (28). The presence of otitic meningitis, particularly if recurrent, should raise suspicion for an abnormal route of communication from the middle ear and mastoid to the CSF. The rapid onset of meningitis with AOM in a child with sensorineural hearing loss may indicate the presence of an inner ear malformation that allows communication through the oval or round windows to the vestibule, cochlea, and internal auditory canal. Accordingly, temporal bone imaging may reveal Mondini malformation, enlarged vestibular aqueduct, common cavity malformation, or congenital stapes footplate fixation. Similarly, AOM can lead to rapid onset of meningitis in patients with CSF leaks associated with tegmen dehiscences (congenital or iatrogenic), meningoencephaloceles through the middle or posterior fossae, or through a patent tympanomeningeal fissure (29). Bacterial contamination of the CSF may also occur with AOM following surgical or traumatic dural injury, stapes subluxation, or cochlear implantation (30). Patients with meningitis associated with CSOM should be suspected of having bacterial extension of infecting organisms directly through the dura. Additionally, it is possible for bacteria to enter the meninges through the labyrinth by a cholesteatoma-induced fistula.

Lumbar puncture (LP) is performed to confirm the clinical diagnosis and identify the causative organism. CT or MRI should be obtained first to identify findings suggestive of increased intracranial pressure that might predispose to herniation with LP as well as to rule out intracranial abscess, subdural empyema, or cerebritis. Meningitis typically leads to elevation of the opening pressure, and the CSF has high protein, low glucose, and an increased white blood cell content leading to a cloudy appearance. The CSF should be sent for Gram stain and culture. As cultures from the CSF and middle ear may differ, samples should also be taken at the time of myringotomy to assist in selection of antibiotic therapy. High-resolution CT of the temporal bone will delineate bony architecture and reveal inner ear malformations, tegmen defects, and destructive lesions. MRI should be obtained in all cases to identify additional intracranial complications.

Acute bacterial meningitis associated with AOM is treated with myringotomy (wide-field or with PE tube placement to maintain drainage) and intravenous antibiotics. A third-generation cephalosporin and vancomycin should be instituted empirically while awaiting culture results that will direct further therapy (31). Despite effective antibiotic treatment, about one-third of meningitis survivors suffer neurologic sequelae such as deafness, behavioral disorders, and cognitive dysfunction (32). Dexamethasone, started with or before the first dose of antibiotics, has been shown to significantly reduce the rates of death and hearing loss in patients with pneumococcal meningitis, without interfering with antimicrobial treatment (33). While most cases do not require further surgery, inner ear malformations (Mondini) and clear sources of CSF leakage (meningoencephalocele) require repair at the conclusion of meningitis treatment to prevent further infection. Continuation of antibiotics in the perioperative period is wise in these instances.

When meningitis results from subacute or CSOM, the ear disease needs to be surgically managed. Direct disease extension into the meninges has often occurred and it is important to expose the diseased dura, remove excess dural granulation tissue, and inspect for dural defects or occult abscesses. The timing of the mastoid operation is dictated by the patient's neurologic and physiologic condition, and is generally performed once the patient is deemed stable to undergo surgery.

Extradural (Epidural) Granulation Tissue or Abscess

Granulation tissue and abscess may form between the temporal bone and adjacent dura when acute coalescent infection or chronic otitis with or without cholesteatoma erode surrounding bone. Pockets of infection then expand along the face of the posterior or middle fossae. Epidural granulation tissue and abscesses may present with headache and fever, but are often clinically silent until large (34). Contrast-enhanced CT may reveal erosion of the sigmoid plate or tegmen and, in cases of larger extradural abscesses, a rim-enhancing lentiform epidural fluid collection. Enhanced MRI is superior to CT in demonstrating small intracranial suppurative lesions. An epidural abscess appears as a crescentic fluid collection that is mildly hyperintense relative to CSF on T1-weighted images and isointense to CSF on T2-weighted images (35). Epidural abscess is often a precursor to other complications that can be identified with MRI including lateral sinus thrombophlebitis and brain abscess.

Management of extradural granulation tissue and abscess begins with intraoperative identification. Extradural abscesses may be missed unless care is taken to observe the dura of the middle and posterior fossae through thin bone. The mastoidectomy should be extended to allow for careful inspection of the dura of the tegmen tympani, tegmen mastoideum, sigmoid sinus, and posterior fossa bone medial to Trautmann triangle. Bone overlying abnormal dura should be removed until normal dura is encountered. Granulation tissue may be carefully removed with a blunt elevator, scraping parallel to the plane of the dura. A portion of granulation tissue may be left behind to avoid dural penetration and CSF contamination. If an abscess is identified, exposure via removal of the overlying bone suffices for drainage.

Brain Abscess

Otogenic brain abscesses may arise from AOM or COM. Cholesteatoma has supplanted AOM as the cause of most cases (36). The infection is typically polymicrobial with

a relatively high proportion of anaerobes (37). Venous thrombophlebitis allows bacteria to spread from the mastoid to the brain parenchyma.

A brain abscess has four clinical stages (38). The first stage is invasion (initial cerebritis), during which the destructive brain infection may present with a low-grade fever, malaise, drowsiness, loss of ability to concentrate, and headache. These symptoms are subtle and frequently overlooked and may spontaneously resolve after several days. The second stage, localization (latent or quiescent abscess), when the tissue becomes necrotic and edematous, may be clinically silent and last for weeks. During the third stage, enlargement (manifest abscess), an actual abscess forms in the region of the previous cerebritis. Patients may present with high fever, headache, focal neurologic symptoms, or loss of consciousness. Abscesses of the temporal lobe may present with seizures, visual field deficits, and hemiparesis. Cerebellar abscesses may present with vertigo, nystagmus, ataxia, and dysmetria. In the fourth stage, termination (rupture of the abscess), the abscess capsule ruptures into the ventricle or into the subarachnoid space. This results in a rapidly progressive, frequently fatal, outcome.

Diagnosing a brain abscess at an early stage may be difficult and calls for a high level of clinical suspicion when confronted with signs of a possible impending complication (Table 149.4). CT and MRI with gadolinium will identify a hypointense center with a hyperintense capsule about a formed abscess. MRI offers additional precision in identifying extraparenchymal (intraventricular or subarachnoid) spread. Diffusion-weighted MR imaging may be used for abscess surveillance and to distinguish abscesses from ring-enhancing malignancies (39). Since brain abscesses can take several weeks to manifest, even if an initial MRI is negative, repeat scanning should be considered in 2 to 3 week intervals if the index of suspicion remains high.

Management of a brain abscess requires immediate broad-spectrum parenteral antimicrobial therapy and neurosurgical consultation. If surgical treatment of the brain abscess is recommended, it takes priority over management of the otologic disease. A surgical approach to treat the ear disease can be undertaken once neurologic stability has been achieved with antibiotics, aspiration, open drainage, or abscess excision.

Subdural Empyema

Subdural empyema is a purulent infection that has formed between the dura and the pia–arachnoid membranes. The subdural space may be seeded via venous channels or infection in adjacent bone or brain. It is the rarest complication of OM. Because of the mass effect and the close proximity to the cerebral cortex, symptoms progress rapidly and patients present with severe headache, marked focal neurologic deficits, seizures, and loss of consciousness. Meningeal signs are pronounced.

CT with intravenous contrast may miss early subdural abscesses but can detect larger lesions as hypodense extracerebral collections with an enhancing medial border. Contrast-enhanced MRI is more sensitive and may readily demarcate the enhancing rim and extension of infection (40). Lumbar puncture may precipitate herniation in this setting and should be avoided if the lesion is detected by imaging first.

Subdural empyema is a neurosurgical emergency. Treatment of subdural abscess requires emergent drainage and the institution of parenteral antibiotics. Treatment of the associated ear disease is accomplished after neurologic stabilization.

Sigmoid Sinus Thrombophlebitis

Sinus thrombophlebitis may develop when overlying coalescent infection, granulation tissue, or cholesteatoma incites sinus wall inflammation. The sigmoid sinus is most susceptible because of its prominent location adjacent to the mastoid air cells. Retrograde thrombosis of cerebral veins (Labbé) and sinuses (transverse, sagittal, petrosal, and cavernous) may result in dangerous degrees of intracranial hypertension, brain abscess, infarct, and death (41). The thrombus may propagate to the internal jugular vein and jugular bulb, generating septic emboli and/or a jugular foramen syndrome. While AOM remains a common inciting factor in children, COM with cholesteatoma is an increasingly frequent cause in adults and older pediatric populations. Prothrombotic factors, including elevated levels of lipoprotein apolipoprotein, antibodies to beta 2-glycoprotein and cardiolipin, and heterozygosity for factor V Leiden mutation, may predispose patients to sigmoid sinus thrombophlebitis during AOM (42).

Modern antibiotic therapy has decreased the incidence of sigmoid sinus thrombosis (43) and altered the typical clinical presentation. In regions and circumstances in which AOM and COM go untreated, sigmoid sinus thrombosis may present with the rapid onset of prominent otologic symptoms (otorrhea, otalgia, postauricular pain/erythema), severe headache, torticollis, and the classic high-spiking "picket fence" fever of sepsis with leukocytosis (44–46). When there is greater access to care, patients often have a history of AOM or COM that was treated with antibiotics in preceding weeks and may have only mild symptoms. Headache and unilateral neck pain are still common, but fevers may be low grade and leukocytosis may be absent. The symptom duration is longer (often more than 2 weeks) and neurologic symptoms are more prevalent, including diplopia from CN VI palsy and symptoms of intracranial hypertension (headache, nausea, neck stiffness, photophobia, dizziness/ataxia) (46,47). Nevertheless, the otoscopic examination is usually abnormal, revealing AOM, effusion, retraction, or signs of COM. Recent series demonstrate that bacteriology may diverge from beta-hemolytic *Streptococcus* and *S. pneumoniae* to include mixed infections with *Pseudomonas*, *Staphylococcus*, (including MRSA), *H. influenza*, *Klebsiella*, *Enterococcus*, *Proteus*, and anaerobes (46,48,49).

After a careful otologic examination, the diagnosis is confirmed with imaging studies. Head and temporal bone CT, with contrast, will reveal associated pathology in the mastoid and perisinus enhancement. The enhancement of the triangular sinus wall around nonenhancing intraluminal thrombus produces the pathognomonic "delta sign" in up to one-third of cases (49). MRI with MRV/MRA is more sensitive in detecting sigmoid sinus thrombosis and delineates the extent of the thrombus and the integrity of collateral circulation while also identifying other intracranial complications (49).

The treatment of lateral sinus thrombophlebitis entails prompt initiation of broad-spectrum antibiotics combined with surgery. A wide myringotomy is performed or a pressure equalization tube is placed. Mastoidectomy is performed to expose the inflamed sinus wall and diseased dura and to remove excess granulation tissue. Subperiosteal and epidural abscesses can be treated concomitantly. The opinions of experienced surgeons differ over the extent of additional surgery that is necessary, ranging from none to sinus resection (49). The bone over the sinus and surrounding dura may be removed and the sinus may be carefully aspirated to detect free blood flow. Venotomy may be performed for the evacuation of infected thrombus or intraluminal abscess. Some have advocated Fogarty catheter thrombectomy be used with caution to reestablish flow, after gaining control of the internal jugular (IJ) vein in the neck. The authors consider this unwise due to the potential of releasing emboli and rupturing the sinus intracranially. Ligation of the IJ may be considered in the presence of septic emboli. Recanalization has been observed in patients receiving a range of treatments, from nonsurgical medical management, mastoidectomy, and venotomy with or without thrombectomy. Currently, there is no clear evidence that a given treatment approach is superior to another in its ability to reduce recovery time and increase the likelihood of recanalization (50).

The use of anticoagulation to prevent thrombus propagation is also a matter of debate. It is unlikely to be of benefit when the thrombus is isolated to the sigmoid sinus, but it should be considered in patients with imaging evidence of thrombus progression or extension to additional sinuses, neurologic changes, embolic events, or persistent fevers despite surgical intervention (51). The risk of bleeding can be significant, particularly in the pediatric population. Thrombolytics are not recommended as they may dislodge septic emboli in infected vessel walls.

Otitic Hydrocephalus

Otitic hydrocephalus is defined as increased intracranial pressure without ventricular dilatation, meningitis, or intracranial abscess in patients with acute or chronic middle ear infection. Increased intracranial pressure may manifest with headache, nausea and vomiting, papilledema, and diplopia from ipsilateral abducens nerve (cranial nerve VI) palsy.

The etiology of otitic hydrocephalus is hypothesized to be diminished CSF resorption by arachnoid granulations secondary to thrombosis in a dominant lateral dural venous sinus (50,52). Modern imaging has demonstrated that sagittal sinus thrombosis is not a necessary precursor, but inadequate cross-communication at the torcula with occlusion of the dominant outflow tract may impair venous drainage sufficiently to raise intracranial pressure (47,52).

MRI with MRV readily identifies lateral sinus thrombosis with total occlusion. If lumbar puncture is deemed safe based on central imaging, opening pressure will be elevated, but CSF studies will reveal normal biochemistry and cytology. Patients should undergo neuro-opthalmologic examination.

Treatment of otitic hydrocephalus requires mastoidectomy appropriate for the disease, exposure of all diseased dura to normal dura, and removal of excess extradural granulation tissue. Management of sigmoid sinus thrombophlebitis is discussed above. The treatment additionally involves medically lowering intracranial hypertension and careful monitoring for reductions in visual fields and visual acuity. Initial therapy may include corticosteroids, acetazolamide, mannitol, furosemide, and/or repeat lumbar puncture. As resolution of symptoms is observed in patients even in the setting of persistent lateral sinus thrombosis, recovery from otitic hydrocephalus is purported to be secondary to development of compensatory collateral venous drainage (50,52). Thus, management often extends for months beyond the initial surgical approach to the sinus and ventriculoperitoneal shunts may be necessary to reduce intracranial hypertension on a long-term basis. Failure of these measures to reverse progressive visual deterioration necessitates fenestration of the optic nerve sheath (53).

HIGHLIGHTS

- Intratemporal (extracranial) complications of OM include
  - Mastoiditis (acute, coalescent, chronic, or "masked")
    - With or without subperiosteal abscess or Bezold abscess
  - Petrositis
  - Labyrinthitis
  - Facial paralysis
  - Labyrinthine fistula
- Intracranial complications of OM include
  - Extradural granulation tissue and/or abscess
  - Sigmoid sinus thrombophlebitis
  - Brain abscess
  - Otitic hydrocephalus
  - Meningitis
  - Subdural abscess

- Important clinical signs of impending complications include the persistence or recurrence of acute infection within 2 weeks of treatment, or the persistence of foul-smelling discharge despite treatment.
- Persistent low-intensity pain of 1 week's duration during specific antibiotic treatment for suppurative OM suggests the diagnosis of "masked mastoiditis."
- Retro-orbital pain during ear infection, a key sign of petrositis, is not always volunteered in the patient's history and must be specifically elicited.
- Extradural granulation tissue over the sigmoid sinus is predictable in mastoiditis and the key to three additional intracranial complications (sigmoid sinus thrombophlebitis, brain abscess, and otitic hydrocephalus).
- Anaerobic organisms are frequently found in masked mastoiditis or mastoiditis with subperiosteal abscess and are not found in AOM.
- The organism associated with AOM that most frequently causes meningitis is *S. pneumoniae*.
- *Streptococcus faecalis*, *Proteus* sp., and *B. fragilis* are the organisms most frequently found in brain abscesses.
- *Pseudomonas aeruginosa*, *Bacteroides* sp., and anaerobic streptococci are most commonly found in association with cholesteatoma.
- The absence of, or resolution of, a subperiosteal abscess may allow a serious intracranial complication to develop because of an unrecognized and undertreated mastoiditis.
- Proper surgical care of most intracranial and intratemporal complications requires visualization through thin bone or actual exposure of the dura of the middle cranial fossa and sigmoid sinus. Failure to do this can result in misdiagnosis and undertreatment of serous intracranial complications.
- A call to see a patient with peripheral vertigo, nystagmus, and hearing loss is a true emergency until it is established that the middle ear is normal.

150 Middle Ear and Temporal Bone Trauma

Rodney C. Diaz *Sally M. Kamal* *Hilary A. Brodie*

Temporal bone trauma can result in significant morbidity and, rarely, mortality. The temporal bone houses or encapsulates many important structures, all of which are at risk of injury with trauma to the temporal bone; these include the facial nerve, vestibulocochlear nerve, cochlea and labyrinth, ossicular chain, tympanic membrane, external auditory canal, temporomandibular joint, lower cranial nerves, jugular vein, and carotid artery. Damage to each anatomic structure can lead to distinctive long- and short-term sequelae.

Adjacent intracranial structures such as the temporal lobe and meninges, abducens nerve, and brainstem may also be injured with temporal bone fracture. Fracture of the temporal bone can expose intracranial contents to the external world, resulting in cerebrospinal fluid (CSF) fistula, meningitis, and brain herniation.

In addition to inducing neurotologic manifestations by direct injury to these structures, temporal bone fractures can have associated intracranial complications such as epidural or subdural hematomas, intraparenchymal contusion or hemorrhage, cerebral edema, posttraumatic encephalopathy, and elevated intracranial pressure. Neurotologic symptoms can also result from shearing strain within the brain tissue with disruption of vessels, axons, dendrites, and synapses (1).

EPIDEMIOLOGY

Injury to the lateral skull has increased with the advent of modern technology; the leading cause of temporal bone fracture is involvement in motor vehicle accidents (2). In the past, 75% of motor vehicle accidents resulted in a head injury. The increased utilization of seat belts and the advent of frontal and side curtain airbags may, however, alter these statistics in the future. When the head trauma is of sufficient magnitude to fracture the skull, 14% to 22% of those injured sustain a temporal bone fracture (3,4). In the largest series of temporal bone fractures reported to date, 31% of the temporal bone fractures in the general population resulted from motor vehicle accidents (2). Assault was the second most common cause, followed by falls and motorcycle accidents. Pedestrian injuries, bicycle accidents, gunshot wounds, all-terrain vehicle accidents, sports injuries, and miscellaneous injuries accounted for a quarter of all cases (2) (Fig. 150.1). The most common injury etiology in temporal bone fractures specific to the pediatric population is equally divided between motor vehicle accidents and falls (between 30% and 60% each) (5–9).

Temporal bone fractures are reported to occur across all age groups with over 70% of fractures occurring in second, third, and fourth decades of life (2). These fractures occur predominantly in males, with a 3:1 to 4:1 ratio of males to females affected (2,10). The predisposition to temporal bone fractures in males is attributed not to an inherent structural weakness of the male skull versus the female skull but rather to biased involvement of males in many of the above at-risk activities. This is evidenced by the fact that head injuries in general also follow a 4:1 male-to-female ratio (10).

In a prospective study of 350 consecutive patients treated for head trauma, 10% were found to have temporal bone fractures on radiographic evaluation using helical CT, whereas only 6% manifested clinical signs of temporal bone fracture on primary evaluation (10). Large retrospective reviews at level I trauma centers have found an incidence of temporal bone fracture in 2% to 4% of consecutive head injury patients (11,12).

Eight to twenty-nine percent of patients with temporal bone fractures sustain them bilaterally (2,10,13,14).

PATHOPHYSIOLOGY

The temporal bones are pyramidal structures in the thick bone of the skull base and consequently require a great force to fracture. Early studies of static loading of the lateral

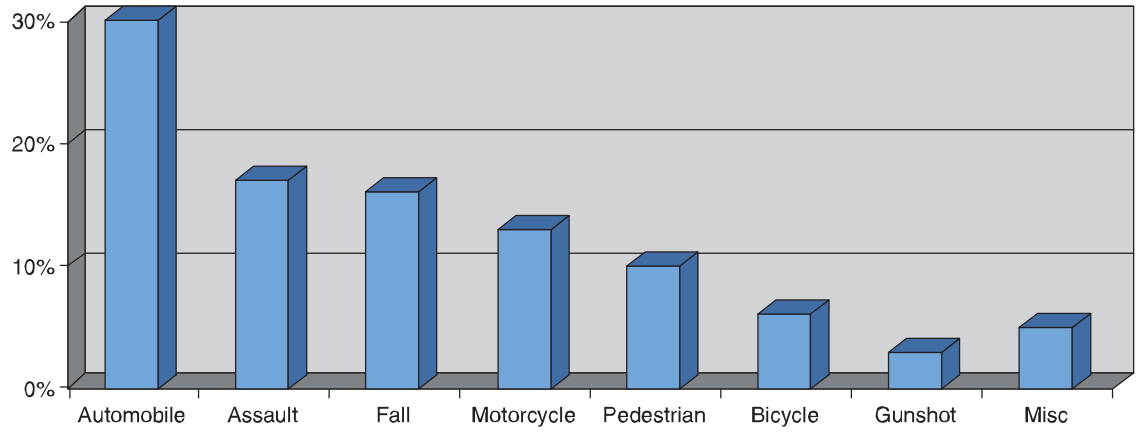

Figure 150.1 Cause of injury.

skull estimated fracture thresholds of 300 to 800 kg (15). More recent dynamic loading studies have estimated the force of lateral impact required to fracture the temporal bones of fresh cadavers at 6,000 to 8,000 N, or approximately 1,300 to 1,800 lb (16,17). Comparison of data from static versus dynamic loading experiments indicates an increase in force tolerance by a factor of two under dynamic loading (18). Such fractures typically take the path of least resistance, which is along structurally weakened points such as the various foramina perforating the skull base.

Sixty percent of temporal bone fractures are categorized as "open" fractures presenting with bloody otorrhea, brain herniation, or CSF draining from the ear canal, eustachian tube, or penetrating wound site (2). These patients are at greater risk for meningitis than those without evidence of an intracranial connection. In addition, those patients with fractures traversing the otic capsule are at even still greater risk of meningitis, sometimes delayed for years or decades, due to an inability of the otic capsule enchondral bone to remodel and heal (19–21). Pollak reported a 51-year-old man who died of meningitis who had suffered an otic capsule–disrupting fracture in childhood (20). The histopathology of his temporal bone revealed pus in the middle ear extending through an unhealed fracture line across the otic capsule. The fracture line contained a loose fibrous tissue. Membranous bone, such as that along the tegmen, has the capability to form callus and heal, whereas the enchondral bone of the otic capsule does not. Fractures through the otic capsule will generally only partially fill with fibrous tissue, although the surface may potentially seal with periosteal bone reaction (20) (Fig. 150.2).

Trauma to the temporal bone often results in one or more neurotologic complications, depending on the severity of injury and type of fracture, and can vary between adult and pediatric populations. Table 150.1 summarizes incidence of common complications of temporal bone fractures in the general and pediatric populations (2,6).

CLASSIFICATION

Temporal bone fractures have traditionally been divided into transverse and longitudinal fractures, based on the relationship of the fracture line to the axis of the petrous ridge (11,22,23). Some authors argue that the majority of fractures are actually oblique as opposed to longitudinal and/or are quite frequently mixed (24,25). This anatomical classification scheme is being replaced with a new structural scheme classifying fractures by whether they disrupt or spare the otic capsule, the bone housing the cochlea and semicircular canals (2,26,27) (Figs. 150.3–150.5).

Fractures that spare the otic capsule typically involve the squamosal portion of the temporal bone and the posterosuperior wall of the external auditory canal. The fracture passes through the mastoid air cells and middle ear and fractures the tegmen mastoideum and tegmen tympani. The fracture proceeds anterolateral to the otic capsule, typically fracturing the tegmen in the region of the facial hiatus. Otic capsule–sparing fractures typically result from a blow to the temporoparietal region.

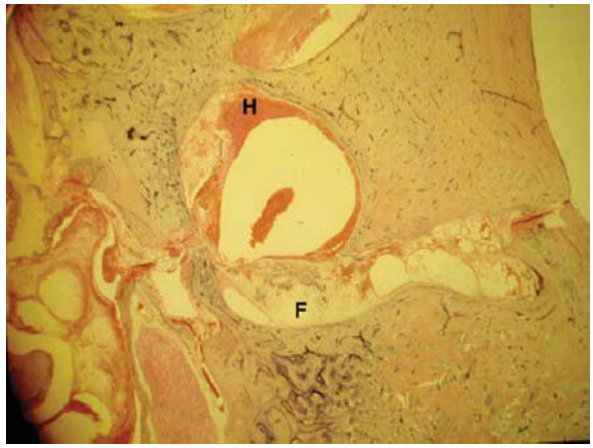

Figure 150.2 Histopathology of a patient who died of meningitis several decades following an otic capsule–disrupting temporal bone fracture. (F, fibrosis with a small amount of ossification within the fracture line in the otic capsule; H, hemorrhage and purulence.)

TABLE 150.1 INCIDENCE OF COMMON COMPLICATIONS OF TEMPORAL BONE FRACTURES IN THE GENERAL AND PEDIATRIC POPULATIONS

Complication	General (%)	Pediatric (%)
Facial nerve injury	7	6
CSF fistula	17	28
Meningitis	2	0.7
Hearing loss	24	33
Conductive HL	21	43
Sensorineural HL	57	52
Mixed HL	22	5

Otic capsule–disrupting fractures pass through the otic capsule generally proceeding from the foramen magnum across the petrous pyramid and otic capsule. The fracture will often pass through the jugular foramen, internal auditory canal, and foramen lacerum. These fractures do not typically affect the ossicular chain or the external auditory canal (28). Otic capsule–disrupting fractures generally result from blows to the occipital region.

Longitudinal fractures are reported to constitute 70% to 90% of temporal bone fractures with the remaining 10% to 30% categorized as transverse (11,24,26,28–31). In two large series using the newer classification scheme, only 2.5% to 5.8% of fractures disrupted the otic capsule (2,25). This would suggest that many fractures that are oriented perpendicular to the petrous ridge do not actually cross the otic capsule. Many of the otic capsule–disrupting fractures are actually oriented in the longitudinal plane (25).

Figure 150.3 Axial bone window CT demonstrates a longitudinally oriented fracture (*arrows*) sparing the otic capsule.

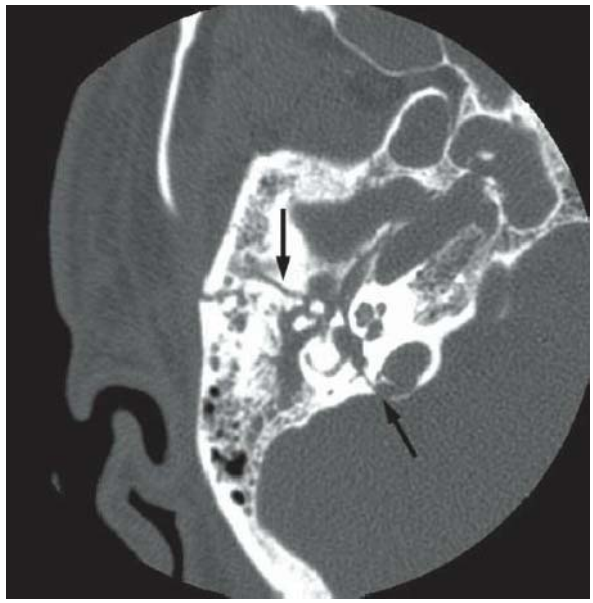

Figure 150.4 Axial bone window CT demonstrates a transverse-oriented fracture, secondary to a motor vehicle accident, disrupting the otic capsule (*arrows*).

The traditional schema of anatomical designation of fracture type was first extensively used in biomechanical studies of cadaveric skull deformation, without correlation to functional outcome (23). In contrast, the newer structural schema underscores the importance of otic capsule involvement in heralding neurotologic sequelae. Otic capsule–disrupting fractures have a much higher incidence of facial nerve paralysis than otic capsule–sparing fractures (30% to 66% vs. 6% to 13%) (2,25,32). In addition, Fisch reported a much higher incidence of nerve disruption in fractures involving the otic capsule (33). There is a two- to tenfold increase in CSF fistula in otic capsule–disrupting fractures as well as a much greater risk of intracranial injuries, compared to otic capsule–sparing fractures (2,25,27). Fractures

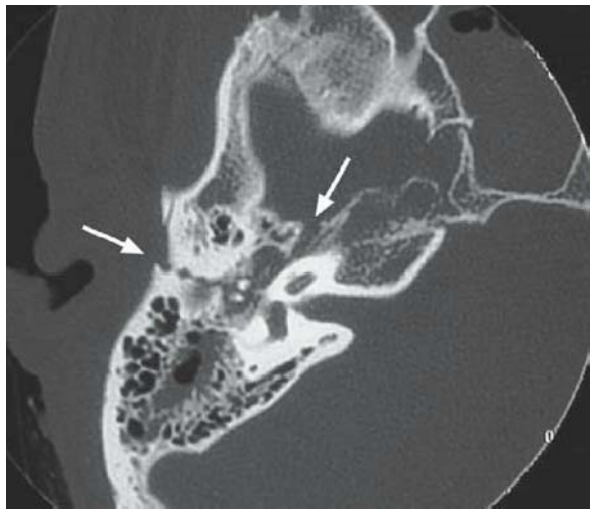

Figure 150.5 Axial bone window CT demonstrates a mixed fracture (*arrows*) that spares the otic capsule.

that disrupt the otic capsule will almost always result in a sensorineural hearing loss, although there are reported exceptions to the rule (34). Hearing loss in otic capsule–sparing fractures tends to be conductive or mixed (2,27). Historically, sensorineural hearing loss has been associated with transverse rather than longitudinal fracture type, but in a recent study, this correlation was not borne out but rather inverted: longitudinal fractures were three times as likely to be associated with sensorineural hearing loss as were transverse fractures (27). This study demonstrated a statistically significant difference in complication rates involving facial nerve injury, CSF fistula, and conductive hearing loss when 155 temporal bone fractures were categorized with the structural schema of otic capsule–sparing versus otic capsule–disrupting fracture types, while concurrently demonstrating no statistical significance when using the traditional classification schema of longitudinal versus transverse fracture types. A recent review of 30 temporal bones supported these findings and noted that otic capsule–disrupting fractures were five times more likely to have facial nerve injury, 25 times more likely to have sensorineural hearing loss, and 8 times more likely to have CSF leak (32).

The newer classification scheme emphasizes functional outcome and better prognosticates those temporal bone fractures that will exhibit neurotologic manifestations. In addition to the predictive value for various complications and comorbidities, categorization of fractures into otic capsule–sparing and otic capsule–disrupting injuries guides the indications for surgical intervention for CSF fistula and facial paralysis as well as the surgical approach to be utilized in their repair.

EVALUATION

It is uncommon for temporal bone fractures to occur in isolation of other bodily injury, and consequently the initial evaluation and management is focused on the urgent life-threatening issues of securing an airway, controlling hemorrhage, evaluating the neurologic status, and stabilizing and evaluating the cervical spine. Following or concurrent with this evaluation, the neurotologic exam is performed. It is extremely important to assess facial nerve function in the emergency room as early as possible, prior to the administration of muscle relaxants, as will be discussed below. The ear exam focuses on the condition of the auricle, ear canal, tympanic membrane, and middle ear.

Clinical Evaluation

The auricles are inspected for lacerations and hematomas. Lacerations are closed after thorough cleaning and debridement of exposed cartilage. Hematomas are drained and pressure bolsters are sutured in place to close the dead space and prevent a recollection of blood. Untreated, the auricular hematomas will result in an auricular chondropathy or "cauliflower ear."

Battle sign is seen in the presence of basilar skull fractures, including temporal bone fractures. Extravasation of blood from the mastoid emissary veins leads to ecchymosis over the mastoid bone and mastoid tip. This sign may be present in the initial clinical assessment but more often appears in a delayed fashion days after the injury.

The ear canal is inspected for fractures along the roof, CSF otorrhea, degree of hemorrhage, and the presence of brain herniation. The ear is examined as aseptically as possible. Blood and cerumen in the ear canal should never be debrided with irrigation. Following stabilization in the emergency room and transfer to the ward or intensive care unit, the ear can be more carefully examined with the aid of an operating microscope. Typical findings include fractures along the scutum and roof of the external auditory canal and/or tympanic membrane perforations. Hemotympanum or bloody otorrhea are almost invariably present and are two of the most common signs of temporal bone fracture (Figs. 150.6–150.8).

The integrity of the tympanic membrane is assessed, as is the presence of hemotympanum. Hemotympanum and any associated serous effusion generally resolve spontaneously, with resolution of concomitant conductive hearing loss, within 4 to 6 weeks and simply require observation. Traumatic tympanic membrane perforations generally heal spontaneously as well, and consequently no acute intervention is necessary.

Hearing is initially assessed clinically at the bedside with a progressively louder whispered voice. Tuning fork examination is useful in delineating conductive from sensorineural hearing loss. Pure tone and speech audiometry are not typically necessary in the acute setting and are obtained after the patient is stabilized. However, in the presence of complications of facial paralysis or CSF fistula in which surgical intervention may be necessary,

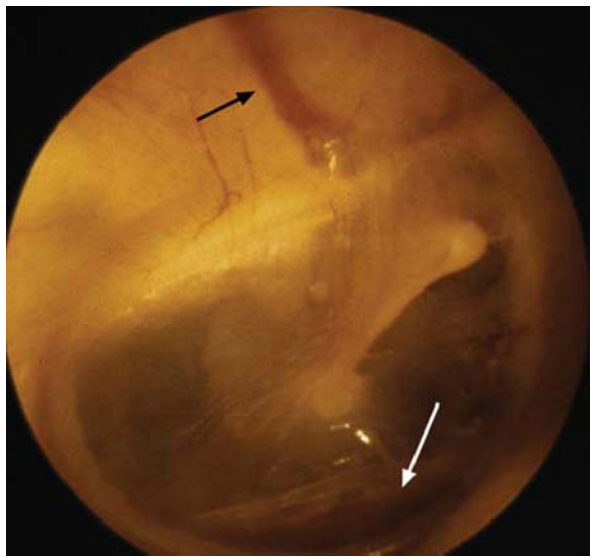

Figure 150.6 Otoscopic image demonstrating a nondisplaced fracture along the scutum (*black arrow*). Blood is layering out inferiorly (*white arrow*).

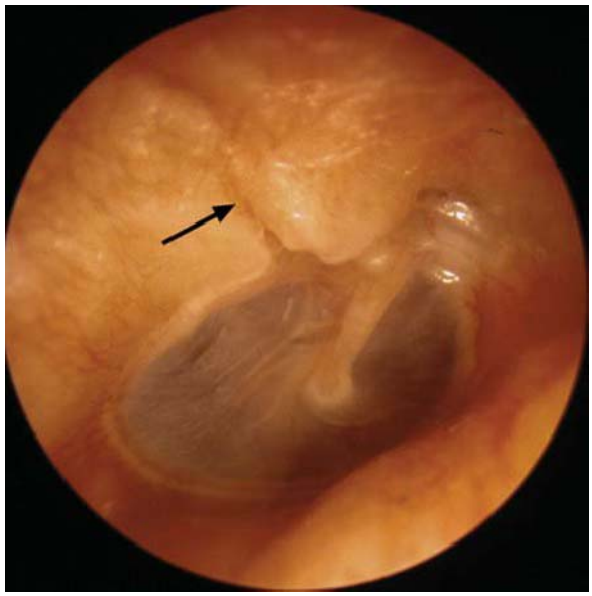

Figure 150.7 Otoscopic image demonstrating a displaced fracture along the scutum (*black arrow*).

preoperative audiometry is necessary as results will dictate the options available for management within the treatment algorithm, as is discussed below.

The neurotologic exam should note the presence or absence of nystagmus as well as the type of nystagmus. Peripheral vertigo generally manifests with horizontal or rotatory nystagmus and is suppressible with visual fixation. Central vertigo may present with vertical or direction-changing nystagmus that fails to suppress and may even enhance with fixation. The most common type of vertigo following head trauma is benign paroxysmal positional vertigo (BPPV) (35). BPPV classically manifests with latent-onset, transient rotatory nystagmus and concomitant vertigo with the Dix-Hallpike maneuver (35,36). The nystagmus occurs with the affected ear down. There is a 2- to 10-second latency followed by 10 to 30 seconds of rotatory nystagmus in the geotropic direction—that is, with the upper half of the globe rotating in fast phase direction towards the ground. Upon returning to an upright sitting position, a second bout of vertigo with nystagmus in the counterrotatory direction is often seen. The nystagmus is fixed in direction and is fatigable with repeated maneuvers. In contrast, central positional vertigo induces direction-changing nystagmus, which has no latency and is non-fatigable. Interestingly, the incidence of vertigo does not closely correlate with the severity of the trauma (37).

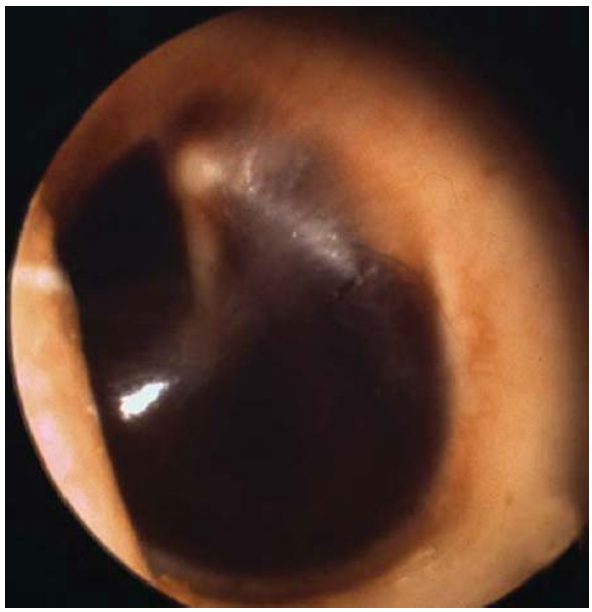

Figure 150.8 Otoscopic image demonstrating a hemotympanum.

Electronystagmography (ENG) is helpful in categorizing and localizing the vestibular injury; however, as with audiometry, it is typically not obtained in the acute setting. The vast majority of posttraumatic vertigo resolves spontaneously. If the symptoms persist following discharge from the hospital, an ENG can be obtained to help clarify diagnosis on an outpatient basis.

Pneumatic otoscopy, which consists of applying positive and negative pressure in the ear canal with a pneumatic otoscope, should not be performed in the acute setting. Application of positive and negative pressure in the potential setting of CSF fistula, and/or communication with the labyrinth if the fracture is otic capsule disrupting, increases the risk of iatrogenic injury from introduction of infection or air into the intracranial space or inner ear. This risk outweighs any potential diagnostic benefit in the acute setting. If the patient continues to experience vertigo or is experiencing fluctuating or progressive hearing loss longer than 1 week after the injury, a perilymph fistula is suspected and pneumatic otoscopy can then be performed to check for nystagmus and vertigo. The continued presence of spontaneous nystagmus following traumatic injury to the temporal bone is also suggestive of a perilymph fistula. Alternobaric testing with pneumatic otoscopy should not be performed if there is evidence of a persistent CSF fistula or infection in the middle ear.

Radiographic Evaluation

Patients with severe head trauma of the magnitude required for a temporal bone fracture will generally already have had a computed tomography (CT) scan of the head to assess for intracranial hemorrhage and other intracranial injuries. Temporal bone fractures can typically be discovered on standard head CT alone and can be traditionally classified as longitudinal, transverse, or mixed, or categorized with the more clinically significant otic capsule–sparing versus otic capsule–disrupting classification, as discussed above. Intravenous contrast-enhanced CT is not necessary for the diagnosis of temporal bone fractures.

Additional imaging of the temporal bone with axial and coronal high-resolution CT scanning (HRCT) is indicated in the presence of facial paralysis, signs of CSF otorrhea or

Figure 150.9 Otoscopic photograph demonstrating a distracted fracture along the roof of the external auditory canal and scutum allowing for potential in growth of canal skin.

rhinorrhea, disruption of the superior wall of the external auditory canal or scutum with potential trapping of epithelium (Fig. 150.9), or suspected vascular injury. HRCT of the temporal bones is also indicated if surgical intervention is required in the management of a neurotologic complication.

HRCT proves an invaluable tool for management decision making in the setting of immediate-onset, complete facial paralysis: A finding of bony impingement of the facial nerve and fallopian canal, either by bony spicules or by translocation of fracture components, is an indication for facial nerve exploration and decompression. In contrast, delayed-onset or incomplete facial paralysis alone does not require further radiologic evaluation with HRCT.

Hearing loss alone, whether conductive or sensorineural, in the absence of other complications also does not warrant additional temporal bone imaging in the acute setting. Demonstration of a transverse fracture or otic capsule–disrupting fracture in the setting of anacusis or profound sensorineural hearing loss will not alter the treatment plan. However, preoperative assessment with CT scanning in patients with a conductive hearing loss of sufficient magnitude to warrant exploration and ossicular reconstruction may provide useful information that may influence the surgical approach.

Ossicular discontinuity following temporal bone trauma can often be imaged on HRCT; types of discontinuities most easily identifiable on HRCT are incus dislocation and malleoincudal subluxation (38). In complete incus dislocation, in which both the malleoincudal and incudostapedial joints have been disrupted, the resulting position of the incus can be quite variable: residing in the epitympanum lateral to the malleus head (causing a "Y" configuration when viewed on coronal cuts), within the external auditory canal, or even not visible at all (presumably extruded from the body or "lost" within the mastoid air cells). Partial dislocation of the incus and subluxation of the malleoincudal joint creates a diastasis of the malleus head "ice cream scoop" from the incus body "cone," with or without rotation of the incus body, on axial imaging. Incudostapedial subluxation and stapes fracture are difficult to ascertain on CT.

Posttraumatic sensorineural hearing loss is highly correlated with otic capsule–disrupting fractures, but many cases present with no radiologic findings. In these cases, an impulsive disruption of the membranous labyrinth, termed cochlear concussion, is theorized (39). Intralabyrinthine hemorrhage is an etiology that can be imaged and is seen as a region of signal hyperintensity within the vestibule and cochlea on noncontrast T1-weighted MR imaging if performed acutely (40,41).

Similarly, identification of perilymph fistula is usually not directly possible on radiographic imaging, but this diagnosis can be suggested when recognition is made of otic capsule–disrupting fracture, stapes fracture, loss of stapes bone, or pneumolabyrinth in the setting of persistent fluctuating hearing loss and vertigo (38,42).

The role of HRCT in the evaluation of potential carotid artery injuries is unclear. Resnick et al. reported a 5% incidence of carotid injury in basilar skull fractures if the fracture spares the carotid canal and an 18% incidence of carotid injury in patients with fractures through the carotid canal seen on HRCT (43). However, Kahn argues that, in an asymptomatic patient, HRCT demonstration of a fracture through the carotid canal yields no valuable additional information (44). Subsequent angiography performed in cases of asymptomatic carotid canal fractures yielded no evidence of carotid artery injury and provided no clinical utility (44). Consequently, in completely asymptomatic patients sustaining a temporal bone fracture, who are neurologically intact, HRCT and angiography are not required. On the other hand, if there are any transient or persistent neurologic deficits in patients with basilar skull fractures, HRCT of the temporal bone together with CT angiography is indicated (Fig. 150.10). MR angiography can also be considered for screening evaluation of the petrous carotid artery.

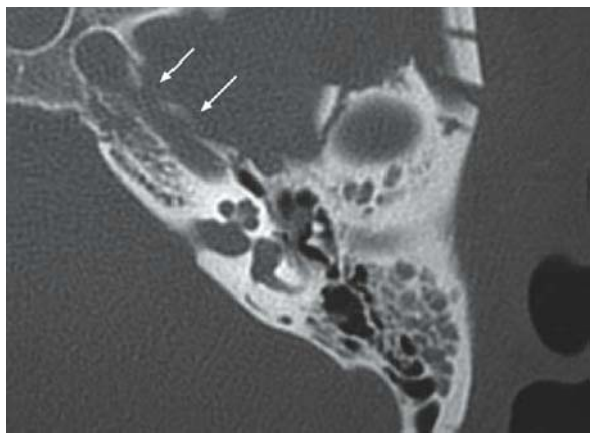

Figure 150.10 Axial bone window CT demonstrates a fracture of the carotid canal (*arrows*).

Sun et al. (45) sought to identify predictive findings of carotid artery injury on CT scan in patients who underwent angiography. Sphenoid bone fracture, petrous carotid canal fracture, and pneumocephalus were evaluated. With all three findings on CT scan, specificity of 85% and negative predictive value of 80% were obtained, while sensitivity was low. Further evaluation of correlation between CT findings and carotid artery injury is warranted.

Conventional skull radiography, including Schüller, Towne, Chamberlain, Stenvers, and basal views as well as tomograms, has been supplanted by HRCT scanning and no longer plays a role in the evaluation of patients suspected of having a temporal bone fracture.

In evaluating temporal bones for fracture on CT, care must be taken to avoid mistaking normal anatomic structures for fracture lines. Extrinsic suture lines (petro-occipital, temporo-occipital, occipitomastoid sutures), intrinsic suture lines (tympanomastoid, tympanosquamous, petrotympanic fissures), and intrinsic channels (cochlear aqueduct, vestibular aqueduct, glossopharyngeal nerve/glossopharyngeal sulcus, subarcuate artery/petromastoid canal, singular nerve/singular canal, Arnold nerve/mastoid canaliculus, Jacobson nerve/inferior tympanic canaliculus, and greater superficial petrosal nerve/facial hiatus) may all mimic fracture lines within the temporal bone (38). Knowledge of their anatomic relationships and distinction with true fracture lines is necessary to prevent incorrect interpretation of CT imaging.

MANAGEMENT

The morbidity and mortality associated with temporal bone fractures result from injuries to the structures passing through the temporal bone or abutting the temporal bone as described above. The most common complications include facial nerve injury, CSF fistula, sensorineural hearing loss, conductive hearing loss, cholesteatoma formation, and stenosis of the ear canal. In addition, rare complications may occur, including abducens nerve injury, trigeminal nerve injury, Horner syndrome, carotid injury, sigmoid sinus thrombosis, traumatic porencephalic cyst formation, and intracranial dislocation of the mandibular condyle (12,46–51).

Facial Nerve Injury

Facial paralysis is a severely disfiguring complication of temporal bone fractures. Six to seven percent of temporal bone fractures result in facial paralysis. This figure represents data based on large prospective and retrospective series of all consecutive patients treated for head injury or temporal bone fracture, thereby avoiding previous systematic bias towards overreporting of clinical complications (2,10). Of these facial nerve injuries, one-fourth are complete. The incidence of facial nerve injury in temporal bone fractures of the pediatric population is 3% to 9%, comparable to that of the adult population (5,8,9).

The incidence of facial paralysis in the literature has previously been reported as high as 30%. However, this estimation is exaggerated due to sampling error: Simple, uncomplicated temporal bone fractures without facial nerve injury are often not referred for otolaryngologic consultation. The incidence of facial paralysis in the literature has also been overestimated by including patients in retrospective reviews who have been referred to a tertiary care center for management of complications of temporal bone fractures such as facial paresis. Since the entire pool of temporal bone fracture patients had not been included in prior statistics, the reported incidence of complications has previously been quite biased.

If head trauma patients are carefully evaluated in the emergency room upon admission, prior to the administration of muscle relaxants, 27% of facial nerve injuries will present with immediate-onset facial paralysis; 73% will have facial motion in the initial examination and subsequently deteriorate (2). The latency in onset of facial palsy ranges from 1 to 16 days. It is crucial to differentiate "delayed onset" from "delayed diagnosis." Delayed onset of facial paralysis is defined as documented facial function in the emergency room that subsequently deteriorates. A delayed diagnosis of facial paralysis occurs when the patient is given a paralytic agent and intubated prior to examination of facial function. In this situation, an assessment of facial function is delayed until extubation. These patients should be categorized as unestablished onset and treated similar to the immediate-onset patients. In one large series, 10% of patients fell into this unestablished-onset category (52).

Many aspects in the management of facial nerve injury remain controversial. One of the main issues to be resolved is the indication for surgical exploration. Since the vast majority of traumatic facial palsies resolve spontaneously, the decision of which injuries to explore is based on prognostic factors for poor outcome. The factors that are assessed in predicting recovery of facial function include timing of onset (delayed vs. immediate onset), severity of the injury (penetrating vs. nonpenetrating), and the presence of associated infection.

The delay of onset of paralysis following temporal bone fracture is the most important of the predictive factors. In one series of 37 delayed-onset facial palsies, five were lost to follow-up and the remainder recovered to a House-Brackmann grade I or II (2). McKennan and Chole (53) described their experience with 17 patients with immediate-onset facial paralysis and 19 patients with delayed-onset paralysis. Complete spontaneous recovery of facial function occurred in 94% of the patients with delayed-onset paralysis. The one remaining patient had a House-Brackmann grade II recovery. In contrast, 8 out of the 17 immediate-onset paralysis patients had facial nerve transections.

Turner reviewed a large series of traumatic facial paralysis treated conservatively (54). His paper included 36 immediate-onset and 34 delayed-onset facial palsies. Complete recovery occurred in 94% of the delayed-onset cases and 75% of immediate-onset palsies. The one patient with delayed-onset paralysis who had no recovery of function developed the facial palsy coincident with acute otitis media. Similarly, in a recent systematic review, the outcomes of 25 patients with immediate paralysis and 20 patients with delayed paralysis treated with conservative management were assessed. Eighty percent of the delayed paralysis patients had complete recovery of facial function while less than 40% of those with immediate paralysis recovered complete facial function (55). Maiman et al. (56), in contrast, found no correlation between immediate- or delayed-onset facial paralysis, treated nonsurgically, and outcome. However, 44 out of 45 of their patients (including both immediate and delayed onset) had satisfactory recovery. Review of the above literature argues strongly against surgical exploration and decompression of delayed posttraumatic and facial paralysis. The natural course of delayed facial paralysis is almost always recovery of facial function to a House-Brackmann grade I or II. There are no convincing data in the literature that demonstrate that surgical intervention in delayed-onset paralysis will increase the probability of complete recovery of function.

May describes the difficulty in differentiating immediate- from delayed-onset facial paralysis. He explored reportedly "delayed-onset" palsies and found on occasion a severed nerve (57). This observation highlights the necessity of careful examination in the emergency room prior to chemical paralysis. Even in comatose patients, painful stimuli will generally induce a symmetric grimace when both facial nerves are intact; unilateral weakness of all facial branches implies a peripheral—that is, facial nerve—lesion, whereas selective weakness of the lower branches with bilateral temporal branch sparing implies a central lesion, proximal to the facial nucleus. Admittedly, information regarding facial nerve function immediately following an injury is not always available. Sometimes the exam is omitted due to attention to other life-threatening complications or because the patient has already received muscle relaxants with intubation. Some patients are not responsive to pain and a grimace cannot be induced. The critical issue is whether or not any facial function has been identified. If facial function is present in the emergency room and subsequently deteriorates, our experience is that the patient will recover without surgical treatment. When reliable information from the emergency room is unavailable, the patient is never documented to have facial function, and the diagnosis of facial palsy is delayed by a few days, these cases must be categorized as "unknown onset" and considered with the immediate-onset group when considering management options.

The degree of facial nerve injury is also a critical factor in guiding the management algorithm. Incomplete paresis rarely fails to completely resolve spontaneously unless an additional insult to the nerve, such as infection, occurs (2). A review of 71 patients with partial facial weakness demonstrated that the overwhelming majority of patients achieved recovery to House-Brackmann grade I and no patients had House-Brackmann grade VI outcome (55). Consequently, only patients with complete paralysis of immediate or unknown onset are considered for surgical exploration.

The degree of injury can be assessed not only clinically with facial motion but also with electrodiagnostic testing using the Hilger facial nerve stimulator; evoked electromyography (EEMG), also known as electroneuronography (ENoG); and standard EMG. The role of electrodiagnostic testing is to assist the clinician in differentiating a neuropraxic injury from a neural degenerative injury and to assess the proportion of degenerated axons. Nerves sustaining a neuropraxic injury proximal to the stimulated portion of the nerve maintain electrical stimulability at all times following the injury. Partial or complete disruption of the nerve results in Wallerian degeneration and consequent decrease or loss of stimulability. However, Wallerian degeneration occurs in a delayed fashion, and the distal segment of the nerves maintains electrical stimulability for 3 to 5 days postinjury (58). Consequently, electrodiagnostic testing cannot reliably differentiate a neuropraxic injury from a laceration of the nerve for up to 3 to 5 days.

Sunderland classified nerve fiber injuries in five categories (59). The first-degree injury is an anatomically intact nerve fiber with a conduction blockade (neuropraxia). These lesions tend to recover completely. The second-degree injury transects the axons but maintains an intact endoneurium (axonotmesis). Again, these lesions also tend to resolve without subsequent deficits. The third-degree injury transects the axon and endoneurium but maintains an intact perineurium (neurotmesis). Aberrant regeneration can occur with third-degree injuries, leaving patients with some weakness and synkinesis. Fourth-degree injuries transect the entire nerve trunk but maintain an intact epineural sheath (neurotmesis). Loss of the conduit of the epineural sheath allows regenerating axons to cross into adjacent fascicles, resulting in a loss of topographic organization. A proportion of the regenerating fibers are also lost due to the healing process and scarring. These lesions result in a high incidence of residual weakness, synkinesis, and hyperkinesis. Complete transection of the entire nerve trunk and epineurium is classified as a fifth-degree injury (neurotmesis) and is associated with poor spontaneous recovery, if any, depending on the degree of diastasis of the nerve stumps. Some authors have advocated a sixth-degree injury classification in which different fascicles of the facial nerve have sustained different degrees of injury of the five traditional injury types described by Sunderland.

The Hilger facial nerve stimulator is used to perform both the minimal nerve excitability test (NET) as well as the maximal stimulation test (MST). The facial nerve is

stimulated percutaneously adjacent to the stylomastoid foramen and the various distal branches. In NET, the branches of the facial nerve are stimulated on both the injured side and on the contralateral side, which serves as a control. The current used is incrementally increased just until threshold is reached, manifested by facial twitching, and this threshold level is recorded for each side individually. A threshold difference of 3.5 mA or greater between the affected and nonaffected sides of the face suggests significant neural degeneration. The test is most useful between 2 and 14 days postinjury in patients with dense facial paralysis to differentiate between neuropraxic and neurodegenerative injuries. The testing is unnecessary in incomplete paralysis in which there is almost always 100% recovery.

May et al. (60) argues that the MST provides a more reliable estimation of the degree of degeneration. In the MST, stimulation of the nonaffected, control side is performed similar to in the NET, but the intensity of the stimulus is further increased until the amount of facial contraction plateaus or is limited by patient intolerance. The affected, injured side is then stimulated with the same current amplitude, and the degree of contraction is subjectively assessed by the physician and compared with that of the unaffected side of the face. The difference in contraction is expressed as equal, mildly decreased, markedly decreased, or no response. The latter two categories are associated with poorer prognosis. Similar to NET, MST is most useful between 2 and 14 days postinjury in patients with dense facial paralysis. Again, any volitional movement of the face would indicate an intact nerve trunk and supercede any electrical testing.

Evoked electromyography (EEMG) has been popularized by Fisch and termed electroneuronography (ENoG) (61). ENoG differs from EEMG only in the use of bipolar stimulating and recording electrodes. Both techniques measure the evoked compound muscle action potential (CAP) and provide similar information to the MST but in an objective fashion. The stimulating bipolar electrodes are placed adjacent to the stylomastoid foramen, and the recording bipolar electrodes in the nasolabial crease. The peak-to-trough amplitude of the CAP is measured on both sides, and the diminution in amplitude of the CAP on the paretic side as compared to the control side is indicative of the percentage of degenerated nerve fibers. EEMG has been demonstrated to be the most accurate electrodiagnostic test for prognostic information (62). Fisch reported that patients in whom the degeneration on EEMG reaches 90% within 6 days of onset of a traumatic facial paralysis have a poorer outcome and consequently should be decompressed (63). Sillman et al. (64) demonstrated a significant association between a CAP decline of greater than 90% and poor recovery of function for idiopathic paralysis, but demonstrated no significant association between CAP decline of greater than 90% and clinical outcome in traumatic paralysis.

The value of EMG in the acute management of traumatic facial paralysis remains controversial. Standard monopolar EMG is performed by insertion of an EMG electrode into the muscle and the spontaneous electrical activity recorded. Two types of information are obtainable: voluntary activity and fibrillation potentials. If voluntary activity is present in the acute postinjury period, the patient has a very high probability of good recovery (64). However, May et al. (65) reported only 75% accuracy in predicting a poor recovery and 62% accuracy in predicting a favorable result. Fibrillation potentials result from denervation of the muscle but are delayed 2 to 3 weeks following the injury and consequently offer little additional information to guide therapy in the acute setting (66).

After defining the at-risk population for poor recovery of function, the next question to answer is: Does surgical intervention alter the outcome? Turner in 1944 reported on 69 patients with varying degrees of facial paralysis following temporal bone trauma (54). Thirty of these patients had complete facial paralysis, all of which were treated nonoperatively. This group of patients was unbiased in that none of his series underwent surgical decompression. Good recovery occurred in 63% of the patients, incomplete recovery with synkinesis in 23%, and poor recovery in 13%. Maiman et al. (56) reported on the outcome of 21 patients with posttraumatic complete facial paralysis. Full recovery occurred in 52% of the patients and incomplete recovery in 43%. One patient had a poor outcome. Brodie and Thompson (2) had eight patients with complete paralysis who met criteria for facial nerve decompression who, for a variety of reasons, did not undergo surgical exploration. Seven of the eight patients had good recovery of function and one patient had a poor outcome. The combined rate of good recovery of function with conservative, nonsurgical management, in the above three studies is 63%.

In contrast, analysis of six case series studies of patients undergoing surgical decompression for complete facial nerve paralysis revealed a combined rate of good recovery of facial function of 51%. This figure excludes severed facial nerves. The criteria to be included in the surgical groups were that the nerves were no longer stimulable with the Hilger facial nerve stimulator or demonstrated greater than 90% degeneration within 6 days or 95% degeneration within 14 days on EEMG/ENoG.

The outcomes in facial nerve function for patients who underwent conservative, nonsurgical management versus those undergoing facial nerve decompression in various series are summarized in Table 150.2 (2,52,54,56,67–70).

It is difficult to compare the recovery rates of facial nerve function in patients undergoing surgical and nonsurgical management. The patients included in the observation studies did not necessarily meet the same criteria as those included in the surgical decompression studies, thereby potentially artificially inflating the positive outcomes in patients treated nonsurgically. In an extensive review and analysis of the literature, Chang and Cass (71) concluded

TABLE 150.2 FACIAL NERVE OUTCOME FOLLOWING COMPLETE FACIAL PARALYSIS

Treatment	*n*	Good (HB I or II)	Incomplete (HB III or IV)	Poor (HB V or VI)	Transected Nerve
Nonoperative					
Turner	30	19	7	4	
Maiman	21	11	9	1	
Brodie	8	7	0	1	
Rate		63%	27%	10%	
Operative					
Kamerer	62	18	15	9	20
Lambert	17	11	0	0	6
Coker	12	5	4	1	2
Brodie	6	4	0	2	0
Darrouzet	65	25	26	5	9
Yeoh	6	4	1	1	0
Rate		51%	35%	14%	(22%)

that there are no studies that prove or disprove the efficacy of facial nerve decompression.

Since Wallerian degeneration is not documented on electrodiagnostic testing for 3 to 5 days following the axonotmesis or neurotmesis, surgical intervention is delayed until several days after the nerve has degenerated. Although decompression of the facial nerve prophylactically in acoustic neuroma surgery has been proven efficacious, the decompression is performed prior to Wallerian degeneration having occurred (72). Demonstrating that decompression of a posttraumatic nonsevered nerve is efficacious remains to be proven in a randomized prospective study.

The key factor in the decision to surgically explore a facial nerve is whether the nerve is suspected of being severed, crushed, or impaled with bone fragments. The incidence of transected nerves in the largest series ranges from 6% to 45% (52,67–69,73).The high frequency of severed nerves in some of these reports is biased by patient selection, as discussed previously. Patients are referred to the tertiary centers performing nerve explorations when they fail to spontaneously recover. However, the vast majority of patients do not have a transected nerve and therefore recover spontaneously and are not referred to tertiary centers.

The probability of severing the facial nerve is actually quite low, but the outcome of a transected nerve following observation alone is poor. Therefore, an attempt should be made to identify patients with crushed, impaled, or otherwise transected nerves, as these are the patients who would most benefit from surgical intervention. Electrodiagnostic testing of nerves with complete paralysis can only differentiate injuries that have undergone Wallerian degeneration from those that have not, that is, Sunderland II–V- versus Sunderland I-degree injuries. Since one cannot differentiate a Sunderland fifth-degree injury (severed nerve) from a second-, third-, or fourth-degree injury on the basis of electrodiagnostic testing, exploration is warranted only in patients with complete, immediate-onset paralysis in whom electrical stimulability is lost; it is these patients who are at greatest risk for crushed, partially severed, or transected nerves. The site of injury to the facial nerve in temporal bone fractures is in the perigeniculate region in 80% to 93% of patients (33,67,68). Lambert and Brackmann (67) found a second lesion in 4 out of 21 patients in the mastoid segment. Accordingly, the approach utilized for the nerve exploration must expose these two regions. Fisch advocates a translabyrinthine approach for transverse fractures and a combined transmastoid/middle cranial fossa approach for longitudinal fractures (63). May described a transmastoid/supralabyrinthine approach to the region of the geniculate ganglion for facial nerve decompression (74). Goin studied this approach in cadaveric temporal bones and found that he could consistently expose the distal labyrinthine segment and geniculate ganglion (75). However, the fundus of the IAC could be exposed in only 60% of the temporal bones. Yanagihara (76) applied the transmastoid/supralabyrinthine approach in 36 patients. Only five temporal bone fractures in his series of 41 patients required a middle cranial fossa approach to expose the geniculate region.

The translabyrinthine approach is advocated for facial nerve exploration in patients with profound hearing loss. The approach provides excellent exposure for decompression, nerve rerouting with direct reanastomosis, and cable grafting. In otic capsule–sparing fractures with ossicular discontinuity, the nerve is explored via a transmastoid/supralabyrinthine approach. This approach generally requires dislocation of the incus and ossicular reconstruction at the completion of the operation. If the patient has any contralateral hearing loss or the anatomy is not conducive for supralabyrinthine exposure, a middle cranial fossa approach is utilized.

Timing of facial nerve repair has in the past been controversial. McCabe advocated repairing the nerve within

the first 3 days or delaying facial nerve reanastomosis for 20 days postinjury (77). This recommendation was based on the observation that regeneration and axoplasmic flow were greatest at 3 weeks postinjury. Barrs studied the timing of facial nerve repair in micropigs and found no advantage of waiting the 3 weeks until the neuronal cell body metabolic activity was maximal (78). This animal model did not show a statistically significant difference in electrophysiologic testing between nerves grafted throughout various times within 3 months of transection.

Fisch advocates exploration when the ENoG indicates 90% degeneration occurring within 6 days (79). He argues that decompression should be performed early to minimize further degeneration. May also advocates early exploration (57). His series demonstrated a correlation between better results and shorter interval between injury and repair.

Late exploration for potentially severed nerves is still indicated, but the role of late decompression remains controversial. Quaranta et al. (80) reported on nine patients decompressed 2 to 3 months after sustaining their temporal bone fractures. Seventy-eight percent recovered to a House-Brackmann grade I or II at 1 year postdecompression. The question as to whether these patients would have recovered spontaneously to the same degree remains unanswered. Clearly, if the nerve was severed and not approximated, spontaneous recovery to a House-Brackmann grade I or II would not occur. In that scenario, a House-Brackmann grade VI would be anticipated. Sanus et al. reported on eight patients with mean time to decompression of 70 days. Six patients had nerve edema and two had bony impingement of the nerve at the time of operation. Long-term follow-up was available for six of these patients, all of whom recovered to House-Brackmann grade III (81). Again, the question remains whether these patients would have had spontaneous recovery to the same degree.

The range in latency to recovery of facial function varies from 1 day to 1 year. Fifty-nine percent of facial palsies that recover spontaneously do so within 1 month, and 88% recover by 3 months postinjury (2).

Summary of Facial Nerve Treatment Algorithm

Patients with delayed-onset facial paralysis are placed on a 2-week course of systemic corticosteroids (unless medically contraindicated) and observed. Although there are no data in the literature supporting or contradicting this recommendation, the rationale for corticosteroid use is based on antiinflammatory activity and the assumption that neural edema is the primary factor in the progression of injury in the traumatized, nontransected nerve (71) (Fig. 150.11).

Patients with complete paralysis of immediate onset are tested with the Hilger nerve stimulator between days 3 and 7 postinjury. If stimulability is present to any degree (implying a physically intact nerve), the patients are observed. If the nerve loses all stimulability within 1 week of the injury, facial nerve exploration is performed.

Facial nerve injuries occurring in an otic capsule–disrupting fracture are typically explored via a translabyrinthine approach: the translabyrinthine approach affords the most direct, complete access to the entire length of the intratemporal facial nerve, and in fractures that cause a profound sensorineural hearing loss, the approach does not engender any significant morbidity than that already sustained.

In otic capsule–sparing fractures, two surgical approaches are utilized. In patients in whom excellent intrinsic exposure of the intratemporal facial nerve can be achieved, that is, with well-aerated mastoid air cell systems or with ossicular discontinuity, a transmastoid/supralabyrinthine approach is chosen. If the patient has a poorly aerated mastoid air cell system or total facial nerve decompression cannot be achieved by the transmastoid/supralabyrinthine approach, a combined transmastoid/middle cranial fossa approach is utilized. If a severed facial nerve is encountered using the transmastoid/supralabyrinthine approach and inadequate exposure for cable grafting occurs, a middle cranial fossa approach is performed.

The transmastoid facial nerve decompression begins with a complete mastoidectomy skeletonizing the tegmen mastoideum superiorly, the sigmoid sinus posteriorly, and the posterior EAC wall anteriorly. The antrum is opened, exposing the short process of the incus and the lateral semicircular canal. The semicircular canals are then skeletonized. The facial recess is opened and the facial nerve is skeletonized from the second genu to the stylomastoid foramen. If there is any evidence of bony trauma in this region, a complete decompression is performed; however, the nerve sheath is not incised. The buttress to the incus is subsequently removed, followed by removal of the incus, and the tympanic portion of the nerve is decompressed. If there is adequate room to proceed, a supralabyrinthine decompression of the intralabyrinthine portion of the facial nerve is performed (Figs. 150.12 and 150.13). A laceration of the facial nerve in this region is cable grafted with a section of the greater auricular nerve. The cable graft is placed in the bony channel of the fallopian canal abutting the sharply incised edges of the facial nerve. To improve exposure, the tegmen can be eggshelled and retracted superiorly. If the exposure remains inadequate, a middle fossa craniotomy is performed. If the fracture involves the proximal portion of the intralabyrinthine segment of the facial nerve, a middle fossa craniotomy is performed.

To begin the middle fossa craniotomy, the squamosal portion of the temporal bone is exposed by extending the postauricular skin incision in a "lazy S" shape up towards the vertex, first extending anteriorly, then posteriorly. The temporalis fascia is reflected inferiorly and the temporalis muscle is split vertically and elevated off of the squamosal portion of the temporal bone. The soft tissue dissection and exposure should extend underneath the zygomatic arch in order to allow adequate exposure for the craniotomy. Self-retaining retractors are adjusted to hold both muscle and skin. A bone window is created

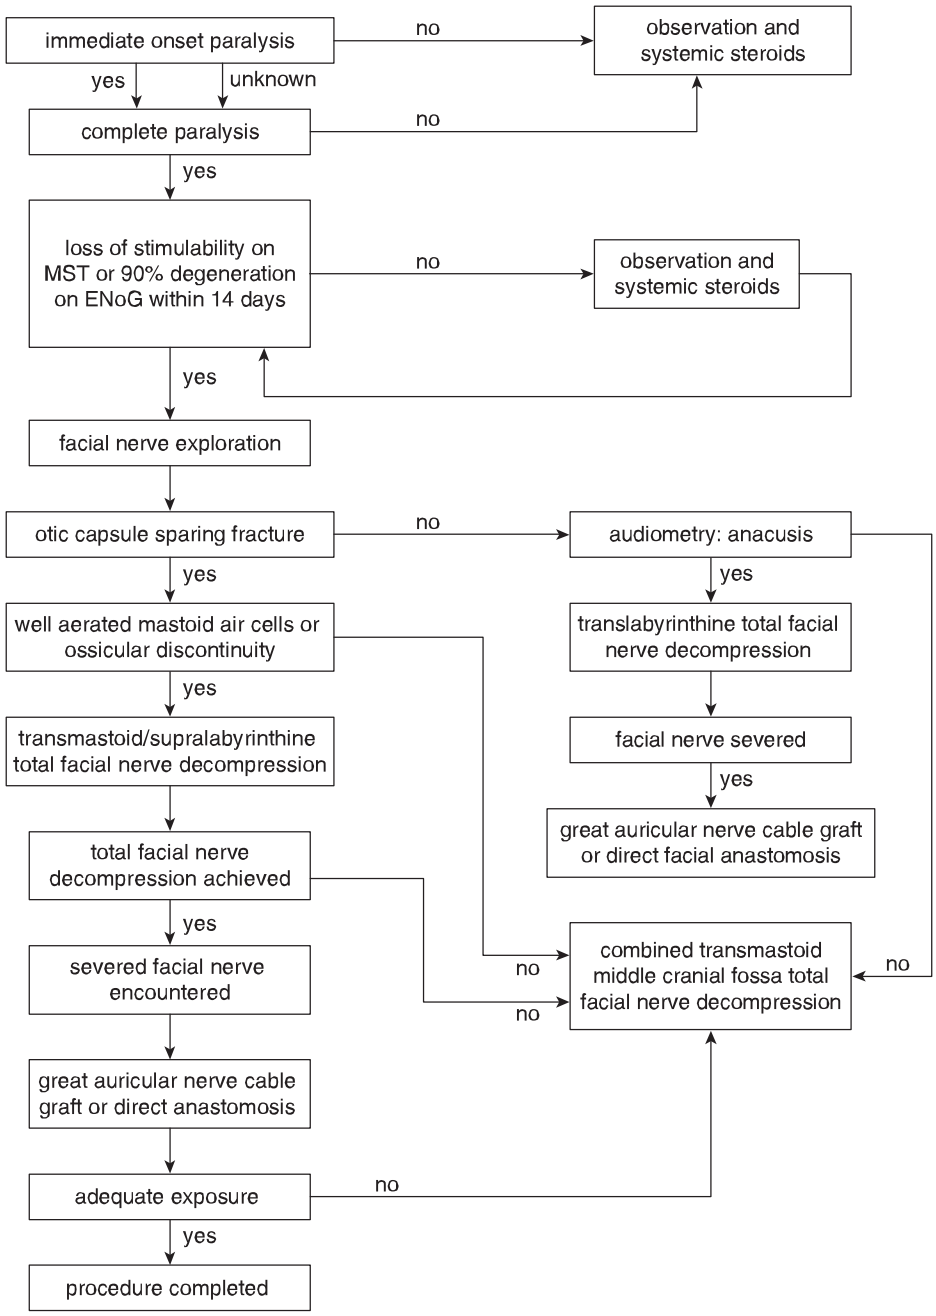

Figure 150.11 Management of traumatic facial paralysis.

with large cutting and then diamond burrs, taking care to avoid lacerating the underlying dura. This bone window is 4 by 4 cm in size and placement is set with the inferior border at the level of the zygomatic root, with two-thirds of the window anterior and one-third posterior to the vertical plane of the EAC. A rongeur is used to remove any remaining bone at the inferior edge of the craniotomy down to the level of the floor of the middle cranial fossa. This allows the optimal surgical line of site with minimal temporal lobe retraction. The House-Urban middle fossa retractor is engaged with the prongs in the edge of the craniotomy. The blade is gradually advanced, as the dura is elevated off the floor of the middle fossa. It is common to encounter dural venous bleeding at the anterior extent of the dissection. This can usually be controlled with a hemostatic agent such as Surgicel or Oxycel. The fracture line and hematoma are generally encountered in the region of the facial hiatus, consistent with the notion of fracture lines following natural foramina within the temporal bone.

The landmarks in the middle fossa are the middle meningeal artery at the foramen spinosum, the greater superficial petrosal nerve at the facial hiatus, and the arcuate eminence. The geniculate ganglion may be exposed

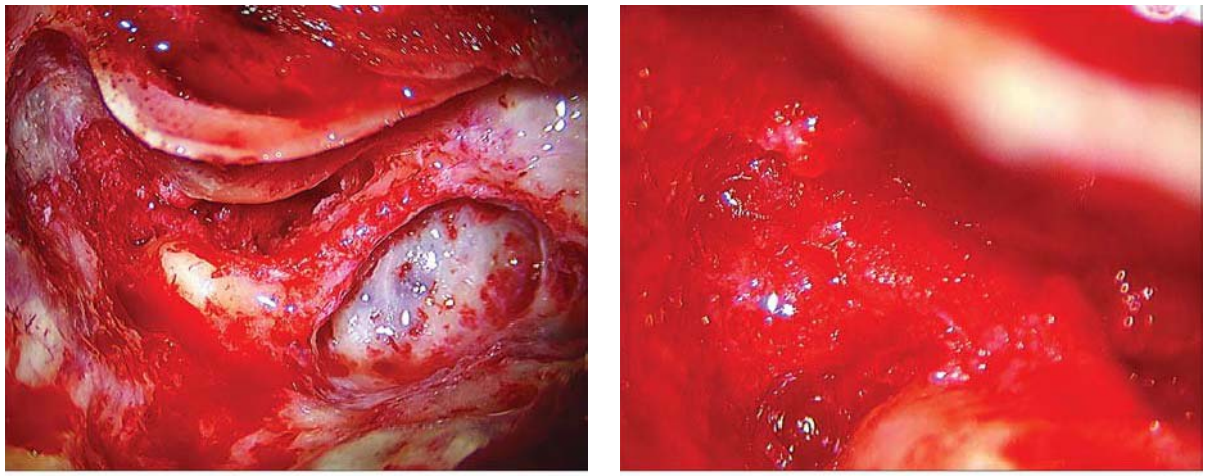

Figure 150.12 Transmastoid/supralabyrinthine decompression of right facial nerve in petrous temporal bone fracture. **A:** Right complete facial nerve decompression via transmastoid approach. The facial nerve is decompressed from the meatal foramen (**far left**) to the vertical segment. The incus buttress has been taken down and the incus resected. The distalmost portion of the facial nerve to the stylomastoid foramen has not yet been decompressed. Note the extremely generous retrofacial air cell tract. **B:** Close-up of supralabyrinthine component of the transmastoid decompression. The horizontal semicircular canal is at the lower border of view. The tympanic and geniculate segments are in center field of view, with the intralabyrinthine segment seen tangentially between the geniculate and horizontal semicircular canal ampulla. The fracture extended through the anterior petrous apex, with the fracture line diastasis exposing the middle fossa dura seen on the left.

without a bony covering on the floor of the middle cranial fossa, so care should be exercised during dural elevation. The landmark for the superior semicircular canal is the arcuate eminence, but the precise location of the canal does not uniformly correspond with the arcuate eminence. The canal may have very little bone coverage and be seen as a blue line after simple dural elevation, or there may be a large number of air cells between the canal and the surface of the tegmen. A coronal CT scan may be helpful in ascertaining this relationship: the association of the contours of the middle fossa floor to the superior semicircular canal as well as the distance between the two can be assessed.

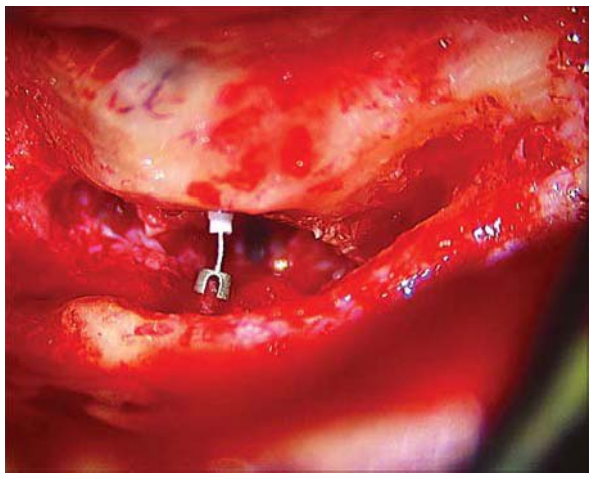

Figure 150.13 Ossicular reconstruction following supralabyrinthine decompression of the facial nerve. During transmastoid decompression, the incus may need to be resected in order to fully decompress the lateral face of the tympanic segment of the facial nerve; traumatic dislocation of the incus requires interposition ossiculoplasty, making this approach favorable. Following completion of facial nerve decompression, interposition ossiculoplasty is readily achieved through the same transmastoid approach, without the need for additional transcanal tympanoplasty, as seen here. In this case, a Bojrab Grace ALTO + HA partial ossicular prosthesis is interposed between the malleus manubrium and stapes capitulum, both easily visible from this view.

Identification of the internal auditory canal and intralabyrinthine portion of the facial nerve can be accomplished in any of numerous ways. House and Glasscock advocated identifying the greater superficial petrosal nerve and following this to the geniculate ganglion (82,83). Fisch suggested using the relationship of the superior semicircular canal to find the internal auditory canal, which is usually offset by 60 degrees (84). Portmann et al. (85) report finding the IAC 8 to 12 mm anteromedial to the location of the superior semicircular canal in the direction parallel to the petrous ridge. The tegmen tympani may be opened with ensuing identification of the ossicles and tympanic portion of the facial nerve, which can then be followed retrograde towards the geniculate ganglion. The method of Garcia-Ibanez is a reliable, often used technique and is described (86).

The bone over the superior semicircular canal is removed using suction irrigation and diamond burrs. A light medial to lateral stroke is used until the blue line of the superior canal is identified. After the superior canal has been identified, dissection proceeds along the meatal plane, which is the line of bone bisecting the angle subtended by the greater superficial petrosal nerve and the superior semicircular canal. Drilling within the confines of this plane will reduce the risk of inadvertent injury to the cochlea. Much

wider drilling may be performed medially, whereas at the lateral extent of the IAC there is very little space between the cochlea and ampulla of the superior semicircular canal. The burr should hug the line of the superior canal as bone removal progresses. The dissection will appear quite deep before the IAC is encountered. Bone should be removed 180 degrees around the IAC, from the lateral aspect of the meatus to the porus acusticus. An eggshell thickness of bone should be left over the IAC. The last step in exposure of the canal is careful removal of this bone and copious irrigation to remove bone dust.

At the most lateral extent of the IAC, the vertical crest or "Bill bar" is identified, with the facial nerve anteriorly and the superior vestibular nerve posteriorly. The dura of the IAC is incised in a longitudinal fashion, along the posterior edge, away from the facial nerve. If the facial nerve is lacerated, the proximal edge is freshened with microscissors. The nerve graft is secured proximally with a single 9-0 nylon suture and distally placed into the bony channel of the tympanic portion of the fallopian canal. A piece of temporalis fascia is placed over the graft. Bone wax is used to fill exposed air cells. A piece of temporalis muscle is placed in the bony defect, and the pedicled temporalis fascia flap is reflected over the floor of the middle cranial fossa. The temporal lobe is released, compressing the fascia over the bony defect. The bone flap is replaced within the craniotomy window, and the temporalis muscle is reapproximated, leaving a gap inferiorly where the temporalis fascia passes. Skin is closed in two layers.

Caution is advised when performing a middle fossa craniotomy for facial nerve decompression in the setting of acute trauma. In these instances, the offending temporal bone fracture may have not only caused injury to the facial nerve but also likely caused disruption of the middle fossa dura overlying the temporal bone, with potential contusion of the temporal lobe overlying these structures. Utmost care must be taken to avoid additional injury to the already disrupted middle fossa dura and contused temporal lobe during dissection, elevation, and retraction in this approach.

CSF Fistulae

CSF fistulae and the potential for meningitis are among the most serious of complications from temporal bone fractures. CSF fistulae occur in 17% of temporal bone fractures (2). CSF fistulae in otic capsule–sparing fractures typically occur through the floor of the middle cranial fossa (tegmen tympani and tegmen mastoideum) into the epitympanum, antrum, and mastoid air cell tract. The CSF will flow out the ear canal if the tympanic membrane is disrupted or into the eustachian tube, resulting in CSF rhinorrhea. In otic capsule–disrupting fractures, CSF flows from the posterior cranial fossa through the disrupted otic capsule into the middle ear.

A unique characteristic of a fracture through the otic capsule is the absence of healing. The otic capsule is adult size at birth and undergoes minimal remodeling throughout life (87). Following a fracture, fibrous tissue will partially fill the crevice, and the adjacent periosteal bone may seal off the fracture but the enchondral bone itself will not heal (19,21). This fibrous scar affords a potential tract for an infection of the middle ear cleft to spread to the intracranial space, leaving the patient at continued risk for meningitis even years after the initial injury.

The onset of CSF leakage following trauma was delayed for greater than 1 week in 28% of the 192 cases surveyed by Lewin (88). Immediate CSF leak results from separation of dural fibers in a traumatized region of dura adjacent to a fracture site. In contrast, delayed CSF leak has been theorized to occur from (a) herniation of meningocele or meningoencephalocele (often termed brain fungus or fungus cerebri) into the fracture site, followed by delayed atrophy of the brain fungus or delayed resolution of elevated intracranial pressure and retraction of brain fungus out of the fracture site or (b) resolution of hematoma previously obstructing the outflow of CSF through the fracture site.

The CSF fistula will continue to leak until fibroblastic proliferation creates a fibrous barrier, which closes the subarachnoid space or the sinus or air cell mucosa covers the bony defect (89). However, in the early stages of repair, the fibrous barrier is weak and the mucosal barrier remains fragile. If the CSF pressure gradient is greater than the healing tensile strength of these vulnerable barriers, the leak will continue. The tenuous, newly formed barrier may be easily ruptured by increased nasopharyngeal pressure or Valsalva (90). Therefore, the importance of enforcing relatively mundane precautions such as avoidance of nose blowing, avoidance of strenuous physical activity or physical therapy, keeping head of bed elevated, and scrupulous bowl care and avoidance of constipation cannot be overemphasized.

A CSF fistula is suspected when clear watery drainage is noted in the ear canal or from the nose. Otorhinorrhea will often drain down the back of the throat. The rate of flow of the discharge will usually increase with exertion or leaning forward. Consequently, when evaluating a patient for a suspected CSF fistula, the patient is asked to lean forward with the neck flexed, collecting nasal discharge into a sterile container. Patients often complain of headaches, which are dull, continuous, and bilateral. The origin of aural and nasal drainage is often obscured by concurrent bleeding or lysis of old blood clot. Once a nasal discharge is suspected of being CSF, it can be differentiated from watery rhinitis, lacrimal secretions, or serosanguinous discharge on the basis of its composition. CSF has elevated glucose, decreased protein, and decreased potassium than nasal secretions. Qualitative tests such as those utilizing glucose oxidase test strips (Clinitest) have been shown

to lack specificity and result in a substantial proportion of false positives (91). Quantitative glucose, protein, and potassium determinations are more accurate in diagnosing a CSF fistula.

A noninvasive technique for identifying and localizing a CSF fistula using protein electrophoresis for beta-2 transferrin was first described by Meurman (92). The beta-2 isoform of transferrin, a protein involved in iron transport, is confined to CSF, perilymph, and aqueous humor, whereas the beta-1 isoform is found globally in serum, nasal secretions, saliva, and tears. Nasal and otic secretions with CSF contamination exhibit an additional band on immunofixation electrophoresis than noncontaminated counterparts. In addition to being noninvasive, a major advantage of this technique is the small amount of fluid specimen required for the test: recommended specimen volume is typically 0.5 mL, and beta-2 transferrin can be detected in sample specimens as small as 50 μL. False-positive results are rare and occur in patients with alcoholic cirrhosis, inborn errors of glycoprotein metabolism, or genetic transferrin variants, in which transferrin allelic variants with similar electrophoretic mobility to the beta-2 isoform are present in sera (93). In these cases, collection and electrophoresis of a concurrent serum sample—which would contain beta-1- as well as beta-2-like bands—can help avoid a falsely positive result interpretation.

Other minimally invasive techniques for detection of CSF otorrhea or rhinorrhea are currently being developed, including detection of beta–trace protein, or prostaglandin D synthase (94,95). Beta–trace protein is synthesized in the meninges and has a 20- to 40-fold increase in concentration in CSF compared to serum. Nephelometric assays of beta–trace protein are being developed and show a specificity and sensitivity of CSF detection comparable to that of current beta-2 transferrin assays (96,97). A recent study in patients with suspected CSF leak was able to quantify values of beta–trace protein in nasal secretions at which 100% positive and negative predictive values of CSF leak could be obtained (98). In addition, the nephelometric technique is comparatively inexpensive and rapid, increasing its potential for further development and use in the clinical setting.

HRCT will generally demonstrate the potential sites of a CSF fistula. When a fracture is seen but the exact site of the fistula has not been identified, CT cisternography with intrathecal contrast (Omnipaque) can be quite useful. HRCT will show a bony defect in 70% of patients with a CSF fistula (99). When a defect cannot be demonstrated by HRCT, rarely will CT cisternography or radionuclide cisternography detect a site of leakage (99). Radionuclide scans tend to lack sensitivity and specificity.

Intrathecal fluorescein is a sensitive and specific test for investigating the presence of a CSF fistula. Following a lumbar puncture, 0.5 mL of a 5% solution of fluorescein is mixed with 10 mL of the patient's CSF and reinjected. Any subsequent otorrhea or rhinorrhea can be collected on micropledgets and examined under a Wood lamp for green fluorescence. Although occasional reports of neurotoxicity (e.g., paraparesis and grand mal seizures) following intrathecal injection of fluorescein appear in the literature, these complications are very infrequent, occurred at higher doses of fluorescein than is currently recommended, and have never resulted in permanent damage (90,100,101). No persistent side effects or complications have been reported with the current recommended dosing. Fluorescein is frequently successful in localizing fistulas when all other methods have failed and can be utilized intraoperatively to aid in the actual repair of the fistula (101–103). Therefore, the continued usage of fluorescein may be justified and the risks of increased morbidity following failure to locate a CSF fistula preoperatively may outweigh the risks involved in its usage.

None of the localizing techniques described above are useful if the CSF leak is quiescent at the time of investigation.

The incidence of meningitis in patients with CSF leaks ranges from 2% to 88% (2,90,104–107). The wide range in incidence is a result of multiple factors, the most significant of which is the duration of leakage (90,105,107,108). Mincy and Leech and Patterson compared the incidence of meningitis in patients with CSF leaks continuing 7 days or less to those persisting for more than 7 days (105,107). Leech and Patterson found only a 5% incidence of meningitis in patients with CSF fistulae of less than 7 days duration, and Mincy reported a similarly low incidence of meningitis in this group of 11%. The incidence of meningitis in patients with leakage for more than 7 days in Leech and Patterson's series was 55% and in Mincy's series was 88%. Spetzler and Wilson demonstrated a 33% incidence of meningitis in persistent fistulae, and Grahne found 54% of his patients with chronic CSF leakage developed meningitis (90,108).

Many studies over the past 25 years have demonstrated no benefit of prophylactic antibiotics in temporal bone fractures in the absence of CSF fistulae (105,106,109–115). The incidence of meningitis in this group is quite low. Rathore pooled the data from many of these studies and found a 4% incidence of meningitis in patients with basilar skull fractures receiving prophylactic antibiotics and a 3% incidence in patients not receiving prophylactic antibiotics (116). Brodie and Thompson (2) demonstrated a 1% incidence of meningitis in 578 patients with temporal bone fractures and no CSF fistulae. Hoff et al. (109) conducted a prospective randomized trial assigning patients with temporal bone fractures into a prophylactic antibiotic treatment group or to a no antibiotic group. None of the patients in either group developed meningitis. All of these studies conclude that prophylactic antibiotics are not indicated, given the low incidence of meningitis in temporal bone fractures without a CSF fistula and the lack of evidence demonstrating any benefit to prophylactic antibiotics in this situation.

However, the risk of meningitis is significantly higher in patients with temporal bone fractures when CSF fistulae are present. Consequently, the role of prophylactic antibiotics must be examined in relation to this subset of trauma patients. Multiple studies over the past three decades have concluded that prophylactic antibiotics did not have a statistically significant effect on the incidence of meningitis in patients with CSF fistulae (106,108,110,111,115,117). However, the number of patients included in the various studies was inadequate for valid statistical analysis. Reevaluation of the literature over the past 25 years using a metaanalysis revealed a statistically significant reduction in meningitis using prophylactic antibiotics in patients with CSF fistula; 320 patients were included in the analysis (118). The incidence of meningitis in patients with posttraumatic CSF fistulae treated with prophylactic antibiotics was 2.1%. In patients who did not receive prophylactic antibiotics, the incidence of meningitis was significantly higher at 8.7% ($P < 0.02$). Individually, none of the studies included in the metaanalysis demonstrated a statistically significant effect of prophylactic antibiotics, which points out the pitfall of statistical analysis with inadequate numbers of patients.

In addition to the inadequate numbers of patients in these prior studies, there are significant problems inherent in this type of retrospective study. How do we define adequate prophylaxis? Do 3 days of perioperative antibiotics for repair of a concomitant open femur fracture constitute adequate prophylaxis of a CSF fistula that persists for 5 days? Do therapeutic antibiotics for a concurrent infection constitute adequate prophylaxis of a CSF fistula? One very important risk factor increasing the risk of meningitis in patients with CSF fistulae is the presence of a concurrent infection. Brodie and Thompson (2) found a 20% incidence of meningitis in patients with concurrent infection and a 3% incidence of meningitis in the absence of concurrent infection. In that study, in the absence of concurrent infection, no patients receiving prophylactic antibiotics developed meningitis within the first month postinjury.

A recent metaanalysis sought to shed light on this issue through evaluation of four randomized control trials over the past 35 years (119). It concluded that prophylactic antibiotics did not have a statistically significant effect on meningitis in the population of patients with basilar skull fractures, either with or without CSF fistulae. These results must be interpreted cautiously. Over half of the included patients were enrolled in a study where pneumocephalus was part of the inclusion criteria (120). The rate of meningitis in this study was 20%, much higher than reported rates in the literature, indicating that this patient population is unlikely representative of the population of patients with temporal bone fractures at large. Given the current lack of conclusive data, confounding variables must be controlled in a prospective multi-institutional study to adequately address the question of the efficacy of prophylactic antibiotics.

The most common infecting organisms in meningitis occurring in the presence of a CSF fistula reported in the literature are *Streptococcus pneumoniae* followed by *Streptococcus* and *Haemophilus influenzae* (106,121,122). Fifty-seven to eighty-five percent of posttraumatic fistulae, which are treated conservatively, cease leaking within 1 week (88,107). Since acute posttraumatic CSF fistulae are associated with a high probability of early spontaneous closure and a low incidence of meningitis, they can be treated conservatively for 7 to 10 days. This treatment includes total bed rest with elevation of the head of the bed; stool softeners; instructions to avoid nose blowing, sneezing, and straining; and repeat lumbar punctures or lumbar drain if the leak persists. All of these measures are directed at maintaining the CSF pressure gradient below the healing tensile strength of the healing barrier. Due to the increased risk of meningitis following persistent CSF fistulae, surgical closure of fistulae persisting greater than 7 to 10 days is recommended.

Closure of CSF Fistulae

The approach chosen to close a CSF fistula is influenced by many factors, including the status of hearing in the affected and contralateral ears, the presence of brain herniation through the tegmen, and the location of the fistula. The treatment algorithm is presented in Figure 150.12. In a patient with a fracture of the otic capsule resulting in profound sensorineural hearing loss, obliteration of the mastoid and middle ear, and canal overclosure is recommended (123,124). The ear canal, tympanic membrane, incus and malleus, and middle ear mucosa are all excised. The external auditory meatus is closed in two layers, and a complete mastoidectomy is performed. The mucosa of the eustachian tube is inverted and a muscle plug is inserted. The incus is then inserted as well, wedging the muscle into place. The eustachian tube and fracture line are covered by temporalis fascia, and the mastoid cavity and middle ear are obliterated with an abdominal fat graft.

The approach for closure of a fistula resulting from an otic capsule–sparing fracture is dictated by the location of the fracture along the floor of the middle cranial fossa, the presence of brain herniation, and the status of the ossicular chain. Fistulae, which occur laterally in the middle cranial fossa, are accessible through a complete mastoidectomy and can be repaired by sealing the mastoid cavity off from the epitympanum and middle ear by placing a temporalis fascia graft over the antrum, facial recess, and retrofacial air cell tracts. A second fascia graft is placed over the fistula and the mastoid cavity is obliterated with a fat graft.

Fistulae, which occur more medially along the tegmen tympani or are associated with brain herniation, are addressed with a combined approach. When the temporal lobe herniates through the tegmen, the damaged brain is debrided via the transmastoid approach and the remaining brain and dura are elevated back up into the middle fossa by way of the middle fossa craniotomy. Temporalis fascia is

placed over the floor of the middle cranial fossa. If a bony defect is present in the tegmen, the craniotomy bone window is split or thinned with a burr and placed along the floor of the middle cranial fossa superior to the fascia to prevent subsequent prolapse. A piece of gelfilm is inserted through the mastoid cavity and antrum and placed over the top of the ossicles in the epitympanum in order to avoid adhesions and postoperative conductive hearing loss.

In the case of a fistula through the tegmen tympani in a patient with an ossicular discontinuity and the absence of brain herniation, the fistula can often be closed via a transmastoid approach alone. A tragal cartilage graft is inserted superior to the superior EAC wall extending to the tympanic portion of the facial nerve. The cartilage graft seals off the epitympanum and prevents herniation of tissue into the middle ear. The epitympanum is filled with a temporalis fascia graft.

Additional techniques have been advocated by other authors. Glasscock et al. (125) have advocated an intradural as opposed to an extradural approach for large defects, arguing that a better closure can be achieved intradurally. Kveton et al. reported on the successful closure of 13 cases of CSF leak using hydroxyapatite cement through a transmastoid approach, in addition to reporting successful closure of 106 out of 109 temporal bone defects of all types (126,127). This approach is highly successful in closing CSF leaks following translabyrinthine removal of acoustic neuromas, but care must be taken in traumatic CSF leaks where the field is much more contaminated. Placement of a foreign body in a potentially contaminated wound increases the chance of infection. One of the other potential complications of closure of tegmen CSF fistulae with hydroxyapatite cement is conductive hearing loss, which may occur if any of the cement migrates to the ossicular chain.

There is a high risk of EAC stenosis and cholesteatoma formation when the ear canal is severely traumatized, as seen with gunshot wounds to the temporal bone (128,129). In this situation, the CSF fistulae are generally closed with resection of the EAC and tympanic membrane and obliteration of the mastoid and middle ear as described above. Extreme care is taken to avoid leaving any fragments of epithelium that may subsequently lead to cholesteatoma formation. All mucosa is removed and the eustachian tube and external meatus are closed as described above (Fig. 150.14).

Hearing Loss

Temporal bone trauma can cause a conductive hearing loss, sensorineural hearing loss, or mixed loss. Otic capsule–sparing fractures extend along the roof of the EAC, often tearing the tympanic membrane in the region of the notch of Rivinus. The fracture proceeds along the tegmen tympani and in 20% of patients disrupts the ossicular chain (11). The most common injuries to the ossicular chain are subluxation of the incudostapedial joint (82%) and dislocation of the incus (57%) followed by fracture of the stapes crura (30%) (130). The majority of stapedial fractures do not occur in isolation but are associated with incus dislocations (11). Fixation of the ossicles in the epitympanum (25%) fracture of the malleus (11%) occurs less frequently (130). One-third of the patients will have multiple concomitant middle ear pathology.

The incidence pattern of ossicular injuries can be explained by the structural features specific to each ossicle. The malleus is well supported by the tensor tympani tendon, the epitympanic ligaments, and the tympanic membrane, and the stapes, being the smallest and lightest bone in the body, is comparatively well supported by the stapedius muscle tendon and annular ligament. In contrast, the incus is relatively heavy, situated with articulating joints on both ends, and is supported by only minor posterior and superior ligaments, thereby making it the ossicle most commonly involved in posttraumatic discontinuity.

Almost universally, patients with temporal bone fractures will experience a hemotympanum with associated conductive hearing loss. Over a few days to few weeks postinjury, the middle ear will re-aerate with resolution of the hearing loss that was attributable to the middle ear fluid. Factors that increase the duration of the middle ear fluid include endotracheal intubation, associated craniofacial fractures, and the presence of a CSF leak. Eighty percent of cases of conductive hearing loss will resolve spontaneously without the need for surgical intervention (131).

Residual conductive hearing loss following resolution of the hemotympanum and healing of the tympanic membrane suggests the possibilities of ossicular fracture or discontinuity. The indications for exploratory tympanotomy and ossicular reconstruction are conductive hearing loss greater than 30 dB that persists for more than 2 months postinjury. However, if the conductive hearing loss is in an only hearing ear, surgery is contraindicated. The audiogram in a mixed hearing loss must be critically assessed to establish the true potential benefit of ossicular reconstruction. If the bone conduction thresholds are more than 30 dB worse than in the contralateral ear, reconstruction, even with an excellent closure of the conductive component of the hearing loss, will provide minimal subjective improvement. In this scenario, the patient would still require a hearing aid to attain usable hearing in the surgical ear. Consequently, unless the mixed loss is profound and the patient cannot benefit preoperatively from a hearing aid, ossicular reconstruction is not recommended.

The most conducive injury for ossicular reconstruction is a dislocation of the incudostapedial joint. In this situation an Applebaum hydroxyapatite or similar prosthesis is inserted between the long process of the incus and capitulum of the stapes, generally resulting in complete or near-complete closure of the air–bone gap. In some instances, minimal to moderate subluxation of the incus and diastasis of the incudostapedial joint can be corrected by

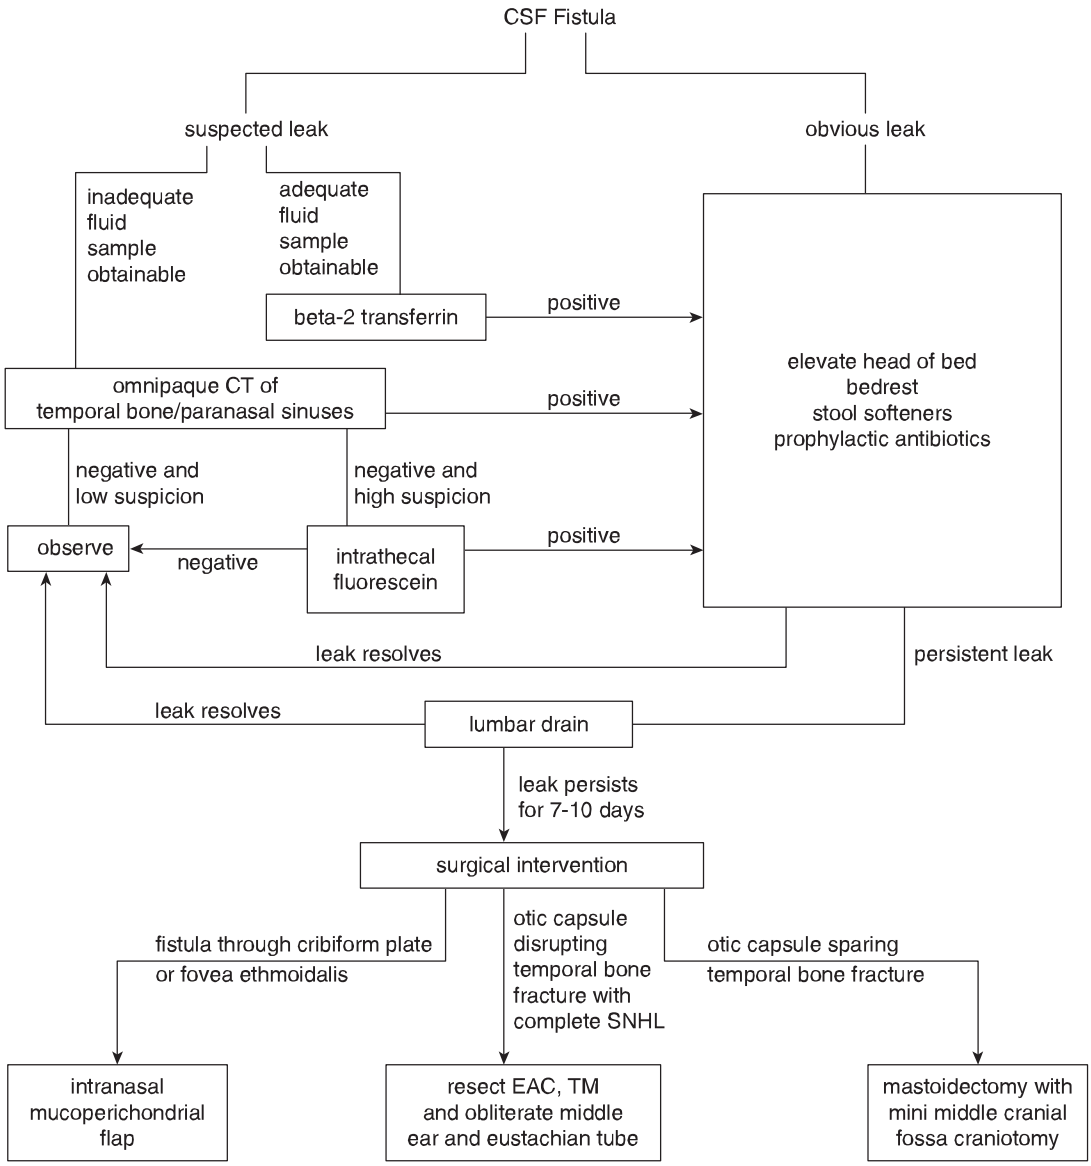

Figure 150.14 Treatment algorithm for the management of CSF fistula.

juxtaposition of the incus long process back onto the stapes capitulum and stabilization of the joint with hydroxylapatite bone cement or even just fascia. Any ossiculoplasty technique in which all three ossicles can be saved in their native orientations has the potential for complete or near-complete closure of air–bone gap (Fig. 150.15).

In contrast, cases in which the incus has been completely dislocated from the chain require interposition reconstruction, as the incus body has been completely destabilized and cannot simply be positioned back into its native orientation in a stable fashion. Dislocation of the entire incus requires bridging the gap between the stapes superstructure and the manubrium of the malleus. A sculpted incus interposition graft is preferred in this situation, although a variety of incus strut replacement and partial ossicular replacement prostheses are available and suitable for this type of reconstruction. The incus interposition is accomplished by drilling a cup in the end of the lateral process of the incus that will fit over the capitulum of the stapes. The long process of the incus is removed and the body sculptured. The articular surface is fashioned to fit under the manubrium. If, in addition to the incus dislocation, the stapes superstructure is fractured, the long process of the incus is left intact and the body and short process sculptured. The superior surface of the body of the incus is fashioned to rest under the manubrium and the long process sits on the footplate. A variety of total ossicular replacement prostheses are available for this purpose as well.

A unique problem occurs when the stapes superstructure is fractured but the incus remains connected to the malleus. These patients are good candidates for a laser stapedotomy.

The hearing results following ossicular reconstruction for traumatic ossicular disruption are superior to those

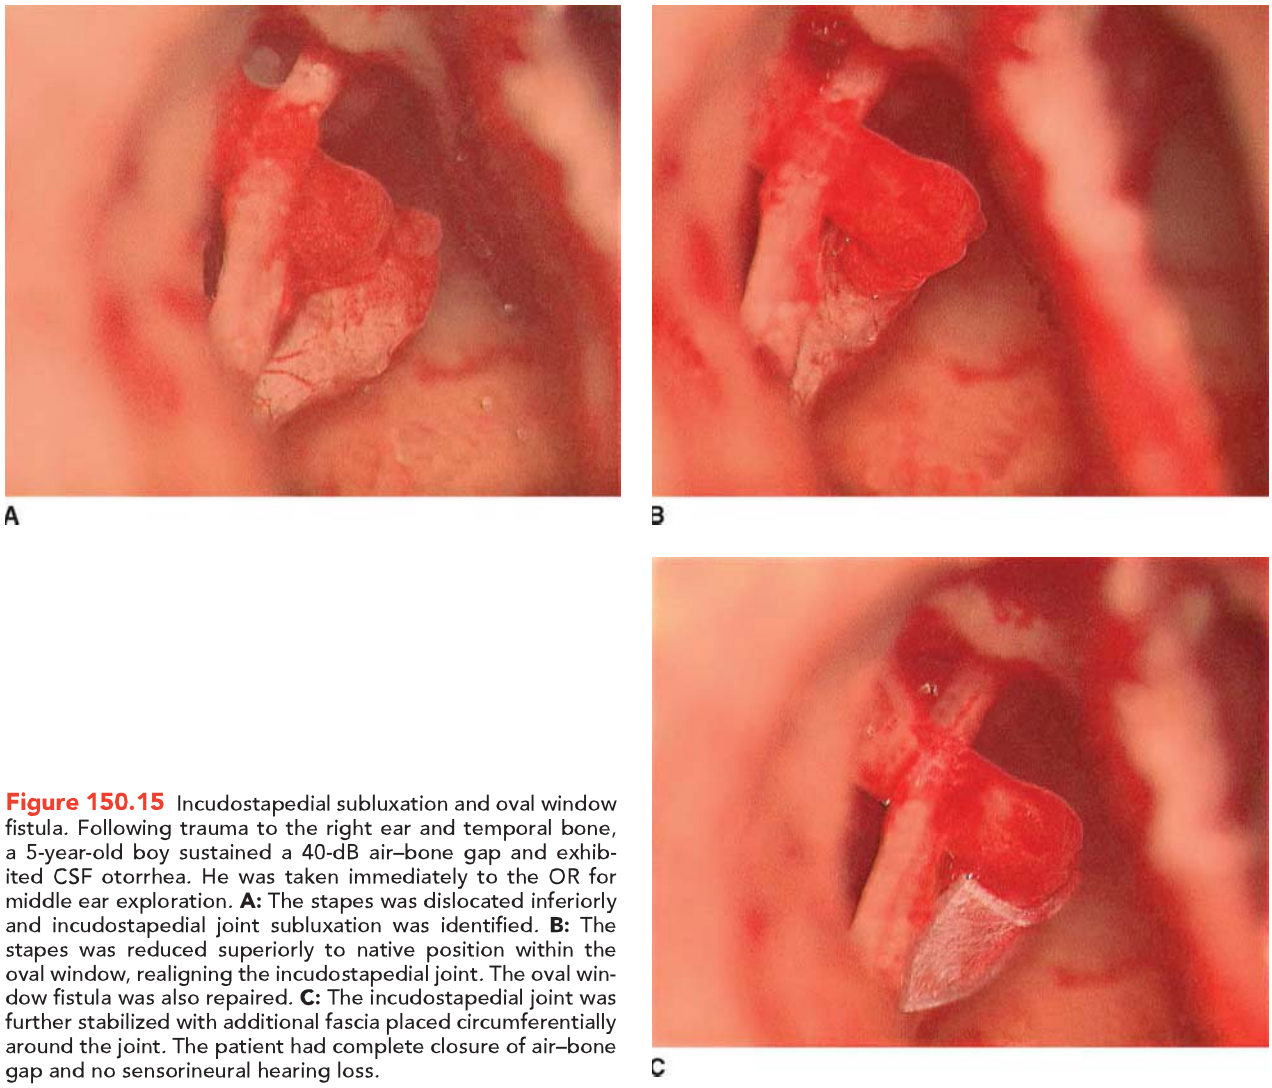

Figure 150.15 Incudostapedial subluxation and oval window fistula. Following trauma to the right ear and temporal bone, a 5-year-old boy sustained a 40-dB air–bone gap and exhibited CSF otorrhea. He was taken immediately to the OR for middle ear exploration. **A:** The stapes was dislocated inferiorly and incudostapedial joint subluxation was identified. **B:** The stapes was reduced superiorly to native position within the oval window, realigning the incudostapedial joint. The oval window fistula was also repaired. **C:** The incudostapedial joint was further stabilized with additional fascia placed circumferentially around the joint. The patient had complete closure of air–bone gap and no sensorineural hearing loss.

performed for chronic otitis media. Hough and Stuart (130) report closure of the air–bone gap to within 10 dB in 78% of patients and complete closure in 45%.

Otic capsule–disrupting fractures typically result in severe to profound sensorineural hearing loss. In addition, bilateral temporal bone fractures can also result in bilateral profound sensorineural hearing loss (132). In addition to the risk of sensorineural hearing loss from temporal bone trauma, patients who sustain closed head injuries in general, with or without temporal bone fracture, are at risk of acute sensorineural hearing loss, which can further progress with time (133). Multiple pathogenic mechanisms can contribute to posttraumatic deafness: disruption of the membranous labyrinth, avulsion or trauma to the cochlear nerve, interruption of the cochlear blood supply, hemorrhage into cochlea, and perilymphatic fistula. Another proposed mechanism is endolymphatic hydrops resulting from obstruction of the endolymphatic duct by the temporal bone fracture (134). Acoustic trauma associated with temporal bone fractures and incus dislocations frequently contributes to a sensorineural component to a mixed hearing loss; 50% of patients with traumatic incus dislocations will have at least 10 dB of sensorineural hearing loss as well, and 18% will have more than 30 dB of loss (135). The sensorineural injury from traumatic incus dislocation appears to occur in the 2 to 4 kHz range.

High-frequency bias for cochlear acoustic injury is observed in traumatic injury to the ossicular chain, such as in cases of traumatic incus dislocation as above, as well as in iatrogenic vibrational injury to the ossicular chain as seen in cases of inadvertent drill injury to the ossicles during otologic surgery. This bias may be closely related to the phenomenon of direct acoustic injury to the cochlea seen in impulsive or severe noise-induced hearing loss, as both mechanisms involve delivery of acoustic energy through the oval window and cochlear basal turn.

Patients may suffer closed head injury (CHI) that spares the temporal bones and otic capsules of fracture yet still is of significant severity to cause sensorineural hearing loss. Such injuries to the cochlea and neurosensory hearing mechanics is sometimes referred to as cochlear

concussion, when sensorineural hearing loss is clearly documented on postinjury audiogram in the absence of any fracture spanning the otic capsule or temporal bone. The traditional literature for concussive neurosensory hearing loss suggests a predilection for acoustic injury at higher frequencies, centered around 4 kHz (136,137). These older studies are limited by their small study populations, case-study-type design, and descriptive reporting of results. Additionally, results often incorporated audiometric findings years following traumatic injury, making it difficult to differentiate hearing loss resulting directly from concussive otic injury and that from age-related changes.

A recent large-scale, prospective study by Munjal et al. (138) reported the pattern of audiologic deficits measured in 290 CHI patients in comparison with 50 age- and gender-matched controls. The majority of these patients were involved in motor vehicle accidents, with the remainder suffering closed head injuries from falls or assaults. Measured hearing losses trended towards larger threshold differences and greater variability at higher frequencies; however, there was only a 5-dB average threshold difference between 250 Hz and 4 kHz for the most severe CHI patients, and there was no frequency-specific difference at all for mild and moderate CHI patients. In addition, there was a direct correlation between degree of threshold drop and severity of CHI. These findings indicate that in purely concussive cochlear injuries—such as those occurring in blunt trauma and CHI—in which there is no differential deposition of acoustic energy through the oval window, the cochlear injury is global and subsequent hearing loss flat rather than high-frequency biased and that the magnitude of such sensorineural hearing loss is directly dependent on the severity of the concussive injury.

As such, the prognosis for recovery of function in patients with anacusis or profound deafness as a result of temporal bone and cochlear trauma is extremely poor; however, patients with moderate to severe loss may have some hearing recovery (131,139). Patients who are experiencing progressive or fluctuating sensorineural hearing loss, suggestive of a possible underlying perilymphatic fistula, may benefit from middle ear exploration and repair of fistula (140).

Cholesteatoma and External Auditory Canal Stenosis

Cholesteatoma formation may occur many years after a temporal bone fracture (128,141). There are four pathogenic mechanisms responsible for posttraumatic cholesteatoma formation: (a) epithelial entrapment in the fracture line, (b) ingrowth of epithelium through the unhealed fracture line or rent in the tympanic membrane, (c) traumatic implantation of tympanic membrane skin into the middle ear, and (d) trapping of epithelium medial to a stenosis of the EAC. The typical location for cholesteatoma resulting from epithelium trapped within the fracture line is in the epitympanum and antrum. The fracture line along the posterior superior canal wall and scutum expands and then closes trapping the canal skin. As the trapped skin grows, it expands into the epitympanum and antrum forming a cholesteatoma. The ingrowth of epithelium through a displaced fracture line may also extend into the same region. Traumatic implantation of tympanic membrane skin will result in cholesteatoma formation within the mesotympanum. Blast injuries can result in displacement of keratinizing stratified squamous epithelium into the mastoid air cells, mesotympanum, epitympanum, and even intracranium (142). The fourth mechanism of cholesteatoma formation, trapping of epithelium medial to an EAC stenosis, results in a canal cholesteatoma. Posttraumatic canal cholesteatomas are the most preventable by careful follow-up, debridement, and stenting when narrowing progresses. Early intervention with stenting at the onset of the stenosis can effectively prevent a problem that is much more difficult to address once the stenosis is mature. The ear canal can be dilated with the insertion of increasing numbers or sizes of merocel sponge packs (i.e., Pope otowick, Schindler pack, or Ambrus pack, in increasing caliber and dilational capacity) saturated with antibiotic solution, replaced every few days. Once the canal is adequately dilated, a larger merocel sponge is inserted to maintain the lumen. A large vented custom ear mold is occasionally required to maintain the lumen in the long term following severe canal injuries. The mold is used throughout the day for 3 to 6 months. When the stenosis is complete and dilation is not possible, a canalplasty and possible tympanoplasty are required. A lateral stenosis of the EAC should not be allowed to persist, even if completely benign in appearance, because of the very high probability of cholesteatoma formation.

Posttraumatic cholesteatoma involving the attic, antrum, or mastoid air cells will often grow for many years prior to detection. Until the cholesteatoma involves the ossicular chain with resultant conductive hearing loss, erodes into the labyrinth causing vertigo or sensorineural hearing loss, compresses the facial nerve resulting in facial paresis, or grows into the middle ear cleft and can be visualized on physical examination, the growth will go undetected.

Vascular Injuries

Injuries to the intratemporal carotid artery are rare but potentially life-threatening complications. Fractures that traverse the temporal bone adjacent to the carotid artery tend to involve the softer fibrocartilage of the foramen lacerum rather than the stouter, more dense bone of the carotid canal. Bloody otorrhea is a common presentation

in temporal bone fractures, and the ear canal is not usually packed initially unless significant hemorrhage is present and must be controlled. In such cases, injury to the petrous portion of the carotid artery should be suspected and the patient taken immediately to either the operating room for carotid ligation or the angiography suite for balloon occlusion.

CT angiography or MR angiography is indicated in patients with focal transient or persistent neurologic deficits. In patients with significant hemorrhage from the ear or nose or with rapid neurologic deterioration, traditional interventional angiography is indicated for confirmation of carotid injury as well as immediate therapeutic intervention if necessary.

HIGHLIGHTS

- The majority of temporal bone fractures are incurred in auto accidents; multiple concurrent injuries are the rule and must be evaluated.
- The new classification system of temporal bone fracture emphasizes functional outcome: otic capsule–sparing versus otic capsule–disrupting injuries.
- The most common complications of temporal bone fractures are facial nerve injury, CSF leak, hearing loss, vertigo, cholesteatoma formation, and ear canal stenosis.
- Assessment of facial nerve function as soon as possible facilitates clinical decision making.
- Delayed-onset facial paralysis merits steroid administration and observation.
- Immediate-onset facial paralysis requires assessment of nerve stimulability. If the nerve will stimulate, observation is recommended. If the nerve will not stimulate, the nerve should be explored.
- The use of prophylactic antibiotics for temporal bone fractures is not indicated. The use of prophylactic antibiotics in the setting of CSF leak is controversial.
- Most posttraumatic CSF leaks close spontaneously. Surgical closure is required for persistent fistula.

Cholesteatoma 151

Ted A. Meyer *Chester L. Strunk Jr.* *Paul R. Lambert*

Cholesteatomas are expansile lesions of the temporal bone lined by stratified squamous epithelium that contain desquamated keratin. Some cholesteatomas are invaginated pouches that can develop from retraction pockets, while others are completely enclosed cysts. They most frequently involve the middle ear and mastoid, but they may develop anywhere within the pneumatized portions of the temporal bone. They may be congenital (infrequently) or acquired.

The accumulation of keratin may cause infection, otorrhea, bone destruction, hearing loss, facial nerve paralysis, a labyrinthine fistula, and intracranial complications such as epidural and subdural abscesses, parenchymal brain abscesses, meningitis, and thrombophlebitis of the dural venous sinuses.

Cholesteatoma is a misnomer originally coined by Johannes Mueller in 1838 when he described "layered pearly tumor of fat, which was distinguished from other fat tumors by the biliary fat or cholesterin that is interspersed among the sheets of polyhedral cells" (1). Cholesteatomas do not contain fat, and they do not usually contain cholesterin. Nevertheless, the term remains, despite a more appropriate term suggested by Schuknecht: keratoma.

The matrix of a cholesteatoma is composed of fully differentiated squamous epithelium resting on connective tissue. The deeper layers of the epithelium of a cholesteatoma matrix show activity in the form of downgrowths into the underlying connective tissue. Cholesteatomas have a layer of granulation tissue in contact with bone. This layer of granulation tissue elaborates various enzymes such as collagenase resulting in bone destruction.

Cholesteatomas are recidivistic by nature. The conditions or processes through which they develop are often present throughout a patient's life. Eustachian tube disease, with negative middle ear pressures, and a retracted eardrum are usually seen in patients with primary acquired cholesteatomas, and this can continue even with the complete surgical removal of a cholesteatoma. The function of the eustachian tube does not necessarily ever improve, and the patient is at risk for further cholesteatoma. If cholesteatoma is left behind surgically, either planned or unknowingly, this is considered residual disease. After being completely removed, if cholesteatoma forms again, this is considered a recurrence.

CONGENITAL CHOLESTEATOMA

Congenital cholesteatoma is defined by Derlacki and Clemis (2) as an embryonic rest of epithelial tissue in the ear without tympanic membrane perforation and without a history of ear infection. Levenson et al. (3,4) have modified the definition of a congenital cholesteatoma to include a normal pars flaccida and pars tensa, no history of prior otorrhea, and no history of prior otologic procedures. Prior episodes of otitis media without otorrhea are not criteria for excluding congenital origin. Two-thirds of the middle ear congenital cholesteatomas are seen as a white mass in the anterior–superior quadrant (Fig. 151.1). They may also be found within the tympanic membrane and in the petrous apex. The mean age at presentation for a congenital middle ear cholesteatoma is 4.5 years, with a male-to-female preponderance of 3:1 (4).

The pathogenesis of congenital cholesteatomas is incompletely understood. In a review of the development of the epibranchial organs, Teed (5) noted an ectodermal epithelial thickening that developed in proximity of the geniculate ganglion, medial to the neck of the malleus. This mass of epithelial cells soon undergoes involution to become mature middle ear lining. Teed believed that if involution failed to take place, this formation could be the source of a congenital cholesteatoma. In pursuit of this theory, Michaels (6,7) undertook a review of fetal human temporal bones and identified a squamous cell tuft present from 10 to 33 weeks of gestation in 37 of 68 specimens studied. He termed this structure the *epidermoid formation*

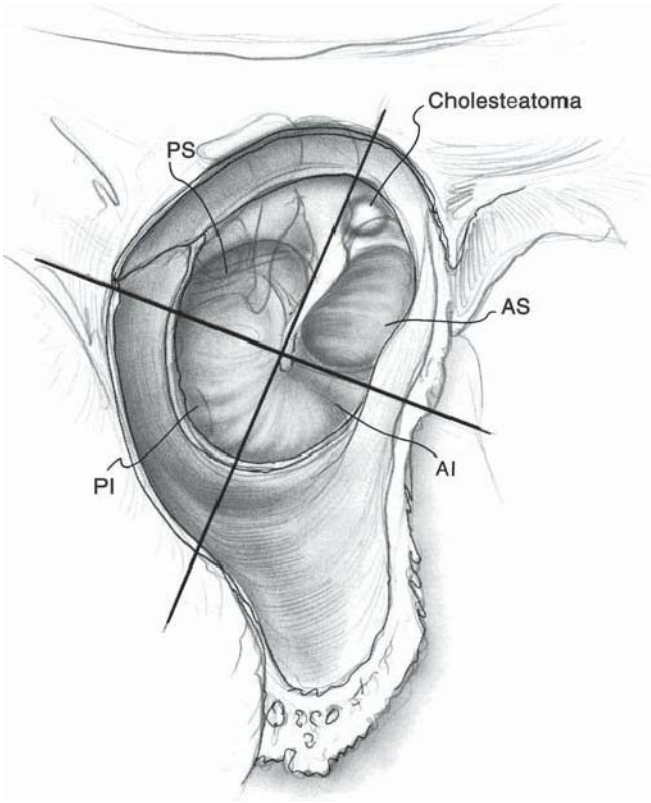

Figure 151.1 Congenital cholesteatoma of the anterior–superior quadrant. AI, anterior inferior; AS, anterior superior; PI, posterior inferior; PS, posterior superior.

and noted it to be located in the anterosuperior wall of the developing middle ear cleft. Failure of the epidermoid formation to involute could be the basis for the development of cholesteatomas in the anterior mesotympanum (8–10). Other investigators implicate ectodermal migration or even metaplasia of the middle ear mucosa in the pathogenesis of congenital cholesteatomas (11,12).

To further complicate the understanding of the development and pathogenesis of congenital cholesteatomas, they have been described as developing in or isolated to the mastoid (13,14). Staging systems and management strategies have been developed by several groups (15–17), with staged surgical procedures recommended for the more complicated or higher-stage lesions.

ACQUIRED CHOLESTEATOMA

Acquired middle ear cholesteatomas come in two varieties: primary or retraction pocket cholesteatoma and secondary cholesteatoma. Cholesteatomas that arise from retraction pockets are known as primary acquired cholesteatomas on the basis that infection has not given rise to the cholesteatoma. Several theories have been advanced to explain the formation of primary acquired or attic retraction cholesteatomas, including invagination of the pars flaccida, basal cell hyperplasia, otitis media with effusion, and perforation of the pars flaccida membrane with epithelial ingrowth

TABLE 151.1 PATHOGENESIS OF CHOLESTEATOMAS

Primary acquired cholesteatomas
Invagination theory
Basal cell hyperplasia theory
Otitis media with effusion theory
Epithelial invasion theory
Secondary acquired cholesteatomas
Implantation theory
Metaplasia theory
Epithelial invasion theory

(Table 151.1). Patients with cleft palates are particularly prone to the development of primary acquired attic cholesteatomas (18–22).

The invagination theory is supported by the observations of Aschoff in 1897 and Wittmaack in 1933 (23). They proposed that an infantile sterile otitis media neonatorum or nonbacterial otitis media develops soon after birth. Before it has had time to resorb, a permanent fibrosis and thickening of the embryonic subepithelial tympanic connective tissue occurs resulting in blockage of the attic causing a localized negative pressure with retraction of the pars flaccida. The fibrosis and thickening in the attic blocks the normal process of pneumatization of the epitympanum and antrum and decreases the pneumatization of the mastoid process and petrous portions of the temporal bone throughout the patient's life. This small dimple-like retraction of the pars flaccida that cannot be reduced by inflation of the eustachian tube is the first stage in the development of an attic cholesteatoma.

A second method by which a small retraction pocket may develop is from long-standing otitis media with effusion (Fig. 151.2). Bluestone and Klein (18) demonstrated that in children with attic retractions, the eustachian tube constricts rather than dilates with swallowing. This results in impaired ventilation of the middle ear and mastoid air cell system and fluctuating or sustained high negative middle ear pressures. Negative middle ear pressure caused by eustachian tube dysfunction can result in retraction of the pars flaccida and collection of desquamated debris.

Like primary acquired cholesteatomas, several pathogenic mechanisms may contribute to the formation of secondary acquired cholesteatomas (Table 151.1). The implantation theory, the metaplasia theory, and the epithelial invasion theory have all been advanced as possible mechanisms involved in cholesteatoma formation. The implantation theory describes the formation of a cholesteatoma by the iatrogenic implantation of skin into the middle ear or eardrum as a result of surgery, a foreign body, trauma, or a blast injury. Cholesteatomas may develop secondary to a myringotomy for ventilating tube

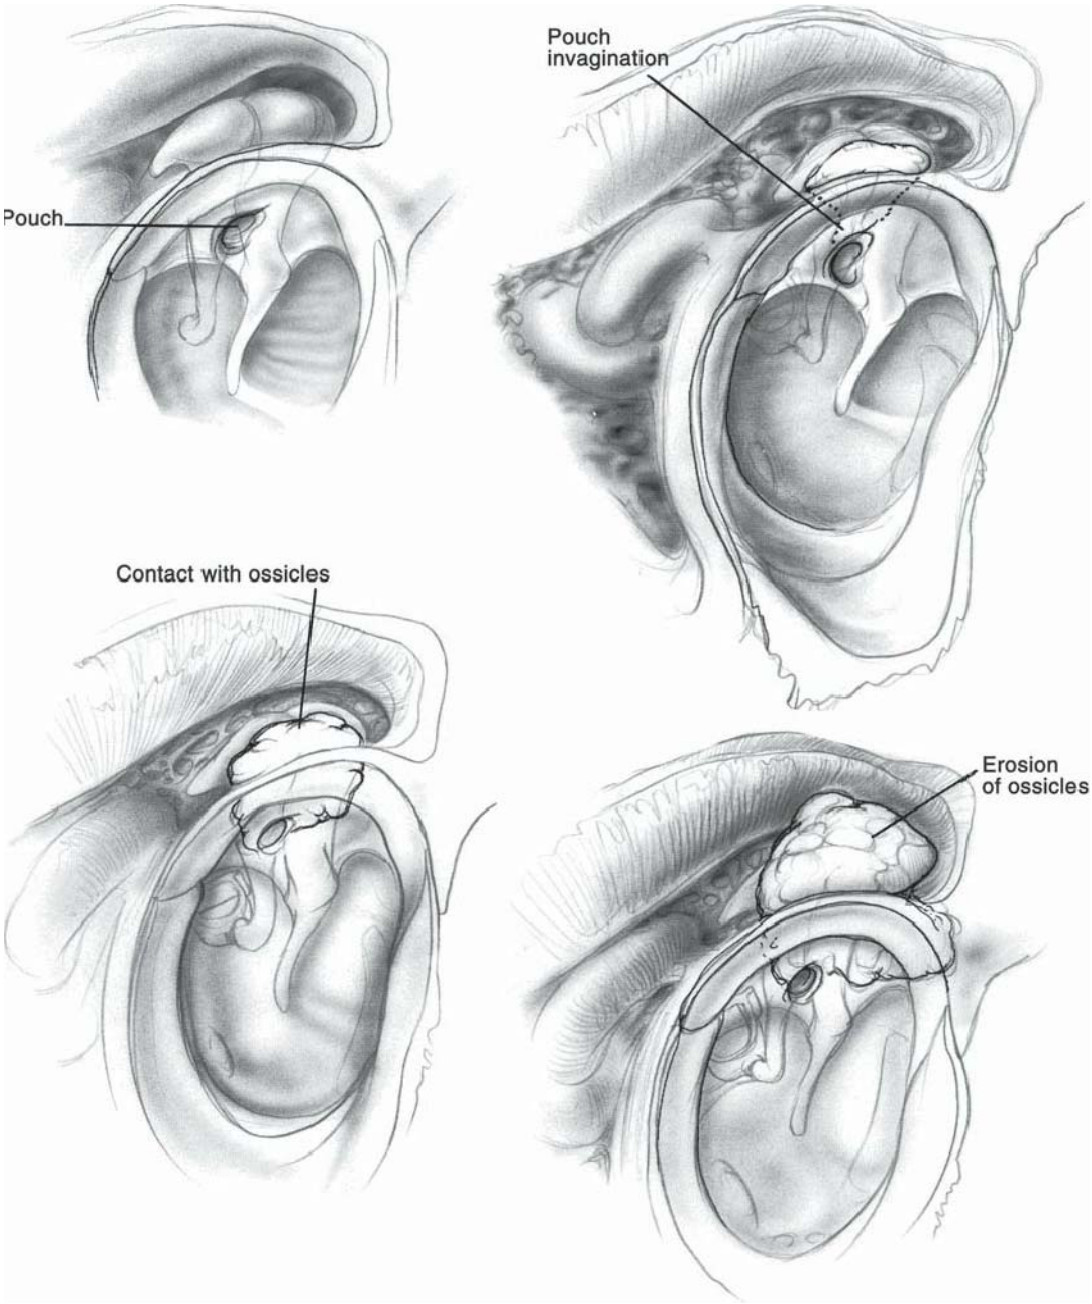

Figure 151.2 Evolution of an attic cholesteatoma.

placement or a tympanoplasty procedure. They occur as a result of epithelial migration or displacement through the myringotomy or from the displacement of a flap of the tympanic membrane into the middle ear at the time of a tympanoplasty. Secondary acquired cholesteatomas are also thought to arise from a perforation as a result of acute necrotic otitis media in childhood (24).

The metaplasia theory describes the transformation of columnar epithelium to keratinized stratified squamous epithelium secondary to chronic or recurrent otitis media. Support for this theory comes from changes that occur in the bronchi in the face of chronic irritation and infection. However, metaplasia is not thought to be a significant cause of cholesteatoma in humans (25). The epithelial invasion theory involves the invasion of the middle ear by skin from the meatal wall of the outer drum surface through a marginal perforation or an attic perforation (26). This is supported by experimental evidence demonstrating that epithelial cells migrate along a surface until they encounter another epithelial surface, at which point they stop migrating; this is known as contact inhibition. If the middle ear mucosa were destroyed by infection, then this would allow for epithelial migration from a marginal perforation. This is the generally accepted theory for the formation of secondary acquired cholesteatomas of the posterior–superior tympanic membrane.

Cholesteatoma may also arise in the external auditory canal (27–31) often after trauma from repeated direct manipulation. Like cholesteatoma in the middle ear, epithelial migration is disrupted in external auditory canal (EAC) cholesteatoma. Patients present with otorrhea, otalgia, bony destruction, and trapped squamous debris, and some have hearing loss. Some EAC cholesteatomas have similar characteristics as keratosis obturans, but in general, surgical removal is the treatment modality of choice for EAC cholesteatoma, where patients with keratosis obturans can usually be managed by frequent office cleanings and topical therapy (32).

A unique feature that cholesteatoma and tympanic membrane epithelium have in common is migration. No other epithelium tested, including skin, vocal cord, and oral epithelium, has shown the locomotion present with tympanic membrane epithelium and cholesteatoma (33). Once a retraction pocket develops, the epithelial migratory pattern is altered and keratin accumulates. This is the second stage in the development of a cholesteatoma. The sac slowly enlarges by accumulation of keratin and other debris until the walls of the attic are reached. Once this point is reached, bone resorption occurs. Three factors appear to be involved in the process of bony resorption: (a) *mechanical*, related to pressure generated by the expansion of cholesteatoma as it accumulates increasing amounts of keratin and purulent debris (34–36); (b) *biochemical*, due to bacterial elements (endotoxins), products of the host's granulation tissue (collagenase, acid hydrolases), and substances related to the cholesteatoma itself (growth factors, cytokines) (37–49); and (c) *cellular*, predominantly induced by osteoclastic activity (50–53). It is likely that bone destruction in cholesteatoma results from a combination of these factors, but clarification is needed regarding their specific roles.

Multinucleated osteoclasts within the subepithelial matrix of a cholesteatoma release acid phosphatase, collagenase, and other proteolytic enzymes that resorb the bone products. The osteoclasts may be further activated by infection, pressure, and Langerhans cells through an immune mechanism. Cholesteatoma debris is a favorite culture medium for bacteria from the external meatus, including staphylococci, *Pseudomonas aeruginosa*, *Proteus*, *Enterobacter*, aerobic and anaerobic nonhemolytic streptococci, diphtheroid bacilli, and *Aspergillus* molds. When the cholesteatoma becomes infected from water contamination, a foul-smelling discharge ensues. An active infected cholesteatoma will resorb bone at a faster rate.

The ability of cholesteatomas to erode bone is what makes them particularly dangerous (Fig. 151.3). Their expansion is dictated by space available, their migratory tendency, and their internal desquamation. Pressure alone may cause bone resorption to take place.

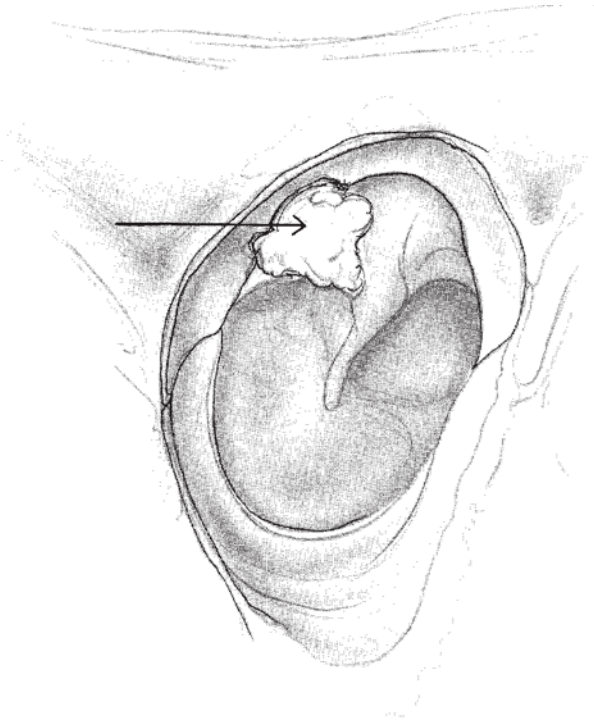

Figure 151.3 Infected cholesteatoma of the attic eroding the scutum (*arrow*).

SURGICAL ANATOMY

Cholesteatomas are channeled along characteristic pathways by ligaments and folds. During the third to fifth fetal months, endothelial-lined sacs develop from evaginations of the first brachial pouch to form the tympanic cavity mucosal folds and ossicular suspensory ligaments. These sacs contact each other, defining the various pouches, spaces, and compartments that divide the middle ear (Fig. 151.4).

The most common locations of origin of cholesteatomas in decreasing frequency are the posterior epitympanum, the posterior mesotympanum, and the anterior epitympanum (54). Epitympanum cholesteatomas originate in a shallow pocket that lies between the pars flaccida of the tympanic membrane and the neck of the malleus. This pouch, known as Prussak space, has as its floor the lateral process of the malleus and its associated mucosal folds lying in the horizontal plane. Cholesteatomas most commonly exit Prussak space by the posterior route: the cholesteatoma penetrates the superior incudal space lateral to the body of the incus. From there, it traverses the aditus ad antrum to enter the mastoid (Fig. 151.5). The cholesteatoma may reach the middle ear by descending through the floor of Prussak space into the posterior space of von Troeltsch, a pouch lying between the tympanic membrane and the posterior mallear fold, the inferior edge of which contains the chorda tympani nerve (Fig. 151.4). This pouch contains a medial, superior, and lateral wall but is open to the mesotympanum inferiorly toward the posterior mesotympanum. Cholesteatomas in this region may involve the stapes, round window, sinus tympani, and facial recess.

The second most common site of origin of cholesteatomas is the posterior mesotympanum (Fig. 151.6). The pars tensa retracts into the mesotympanum to form a cholesteatoma sac that passes medial to the malleus and the incus. Cholesteatomas in this region invade the sinus tympani

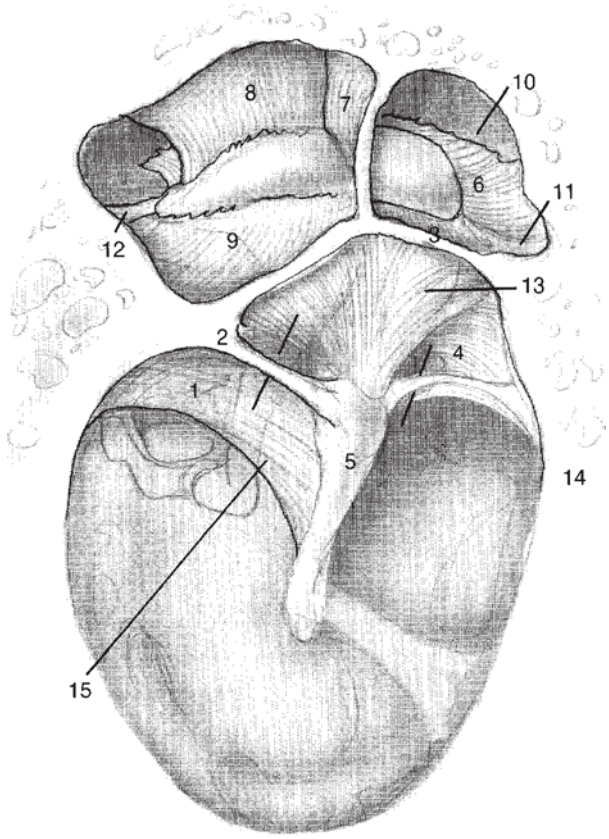

Figure 151.4 Spaces and pouches on the middle ear defined by various ligaments and folds. *1*, posterior mallear fold; *2*, posterior tympanic stria; *3*, lateral mallear fold; *4*, anterior tympanic membrane stria; *5*, malleus (short process); *6*, tensor fold; *7*, superior mallear fold; *8*, superior incudal fold; *9*, lateral incudal fold; *10*, anterior epitympanic space; *11*, anterior mallear ligament; *12*, postincudal ligament; *13*, Prussak space; *14*, anterior pouch (VT); *15*, posterior pouch of von Troeltsch.

and facial recess. The sinus tympani lies between the facial nerve and the medial wall of the mesotympanum. The facial recess is bounded by the fossa incudis and the facial nerve posteriorly and the chorda tympani nerve anteriorly. Both areas are difficult to access surgically (Fig. 151.7) and are common sites of residual cholesteatoma.

Anterior epitympanic cholesteatomas develop as a retraction pocket anterior to the malleus head. The anterior epitympanic space or supratubal recess is limited anteriorly by the middle cranial fossa, the petrous tip, and the root of the zygoma; posteriorly by a bony ridge, termed the *cog*, extending to the cochleariform process; superiorly by the middle cranial fossa; and laterally by the tympanic bone and chorda tympani nerve. The floor of the anterior epitympanum is intimately associated with the horizontal portion of the facial nerve. Cholesteatomas in this region can therefore cause a facial paresis or paralysis (55). Anterior epitympanic cholesteatomas extend to the supratubal recess of the middle ear via the anterior pouch of von Troeltsch, a shallow pouch lying between the tympanic membrane and the anterior mallear fold (Fig. 151.8). If the area anterior to the malleus head is not explored thoroughly during tympanomastoidectomy, cholesteatomas in this region can be overlooked.

PREVENTION

A retraction pocket secondary to eustachian tube dysfunction precedes the development of acquired cholesteatoma. It is good practice to aggressively manage such retraction pockets. A tympanostomy tube should be inserted early in an effort to resolve the negative middle ear pressure and to return the tympanic membrane to a neutral position (Fig. 151.9). However, many retraction pockets persist after tube placement. If the retraction pocket adheres to the ossicles or surrounding structures, it will not reverse. Similarly, if the tympanic membrane has been retracted for a long time and loses all its elasticity, it will not revert to a normal appearance. Tube placement is best done under general anesthesia, where the retraction pocket may be seen to distend as the patient is masked with positive-pressure ventilation. A T-tube or some other long-term ventilation tube is often necessary. If the retraction pocket does not distend with positive-pressure ventilation, then it should be examined carefully to determine the extent and depth of the pocket. Mirror examination or the use of a 90-degree telescope may be used to see hidden borders of the pocket. Most retraction pockets extend into the epitympanum or sinus tympani. If the pocket persists despite tympanostomy tube placement, then surgical exploration may be indicated.

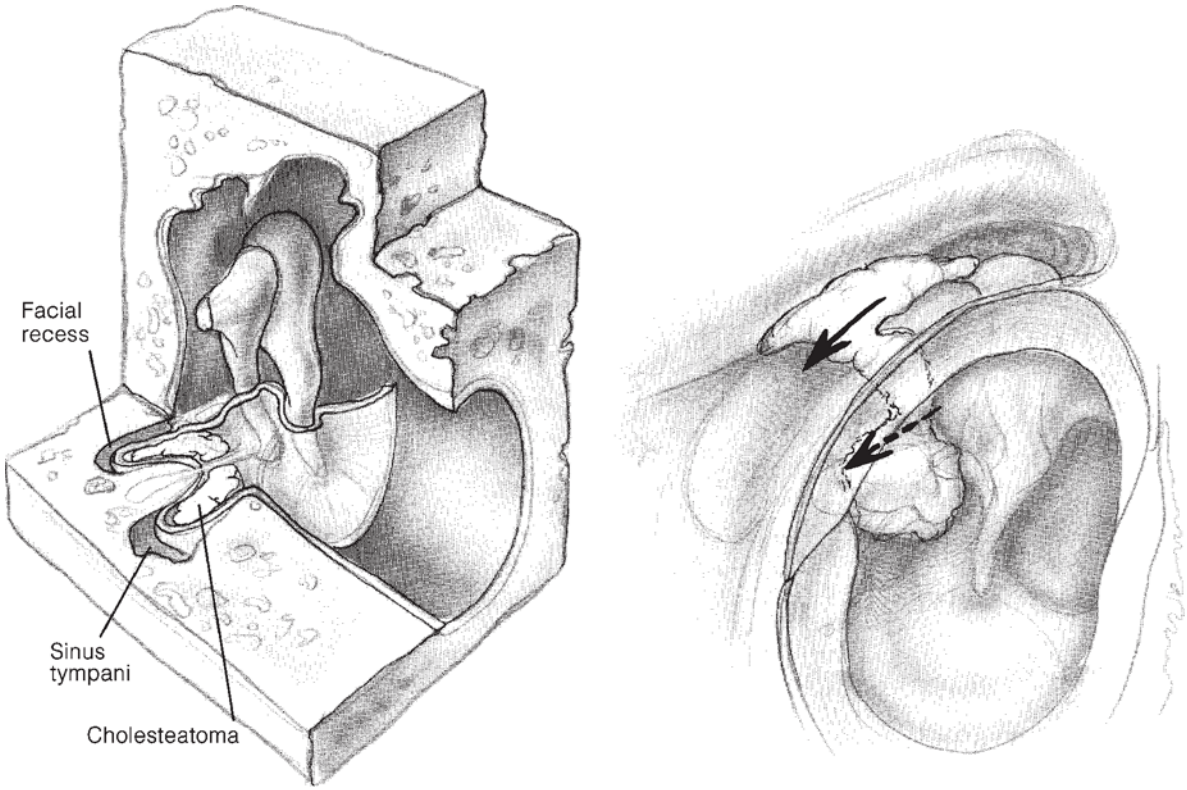

Figure 151.6 Posterior mesotympanic cholesteatoma invading the sinus tympani and facial recess.

PREOPERATIVE EVALUATION

The presence of a cholesteatoma usually requires surgical management unless advanced age or poor health prohibits an operation. However, an elderly patient, with a cholesteatoma that is not infected, and is easily accessible with a microscope in the clinic, can often be managed by serial debridement. Both congenital and acquired cholesteatomas are asymptomatic during early development. Careful questioning of a patient with a middle ear cholesteatoma often reveals many years of subtle ear symptoms, beginning with a progressive hearing loss (usually unilateral). Unilateral hearing loss may be ignored until the cholesteatoma becomes infected secondary to water contamination or an upper respiratory infection, producing a foul-smelling otorrhea. When an infected cholesteatoma is present or there is bone destruction, the purulent discharge tends to be thick, scanty, and fetid. An occasional patient will ignore the

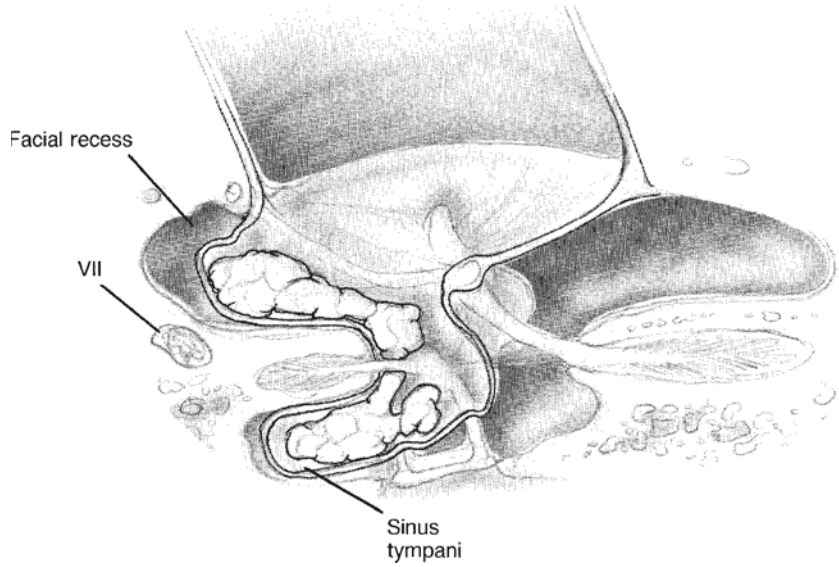

Figure 151.7 Posterior mesotympanic cholesteatoma involving the facial recess and sinus tympani. VII, facial nerve.

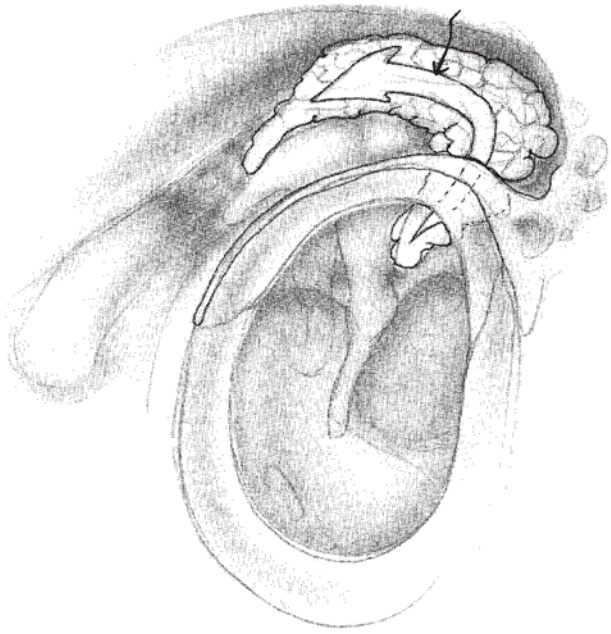

Figure 151.8 Anterior epitympanic cholesteatoma (*arrow*) with extension to the geniculate ganglion.

disease until impending complications develop, heralded by the onset of pain, bloody otorrhea, vertigo, headache, facial paresis, or the appearance of a polyp at the meatus.

The microscopic examination of the ear is the most important diagnostic maneuver in evaluating the presence of a cholesteatoma. The ear must first be meticulously cleaned with cotton-tipped applicators or suction. Acquired cholesteatomas will be noted in the attic or Shrapnell area and in the posterior–superior region, where they are usually associated with erosion of the bony canal. Granulation tissue may arise from the diseased bone of the outer attic wall or scutum or from the posterior bony wall of the external auditory meatus, where it overhangs the facial recess. A polyp consisting of a mass of edematous granulation tissue may protrude through an attic defect. The polyp may continue to enlarge and in fact may extrude through the meatus. If the disease is very extensive, the entire attic and mastoid antrum will be filled with granulation tissue, and the underlying bone will become necrotic and friable over a wide area. General anesthesia may be required in children to perform an adequate examination. Pneumatic otoscopy should be performed in every patient with a cholesteatoma. A positive fistula response characterized by vertigo and nystagmus is very suggestive of erosion into the inner ear, especially the horizontal semicircular canal or less commonly the cochlea. Infected cholesteatomas characterized by fetid, foul-smelling otorrhea and cholesteatomas associated with polyps should be initially managed medically. Dry ears are much easier to operate on than wet, infected ears. While it is not always possible to dry a chronically infected ear with medical therapy, making an effort to calm down active purulence or drainage might make surgery easier. Polyps can be removed with great care in the clinic with microscopic visualization by using a snare, suction, or small cup forceps, or they may be cauterized. However, polyps should never be aggressively pulled out by grasping them because they may be connected to an important underlying structure such as an ossicle or the facial nerve. A vasoconstricting agent applied to a wick will control bleeding. An attic cholesteatoma may be obscured by a crust that looks like cerumen. Removing the crust reveals a whitish keratin mass typical of a cholesteatoma. Granulation tissue can be revealed under the crust as well.

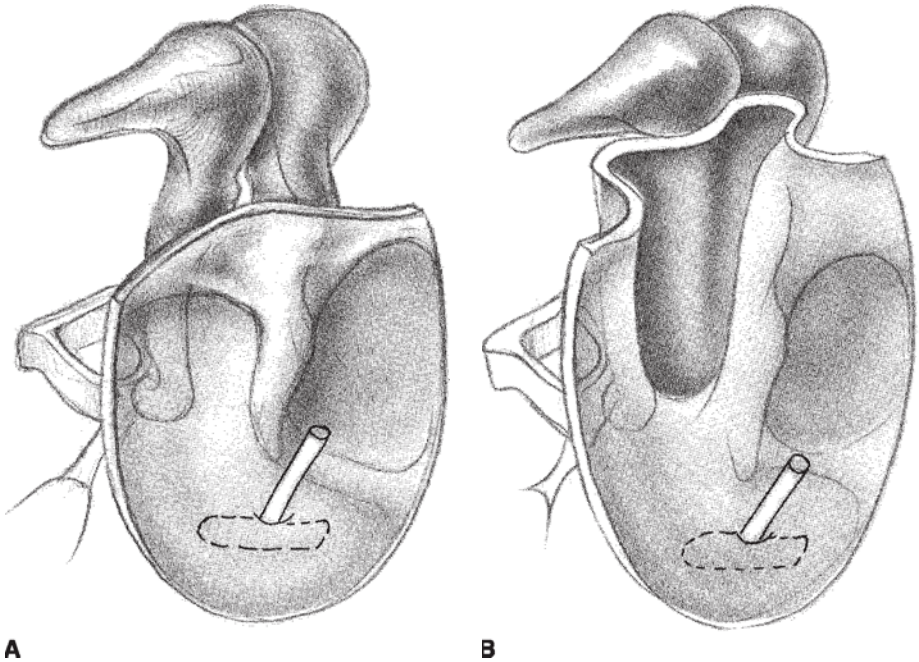

Figure 151.9 **A:** Reversal of a posterosuperior retraction pocket with a tympanostomy tube. **B:** Persistence of a retraction pocket despite tympanostomy tube placement.

Weber and Rinne tests using a 512-Hz tuning fork should be performed and correlated with the audiogram. Preoperative and postoperative audiometric evaluations are essential and should include air and bone thresholds, speech reception threshold, and word recognition. A conductive deficit in excess of 35 dB indicates ossicular discontinuity, usually secondary to destruction of the long process of the incus or the capitulum of the stapes. Alternatively, only a mild conductive hearing loss may be present despite incus erosion if sound is passing through the cholesteatoma directly to the stapes.

The surgical preparation of the patient with an infected cholesteatoma begins with a topical antibiotic drop. Oral quinolones such as ciprofloxacin and levofloxacin are effective with *P. aeruginosa* but are often unnecessary. For medical therapy to be effective, aural toilet is essential. Irrigating the ear with half-strength white vinegar can be effective in controlling infection.

Successful surgical management of cholesteatoma includes exteriorization and removal of all trapped keratinizing epithelium. The goals of surgery should be carefully reviewed with the patient preoperatively. The primary objectives of surgery are a safe, dry ear, with hearing improvement a secondary goal. Specific goals include the following (Table 151.2):

1. Treating complications that have already supervened (extradural abscess, brain abscess, facial nerve palsy, and labyrinthitis)
2. Removing diseased bone, mucosa, granulation polyps, and cholesteatoma to allow drainage and prevent extension of disease to vital structures
3. Stopping the discharge permanently
4. Preserving as much normal anatomy as possible (e.g., posterior canal wall)
5. Preserving or improving hearing

Patients should be carefully counseled about the possible adverse outcomes of surgery: facial paralysis, dysgeusia, vertigo, further hearing loss, tinnitus, recurrent and residual cholesteatoma, cerebrospinal fluid (CSF) leak, and meningitis. The chronic nature of the disease and the need for prolonged follow-up should be stressed. If a mastoid cavity is created, water precautions and the possible need for cavity debridement every 6 to 12 months must be mentioned. The need for second-stage procedures for residual cholesteatoma or ossicular chain reconstruction should be discussed with the patient and performed when appropriate.

TABLE 151.2 SURGICAL GOALS FOR CHOLESTEATOMA

Treat complications
Remove diseased tissue
Obtain a dry "safe" ear
Preserve normal anatomy
Improve hearing

Thin-section (1-mm) computed tomography (CT) scans without contrast, taken in the coronal and axial projections, are often of value in the preoperative assessment of cholesteatomas. It must be emphasized that routine CT scanning is not advocated for cholesteatoma diagnosis, although several alterations of temporal bone anatomy frequently are associated with it. Among these, erosion of the scutum and expansion of the antrum within areas of air cell breakdown and soft tissue density are characteristic. Other features may include ossicular destruction, erosion of the facial canal, mastoid tegmen dehiscence, and erosion into the otic capsule, especially over the horizontal semicircular canal. CT scanning is important in complicated disease and in the evaluation of cholesteatomas and other masses behind an intact tympanic membrane or when the clinical history correlates poorly with physical findings. For example, a CT is usually obtained before surgery when the patient has facial nerve dysfunction, vertigo, or unanticipated degrees of sensorineural hearing loss. Some surgeons also obtain a CT scan when discharge persists despite medical therapy and before revision surgery to anticipate altered anatomy.

SURGICAL MANAGEMENT

Repair of the tympanic membrane is termed a tympanoplasty, and this is required in most patients with cholesteatoma. The advent of the operating microscope greatly facilitated surgery of the tympanum. Cholesteatoma limited to the middle ear can be managed with a tympanoplasty. The status of the ossicular chain must be meticulously evaluated and the extent of the cholesteatoma determined. At times, the cholesteatoma can be removed without disrupting the ossicular chain. If the lateral chain, malleus and incus, are significantly involved with cholesteatoma, the surgeon should consider separating the incus from the stapes and remove the incus. With cholesteatoma medial to the head of the malleus, the surgeon should also consider removing the head of the malleus. Cholesteatoma that is adherent to the stapes can be meticulously removed with microinstrumentation. Many surgeons at this point use a laser to remove cholesteatoma from a mobile stapes. With extensive granulation tissue, significant bleeding, or an exposed facial nerve in the tympanic segment near the stapes, the surgeon should consider leaving some cholesteatoma on the stapes and attempt to remove it at a second look procedure. In addition, cholesteatoma can be difficult to remove from the sinus tympani or from the facial nerve, and the surgeon should evaluate these areas closely at a second procedure.

Surgical treatment of the mastoid in patients with cholesteatoma has gradually evolved. Before the development of the surgical microscope and the high-speed drill, significant morbidity, including facial paralysis, profound sensorineural hearing loss, and dural tears, attended surgery of the temporal bone. Understandably, otologic surgeons of

that day were reluctant to pursue complete removal of cholesteatomas, so a philosophy of exteriorization of cholesteatomas without complete removal emerged. These mastoid cavities, or bowls, led to progressive hearing loss and chronically draining ears, requiring constant supervision.

To avoid cavity problems altogether, the canal-wall-up (CWU) facial recess approach was developed. The posterior canal wall was preserved at all costs. A second stage was planned in 6 to 18 months for removal of residual disease and reconstruction of the ossicular chain. Experience with this philosophy over the past 20 years has resulted in a rethinking of this position by many prominent otologists. A high rate of recidivism approaching 36% in some series (56–62) has resulted in a more individualized approach. Instead of using the same procedure on every ear with cholesteatoma, the procedure is adapted to the extent of disease. The specific operation is determined by local ear factors, general medical factors, and the skill of the surgeon. The local ear factors include the extent of the cholesteatoma, presence of a fistula, clinical assessment of eustachian tube function, degree of mastoid pneumatization, and the degree of sensorineural hearing loss in both ears. General factors include the patient's general medical condition, occupation, and reliability (Table 151.3). The CWU procedure involves preserving the posterior canal wall with or without a posterior tympanotomy (facial recess approach). The posterior tympanotomy is performed through a triangle bounded by the fossa incudis, facial nerve, and chorda tympani nerve. The CWU procedure is indicated in patients with a well-pneumatized mastoid and middle ear space. Relative contraindications to the CWU procedure include a sclerotic mastoid, a labyrinthine fistula, an only hearing ear, and poor eustachian tube function (63–67). The choice of surgical procedure is highly dependent on the status of the opposite ear. Patients with bilateral cholesteatomas are at high risk of recurrence or recidivistic disease, and some surgeons consider a canal-wall-down (CWD) procedure more readily.

The CWD mastoidectomy involves taking down the posterior canal wall to the vertical facial nerve and marsupializing the mastoid into the external ear canal. In a CWD procedure, all accessible air cells are meticulously exenterated. CWD procedures can be divided into those in which the middle ear space is preserved (modified radical mastoidectomy) and those in which the middle ear space is eliminated and the eustachian tube plugged (radical mastoidectomy). A patient with an extensive cholesteatoma might have a large attic defect and a significant portion of the posterior canal wall destroyed from disease. Removal of disease might necessitate a further defect in the posterior ear canal. At this point, the surgeon most likely has removed the incus remnant and the head of the malleus. If reconstruction of the posterior canal is not possible or appropriate, then the surgeon should drill down the posterior ear canal wall to the level of the facial nerve. If it is appropriate to repair the tympanic membrane and create a middle ear space, this would be termed a tympanoplasty with mastoidectomy, or a modified radical mastoidectomy. If it is not appropriate to repair the tympanic membrane, then the eustachian tube can be closed off creating a radical mastoid cavity. At this point in time, a radical mastoidectomy is an uncommon procedure for the majority of otologists.

A more limited procedure is the atticotomy, which involves the removal of the lateral wall of the epitympanum (scutum) to the limits of the cholesteatoma. The atticotomy defect allows for relatively easy cleaning of a narrow epitympanic defect. However, to prevent recurrent cholesteatoma, the atticotomy defect can be blocked with cartilage; this is a variant of a canal-wall-up or canal-wall reconstruction procedure. A more extensive attic cholesteatoma that is lateral to the ossicles and accompanied by a sclerotic mastoid may be managed with a Bondy procedure. This involves the removal of the scutum and portion of the posterior canal wall with preservation of the ossicles and middle ear space. The bony defect is not reconstructed; rather, the cholesteatoma matrix is exteriorized. A patient with a cholesteatoma and poor eustachian tube function as evidenced by absence of middle ear aeration and a sclerotic mastoid should be considered for a CWD procedure (Table 151.4).

Modified radical mastoidectomy
Radical mastoidectomy
Other
Atticotomy
Bondy procedure
CWR
Mastoid obliteration

Numerous variations of a canal-wall reconstruction (CWR) with or without mastoid obliteration procedures have recently been developed to improve exposure and removal of cholesteatoma as in a CWD approach while retaining the benefits of an intact canal wall (improved hearing and avoidance of the bowl cavity) (68–83). In these procedures, a complete mastoidectomy including a facial recess is performed and the posterior canal is removed. The cholesteatoma, the ossicles, and the tympanic membrane are addressed, and the posterior canal wall is replaced. Some surgeons opt to fill the mastoid cavity with bone pate or hydroxyapatite, whereas others leave it open as in a CWU procedure. These techniques have even been used to "repair" radical mastoid cavities. See Chapter 152 for a more complete description of surgical approaches to the mastoid.

With high rates of recurrence or recidivistic disease, especially with CWU or CWR procedures, monitoring the mastoid for cholesteatoma has become extremely important. If cholesteatoma is left behind in the mastoid cavity, or trapped underneath a mastoid obliteration, intracranial or vascular complications can occur even many years after the initial procedure. The advent of diffusion-weighted MRI scans have given the otologic surgeon a noninvasive mechanism to evaluate a patient's mastoid for recidivistic cholesteatoma with fairly high accuracy (84–86).

COMPLICATIONS AND EMERGENCIES

As cholesteatomas expand and become infected, they cause ossicular chain destruction, exposure of the membranous labyrinth, tegmen dehiscence, exposure of the facial nerve, erosion into the temporomandibular joint, extratemporal spread, and infection of the mastoid and intracranial spaces (Table 151.5). See Figure 151.10 for examples of complications from cholesteatoma.

Hearing Loss

Some degree of ossicular chain erosion occurs in most cases of cholesteatoma. Attic cholesteatomas involve the head of the malleus and body of the incus early. As the cholesteatoma expands inferiorly, the lenticular process of the incus and the stapes superstructure are eroded. Pars tensa cholesteatomas that develop from a posterior–superior retraction pocket also involve the lenticular process of the incus and the stapes superstructure. When both of these bones are involved, the hearing loss can be as great as 50 dB. However, if a natural myringostapediopexy develops, then loss may be as little as 20 dB. One should always assume that the ossicular chain is intact in a patient with a cholesteatoma. Cholesteatoma on the lateral surface of the incus can be removed using microsurgical ear instruments without disturbing the ossicular chain. Involvement of the medial surface of the incus often requires removal of the incus by first separating the incudostapedial joint, then the incudomalleolar joint. Cholesteatoma extending medial to the head of the malleus into the anterior epitympanic space (or supratubal recess) usually requires removal of the incus and the head of the malleus. Removal of cholesteatoma from the stapes should be done last by dissecting parallel with the stapedius tendon in a posterior to anterior direction to avoid dislocating the footplate and causing sensorineural hearing loss. One should avoid superior or inferior movement as well as depression of the stapes. The tympanic membrane is grafted to seal the middle ear, and Silastic sheeting is placed over the promontory to prevent adhesions. A second-stage procedure is performed in 6 to 18 months to remove residual cholesteatoma and reconstruct the ossicular chain. If cholesteatoma removal is certain and the mucosal involvement is minimal, the ossicular chain can be reconstructed at the primary procedure.

TABLE 151.5 COMPLICATIONS AND EMERGENCIES CHOLESTEATOMA

Conductive and sensorineural hearing loss
Labyrinthine fistula
Vertigo
Facial paralysis
Extratemporal cholesteatoma
Erosion into temporomandibular joint
Intratemporal infection
Intracranial infection
Brain herniation

Labyrinthine Fistula

A labyrinthine fistula may be found in up to 10% of patients with long-standing cholesteatomas or in revision cases. One should suspect a fistula in patients with chronic ear disease who have sensorineural hearing loss and/or vertigo induced by noise or pressure changes in the middle ear. A positive fistula test with manipulation of the external canal may be present, although its absence does not exclude a fistula. Suppurative labyrinthitis with complete loss of hearing and vestibular function may occur secondary to a fistula from a cholesteatoma. High-resolution, thin-section CT of the temporal bone may reveal a fistula of the semicircular canals or the basal turn of the cochlea. Fistulae of the horizontal semicircular canal are most common (87). The procedure of choice in labyrinthine fistulae is a modified radical (CWD) mastoidectomy. This avoids leaving residual disease concealed in the mastoid cavity and necessitating the patient to undergo multiple procedures. Management of the matrix covering the fistula depends on several factors, including the infection status of the ear, the degree of sensorineural hearing loss in the involved ear as well as the opposite ear, the size and location of the fistula, and the surgeon's skill. In the patient with a fistula of the only hearing ear, a CWD procedure is performed and the matrix is left intact over the fistula. Attempting to remove it places the patient at significant risk for a permanent total sensorineural hearing loss. If the opposite ear has normal hearing and eustachian tube function,

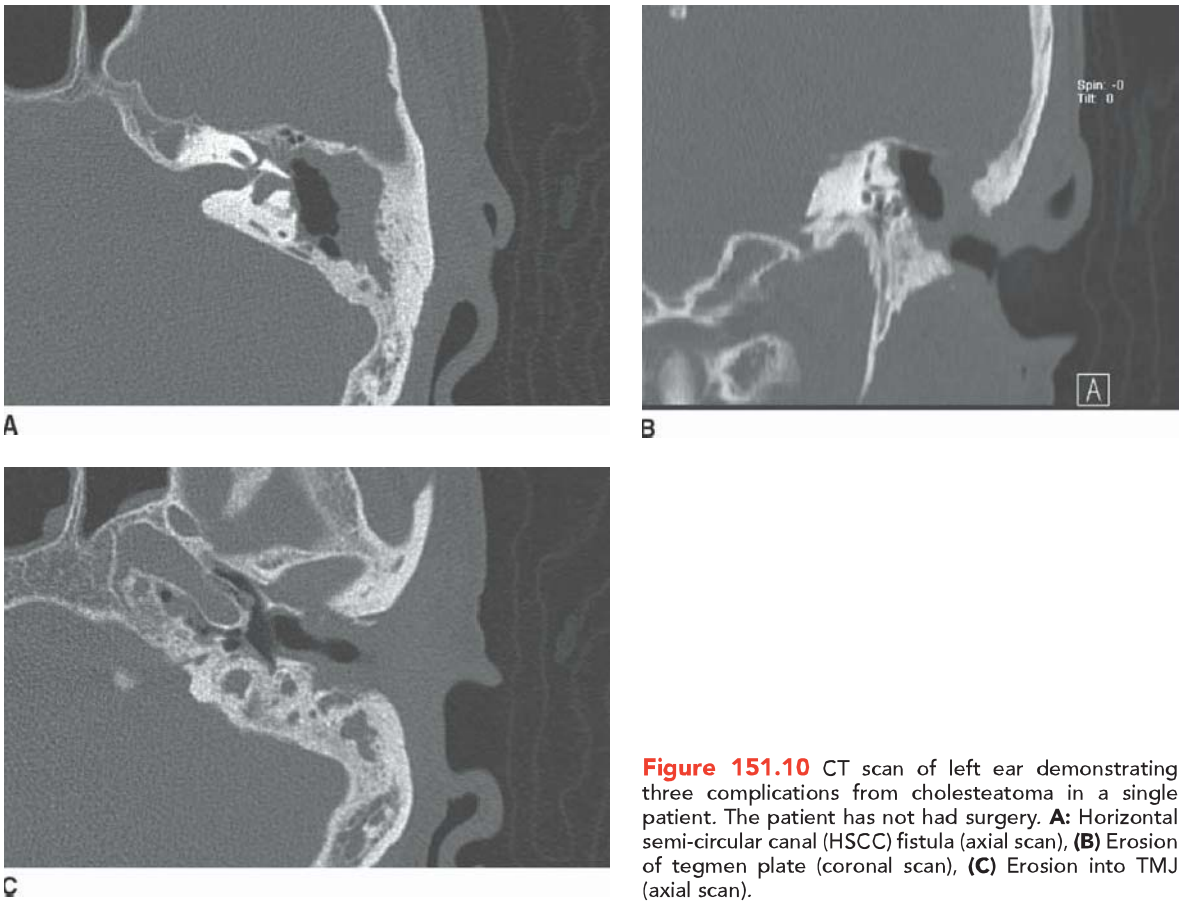

Figure 151.10 CT scan of left ear demonstrating three complications from cholesteatoma in a single patient. The patient has not had surgery. **A:** Horizontal semi-circular canal (HSCC) fistula (axial scan), **(B)** Erosion of tegmen plate (coronal scan), **(C)** Erosion into TMJ (axial scan).

then the surgeon can be more selective in management. If the fistula involves one of the semicircular canals and the mastoid is small, then a CWD mastoidectomy, leaving the matrix on the fistula, is appropriate. If there is a small semicircular canal fistula and the mastoid cavity is large, then the skillful surgeon may elect to perform an intact canal wall procedure, remove the matrix, cover the fistula with fascia, and plan a second procedure. If the hearing is normal, then the matrix covering extensive fistulae of the vestibule or cochlea should be left alone. If cochlear function is profoundly depressed, the matrix should be removed and the fistula covered with fascia. The removal of matrix over the fistula and then immediately covering it with fascia should be the last part of the procedure. Suction should not be used around the fistula site; only blunt dissection is appropriate. If the semicircular canal is inadvertently opened by a drill, then the iatrogenic fistula should be immediately covered with fascia. Parenteral antibiotics and steroids may be helpful. Postoperative vertigo is a sign of labyrinthine and cochlear trauma. A bone-conduction audiogram may be depressed immediately but may recover in 4 to 6 weeks in some cases.

Facial Paralysis

Facial paralysis in patients with cholesteatoma may develop acutely due to infection or slowly due to chronic expansion. In either case, surgery should be performed as soon as the paralysis is recognized. High-resolution, thin-section CT with both axial and coronal scanning will localize the involvement. A common site of nerve involvement is the geniculate ganglion (87). A mastoidectomy with facial recess approach will expose the horizontal and vertical portions of the facial nerve. Moody and Lambert (88) recently reviewed their cases of surgical cholesteatoma and found a high rate of dehiscence of the facial nerve. This should be expected in the case of a facial paralysis. Removing the cholesteatoma and decompressing the facial nerve are sufficient if the nerve is anatomically intact; opening the sheath of the facial nerve is unnecessary. A middle fossa approach is required for cholesteatomas involving the petrous apex. Intravenous antibiotics and high-dose steroids are helpful. The House-Brackmann facial nerve grading system should be used to assess the degree of facial paralysis, and the intraoperative use of a facial nerve stimulator/monitor is helpful. Iatrogenic injury of the facial nerve at the pyramidal turn may occur with drilling of the mastoid. The horizontal segment of the facial nerve may be injured during blunt removal of the cholesteatoma in the middle ear. Immediate repair is performed when the injury is recognized, and decompression of the facial nerve for several millimeters on either side of the injured segment is recommended. A delayed facial paralysis within a few days of surgery indicates minor trauma, with recovery expected within 6 weeks. These patients are treated like those with

idiopathic facial paralysis and given high-dose steroids. Antiviral therapy may also be beneficial.

Infections

Serious infections associated with cholesteatoma include periosteal abscess, lateral sinus thrombosis, meningitis, and intracranial abscess. A high-resolution, thin-section, contrast-enhanced CT scan is performed. Infections of this nature occur in less than 1% of all cholesteatomas because of the widespread use of antibiotics and the tendency to operate earlier. The most dangerous type of infected cholesteatomas are those where drainage through the external auditory canal is obstructed by an inflamed and narrow canal. The egress may be further blocked by mucosal edema, squamous debris, or a polyp. Early intervention to remove cholesteatoma and provide adequate drainage is required.

Periosteal abscess may develop behind a cholesteatoma and inflammation that is blocking the aditus ad antrum or from an extensive cholesteatoma that erodes through the mastoid cortex. It presents as an inflamed, fluctuant postauricular mass. High-dose antibiotics are begun and adjusted according to needle aspiration culture results. Surgery is performed after 24 to 48 hours of antibiotics. It is important to be aware that the dura or lateral sinus may be exposed by disease.

Lateral sinus thrombosis may occur from an infected cholesteatoma. It presents with a characteristic high, spiking fever in a picket-fence pattern. Treatment requires high-dose antibiotics and surgery similar to management of lateral sinus thrombosis in association with acute coalescent mastoiditis. If the cholesteatoma is extensive, a CWD mastoidectomy should be performed (89).

Patients who develop headaches on the side of a cholesteatoma should have a CT scan to rule out an impending intracranial complication. Pain and headache may arise from involvement of dura by the cholesteatoma, by a developing epidural abscess, or because of loculated abscess. Cerebellar or temporal lobe abscesses may exhibit only mild symptoms such as low-grade fever, mild ataxia, or mental changes. Intracranial abscesses should be managed by the neurosurgeon after beginning intravenous antibiotics. After control of the intracranial problem, the otologist can then manage the ear disease. See Chapter 138 for more information on intracranial complications.

Brain Herniation

Brain herniation may develop following previous mastoid procedures presenting as an encephalocele or meningoencephalocele through a defect in the tegmen tympani or tegmen mastoideum. The etiology is thought secondary to aggressive drilling that exposes and traumatizes the dura during previous mastoid surgery. Subsequent brain herniation can be prevented by carefully inspecting any exposed dura for injury. If a tegmen defect is small and the dura is intact, no further treatment is necessary. If there is a disruption in the integrity of the dura with or without a CSF leak, repair is necessary. Many of these defects can be successfully treated from the mastoid. One should circumferentially elevate the dura from the tegmen with a blunt instrument and remove 1 mm of bone from around the site of injury to expose normal-appearing dura. Bleeding is controlled with low-energy bipolar cautery rather than monopolar cautery to avoid injury and thrombosis of cerebral vessels. The surgeon should circumferentially insert temporalis fascia, cut larger than the defect, between the dura superiorly and the tegmen inferiorly. Defects larger than a few millimeters require conchal cartilage or a bone chip for support to prevent herniation. If an established encephalocele or meningoencephalocele is encountered, it should be removed. A biopsy is needed to confirm brain tissue and rule out a malignancy. One should carefully dissect the circumference of the mass to identify its site of origin. In most cases, the encephalocele in the epitympanum or mastoid is necrotic and functionless. The herniated brain tissue is removed to the level of the tegmen and dural defect and repaired as described previously. For larger defects, a mini-craniotomy is performed by making an opening in the squamosa laterally, just above the plane of the tegmen. The dura can then be elevated off the floor of the middle fossa and the defect repaired with fascia and cartilage or bone.

Extratemporal Cholesteatoma

Cholesteatoma can also escape the confines of the temporal bone after otologic surgery in rare instances (90). Concern of cholesteatoma (epidermal inclusion cyst) should arise in a patient with a lesion in or around the parotid gland with a history of prior ear surgery (Fig. 151.11).

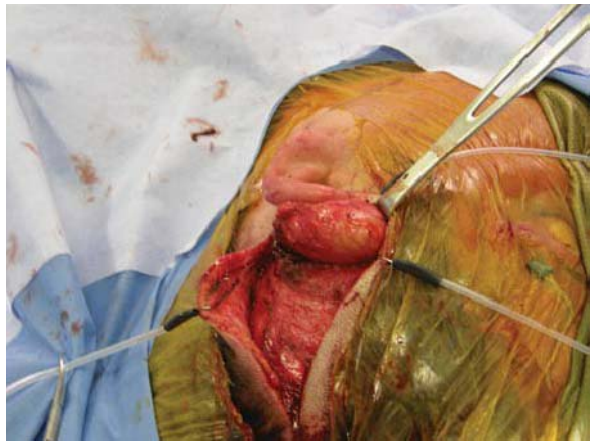

Figure 151.11 Intraoperative photograph of a patient with a cholesteatoma anterior to the left ear in the infratemporal fossa. The patient had multiple ear surgeries for cholesteatoma including a CWD tympanoplasty with mastoidectomy. Except for the mass, the patient was asymptomatic.

HIGHLIGHTS

- The only epithelium that migrates is that of the tympanic membrane and cholesteatoma.
- The posterior epitympanum is the most common location for acquired cholesteatomas.
- Posterior mesotympanic cholesteatomas are common sites of residual cholesteatoma; epitympanic cholesteatomas are common sites of recurrent cholesteatoma.
- Posterior mesotympanic and epitympanic retraction pockets should be managed with either a ventilating tube or a cartilage-supported tympanoplasty if the pocket is adherent.
- Aural polyps can be snared but should not be pulled aggressively because they may be attached to an ossicle or the facial nerve.
- An ideal candidate for a CWU mastoidectomy is a patient with a well-pneumatized mastoid and a cholesteatoma limited to the posterior mesotympanum and antrum.
- The operative approach chosen is dictated by the disease and the hearing status of the involved and contralateral ears.
- Removal of cholesteatoma from the stapes should be done last by dissecting parallel with the tendon.
- One should assume that the incudostapedial joint is intact unless proved otherwise by direct inspection.
- Patients with cholesteatomas who develop new headaches on the same side should have a CT scan to evaluate a potential intracranial problem.

Surgery of the Mastoid and Petrosa

152

Richard A. Chole *Hilary A. Brodie* *Abraham Jacob*

HISTORY

Infections of the ear were recorded as early as 380 BC in the Hippocratic canon, and surgery of the mastoid and petrosa developed as a treatment modality for suppurative ear disease. During the 16th century, Fabricius Hildanus reported a case of spontaneous drainage from a postauricular abscess, for which he advocated early incision and drainage. Riolan the Younger described a procedure akin to mastoidectomy in 1649, and John Luis Petit performed the first surgical trephination of the mastoid in 1774. Petit exposed the mastoid cortex, performed a trephination, and then enlarged the surgically created fistula. JGH Fielitz reported five similar cases in 1785; however, the procedure fell into disrepute after the sensational death of Danish physician Johanne Gust Von Berger in 1792. He died of meningitis 12 days after a mastoidectomy performed by Koelpin and Callisen. Fortunately, Schwartze repopularized the operation in 1873. Since then, technological advancements such as the operating microscope, the high-speed drill, and specialized microsurgical instruments have led to significant improvements in the treatment of mastoid disease. Regions of the skull base previously thought to be inaccessible such as the petrous apex, the complete course of the facial nerve, the endolymphatic sac, and the cerebellopontine angle were now within reach. Indications for temporal bone surgery (Table 152.1) include acute otologic infections (see Chapters 149 and 151), chronic infections with or without cholesteatoma (see Chapters 151 and 149), trauma (see Chapter 150), facial nerve disorders (see Chapter 155), vestibulopathy (see Chapter 166), and tumors of the skull base (see Chapter 147).

SURGICAL TECHNIQUE: MASTOIDECTOMY

Incisions

The two principal incisions used for access to the mastoid cortex are the postauricular incision of Wilde and the endaural incision of Lempert. The postauricular incision provides better overall exposure and allows complete access to the mastoid tip. In adults, the incision is placed 8 to 10 mm posterior to the postauricular sulcus, where it is hidden by the pinna (Fig. 152.1). This incision can be placed more posteriorly for wider exposure as might be necessary during translabyrinthine access to the cerebellopontine angle. It should not be placed directly in the postauricular crease, however, because such placement creates a deep, difficult-to-clean postauricular furrow. In children younger than 2 years, the inferior portion of this incision must be placed more posteriorly than in adults (Fig. 152.1). This is because the tympanic ring in children is underdeveloped, mastoid pneumatization is incomplete, and the stylomastoid foramen is shallow. Therefore, the facial nerve is vulnerable to injury. The surgeon should also keep in mind that congenital anomalies of the temporal bone can result in highly variable facial nerve position.

The postauricular incision is first outlined with a marking pen and infiltrated with a mixture of local anesthetic and epinephrine. The skin and subcutaneous tissues are incised sharply down to the temporalis fascia (superior to the inferior temporal line) and down to the periosteum overlying the mastoid cortex (inferior to the inferior temporal line). The ear flap is elevated anteriorly to identify the posterior edge of the external ear canal. Additional

TABLE 152.1 CLINICAL INDICATORS FOR MASTOIDECTOMY

Strategy
Indicators (one of the following)
- Persistent or recurrent otorrhea
- Persistent or recurrent ear pain
- Conductive hearing loss
- Tympanic membrane perforation and/or cholesteatoma
- Acute mastoiditis with osteitis
- Neoplasm of temporal bone
- Fracture of temporal bone with CSF leak
- Facial nerve paralysis requiring decompression of the facial nerve

Laboratory tests (as indicated)
Audiogram
Other tests (as indicated)
Type of anesthesia (as indicated)
Location of service (as indicated)

Process
Criteria for discharge
- Recovery from anesthesia
- Absence of significant vertigo
- Absence of signs of meningitis or toxic shock syndrome

Outcome
Results
Follow-up
- Healing of mastoid cavity if present
- Healing of surgical wound
- Resolution of presenting symptoms
- Evaluation of hearing

CSF, cerebrospinal fluid.
The American Academy of Otolaryngology—Head and Neck Surgery and the American Society for Head and Neck Surgery have published Clinical Indicators for surgical procedures. These Clinical Indicators are educational statements that have been drafted to assist surgeons in their practice and to promote discussion. These Indicators are not practice guidelines nor do they represent standards of practice with which individuals must conform.

elevation superior to the ear canal exposes the root of the zygoma. Posterior to the ear canal, the postauricular muscle and pericranial soft tissues are incised and elevated in the same plane as described above. This dissection is carried to the mastoid tip. Care must be taken not to dissect anterior to the tip because this endangers the facial nerve in the stylomastoid foramen. Unless the mastoid tip is to be removed, the sternocleidomastoid muscle's insertion onto the tip should not be severed. This minimizes postoperative discomfort. Thus far, the skin and soft tissues of the pinna have been laid anteriorly, but the periosteum still remains attached to the mastoid cortex.

The mastoid cortex is now exposed to start the drilling process (Fig. 152.2). A T-shaped incision is made through the soft tissues and periosteum overlying bone. The superior limb of the "T" is placed along the inferior temporal line (inferior margin of the temporalis muscle) starting at a point just superior to the anterior–superior ear canal. This incision extends posteriorly as far as is needed for adequate exposure. An inferior limb to the "T" is fashioned

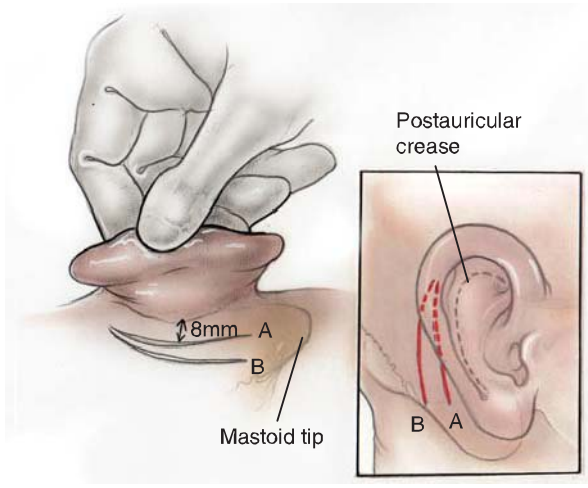

Figure 152.1 Placement of postauricular incisions in adults (*A*) and infants (*B*).

from the mastoid tip to the superior limb just described. Periosteal elevators are then used to elevate the periosteum of the mastoid cortex toward the posterior margin of the ear canal (Fig. 152.2). Superior to the ear canal, the periosteum should be elevated anteriorly along the zygomatic root. Inferior to the ear canal, the surgeon should elevate the periosteum to the anterior margin of the superior aspect of the mastoid tip. If the tip is to be removed, the surgeon must remove all the periosteum from its surface. Taking a few moments to get this anterior extension, superiorly and inferiorly, will allow the ear to be held forward easily with self-retaining retractors. The periosteum can also be elevated somewhat down the ear canal to release tension and prevent a canal laceration.

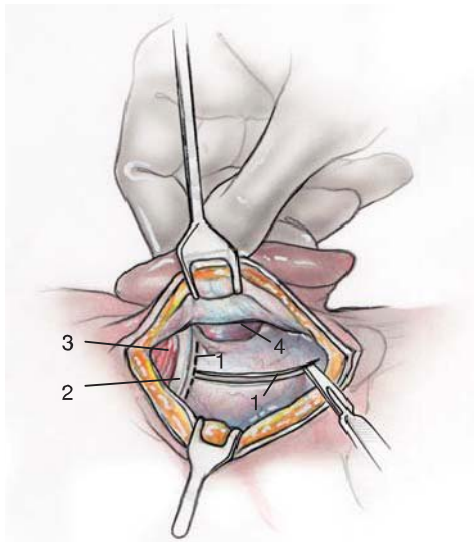

Figure 152.2 After exposure, the periosteum of the mastoid cortex is incised with a "T"-shaped or an "L"-shaped incision. The periosteum is then elevated off the mastoid cortex, exposing the posterior wall of the external auditory canal. *1*, Periosteal incisions; *2*, Temporal line; *3*, Temporalis m.; *4*, Posterior canal skin.

Self-retaining retractors should now be placed to hold the auricle forward. The suprameatal spine of Henle marks the lateral extent of the posterior–superior bony ear canal. The surgeon has raised two anteriorly based flaps: (a) the pinna and subcutaneous tissues and (b) the deeper musculoperiosteal tissues. This deeper flap can be used to partially obliterate the mastoidectomy cavity at the end of a canal-wall-down mastoidectomy. After an intact-canal-wall mastoidectomy, however, both layers should be closed to maintain a patent meatus and a properly positioned auricle.

Endaural incisions were first described by Kessel in 1885 and later popularized by Lempert (1) in 1938. These incisions expose a limited portion of the mastoid cortex. First, a posterior canal wall incision is made from the 12-o'clock to the 6-o'clock position just medial to the bony cartilaginous junction (Lempert I incision). From the 12-o'clock position of the Lempert I incision, a medial-to-lateral incision is made into the incisura between the tragus and root of the helix (Lempert II incision). A relaxing incision is then made at the inferior margin of the Lempert I incision (in a medial-to-lateral direction) (Fig. 152.3A). This allows the posterior ear canal and conchal skin to be mobilized (Fig. 152.3A and B). Skin, soft tissues, muscle, and periosteum over the mastoid cortex are elevated using

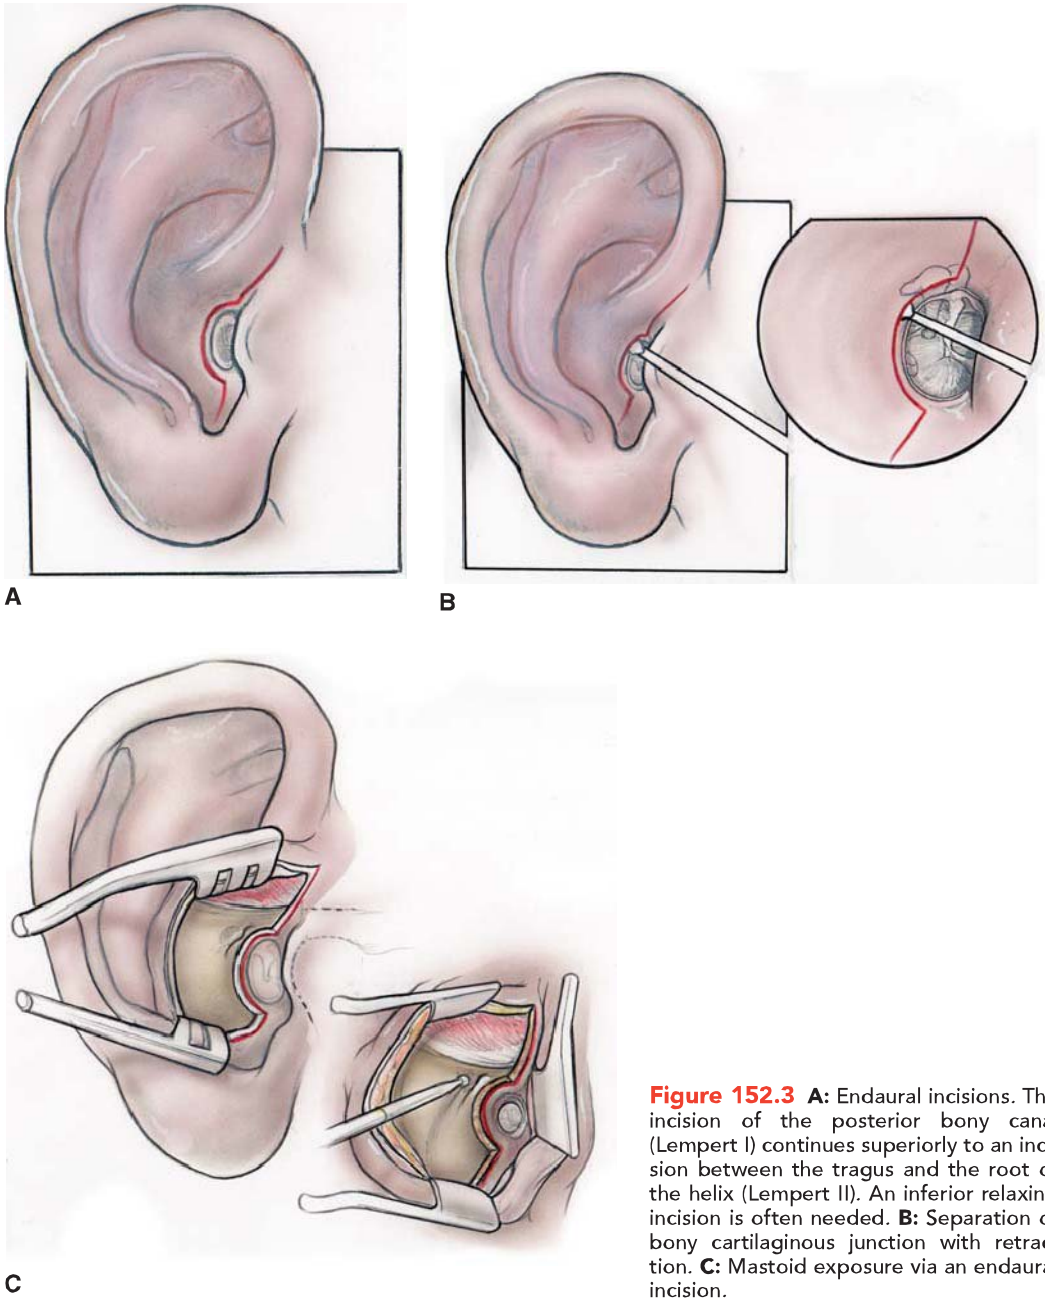

Figure 152.3 **A:** Endaural incisions. The incision of the posterior bony canal (Lempert I) continues superiorly to an incision between the tragus and the root of the helix (Lempert II). An inferior relaxing incision is often needed. **B:** Separation of bony cartilaginous junction with retraction. **C:** Mastoid exposure via an endaural incision.

Lempert elevators, and a self-retaining retractor is placed. Indications for this incision include simple mastoidectomy in very poorly pneumatized temporal bones, atticotomies, canaloplasties, and some tympanoplasties. The endaural incision is closed in a layered fashion approximating deep tissues and then skin.

Surface Landmarks

The inferior temporal line (linea temporalis) defines the inferior limit of the temporalis muscle and provides a topographic landmark for the approximate level of the floor of the middle cranial fossa. Inferior to the temporal line is a protuberance at the posterosuperior margin of the ear canal called the suprameatal spine of Henle. Macewen triangle (cribrose area) is a depressed pit just posterior to the spine of Henle and serves as a topographic landmark for the underlying mastoid antrum. The antrum is typically located 15 mm medial to the cribrose area. The zygomatic root is palpable anterior–superior to the ear canal. The anterior, inferior, and posterior–inferior walls of the external auditory canal are formed by the tympanic bone while the region between the tympanosquamous and tympanomastoid suture lines (i.e., the posterior–superior bony ear canal) is made of squamous bone (Fig. 152.4). The canal skin in this region is thicker and more vascular than the inferior canal skin. When creating a laterally based conchal flap, this thickened "vascular strip" is elevated and preserved. The surface anatomy of the adult and young child's temporal bone differs (Fig. 152.5). Children younger than 2 years have immature tympanic rings and poorly developed mastoids. In children or adults with canal atresia, mal-development of the tympanic bone may result in facial nerve exit directly from the mastoid cortex (2).

Types of Mastoidectomy

The ear canal is made up of a cylinder of skin contained within a bony cylinder. In the normal ear, the tympanic membrane is the medial boundary for both those cylinders. During routine office examination, it is not possible to see the epitympanum or mastoid region when the canal wall is intact. This is because the scutum blocks the epitympanum from view, and the posterior canal wall blocks access to the mastoid cavity. Therefore, removing the superior and posterior aspects of the bony canal allows direct access to the epitympanum and mastoid. This has the advantage of more thorough postoperative examination of the ear in the office; however, it leaves patients with cavities that require lifelong maintenance.

Mastoidectomy procedures can be categorized as *canal-wall-up* and *canal-wall-down* operations. Canal-wall-up procedures include the so-called simple mastoidectomy and the complete mastoidectomy with and without a facial recess approach. Canal-wall-down operations include the radical mastoidectomy, the modified radical mastoidectomy (MRM), and the Bondy MRM. A radical mastoidectomy removes the posterior and superior bony ear canal as well as the tympanic membrane, malleus, and incus. The stapes is usually preserved. The eustachian tube is obstructed, and no middle ear space remains. The entire cavity becomes lined with squamous epithelium. The radical mastoidectomy is "modified" when the tympanic membrane is reconstructed and mucosa-lined middle ear space is created. Ossicular reconstruction can also be performed during a MRM. The Bondy MRM is performed when disease spares the middle ear and only involves the epitympanum and mastoid. The scutum and posterior bony ear canal are removed to exteriorize the antrum and epitympanum, but the middle ear is not entered. Tympanoplasty and ossicular reconstruction can be performed whether the canal wall is taken down or left intact.

Simple Mastoidectomy

A simple mastoidectomy (sometimes called a transmastoid antrotomy) has limited usefulness; it is most commonly used to drain acute mastoid infections that do not respond to antibiotics. The procedure involves removing the mastoid cortex, drilling through the lateral air cells,

and entering the antrum. The remainder of the air cell system is not exenterated. A thorough knowledge of the three-dimensional anatomy of the temporal bone is necessary for even this most direct of approaches (Fig. 152.6).

Complete Mastoidectomy

The complete mastoidectomy affords access to the antrum, attic, labyrinth, endolymphatic sac, and vertical segment of the facial nerve. All the air cells along the tegmen, sigmoid sinus, facial nerve, and semicircular canals are usually removed. The epitympanum is made accessible through the aditus ad antrum, and the incus and head of the malleus can be inspected directly. The incus and the head of the malleus may be removed for greater access to the supratubal recess in the anterior part of the attic.

Using the postauricular incision, the ear is laid forward and the mastoid cortex exposed as described above. The temporal line, spine of Henle, cribrose area, and posterior bony ear canal are used as the initial landmarks for drilling. The location of the mastoid antrum can be approximated by the intersection of a horizontal and vertical line drawn tangential to the superior and posterior margins of the bony external auditory canal. A large cutting burr and continuous suction/irrigation are used to begin the mastoidectomy. Cortical bone is removed inferior to the middle fossa dura (tegmen mastoideum), the posterior edge of the bony ear canal is delineated, and the sigmoid sinus is identified. It is useful to widely saucerize the mastoidectomy bowl by removing any overhanging edges. This permits more light to enter the cavity and allows the surgeon to bring in his or her instruments into the operative field at an angle rather than directly along his or her line of sight. After determining the level of the tegmen, air cells lateral to the sigmoid sinus should be removed to see the blue hue of the sinus through thin bone. The sinodural angle, marking the posterior–superior limit of the mastoid cavity, is then opened. Drilling proceeds medially along the tegmen toward the epitympanum. Keeping this anterior–superior portion of the dissection as the deepest portion of the cavity avoids inadvertent injury to the facial nerve. Körner septum is a plate of bone lateral to the antrum, and it represents the posterior extension of the petrosquamous suture line within the mastoid (3) (Fig. 152.7). The superior aspect of Körner septum must be removed to enter the mastoid antrum. The floor of the antrum, which is the lateral semicircular canal, is a vital landmark that must be clearly visualized (Fig. 152.8). Otic capsule bone of the labyrinth usually appears to be a slightly lighter hue when compared with the surrounding membranous bone.

Once the antrum is entered, the bone of the posterior ear canal wall must be thinned, although excessive thinning may lead to delayed dissolution of this structure. Identifying the posterior incudal ligament (often seen as a white streak through thin bone just inferior to the fossa incudus) is a useful landmark in finding the incus. By flooding the antrum with clear irrigant, the surface of the fluid forms a lens that will bend light from the microscope and allow the surgeon to see the incus before actually coming upon it (Fig. 152.8). Touching the incus with a rotating burr must be avoided because transmission of

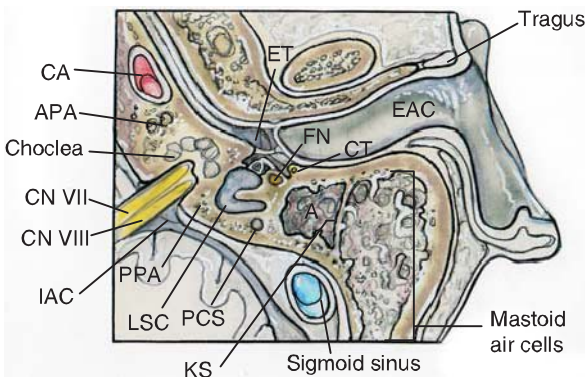

Figure 152.6 Axial section of a right adult temporal bone.

high-frequency mechanical energy to the inner ear can cause sensorineural hearing loss. Once the incus body is identified, removing the bone lateral to the ossicles (between the tegmen tympani and bone of the superior ear canal) opens the epitympanum. Carrying this dissection anteriorly will expose the head of the malleus.

Having found the antrum, the horizontal semicircular canal, and the incus, attention can now be directed to identifying the facial nerve. Bony trabeculae on the bony external auditory canal are removed from a lateral to medial direction. As this dissection proceeds medially, facial recess air cells anterior to the facial nerve will be encountered. The second genu of the facial nerve is located immediately anterior and inferior to the midpoint of the horizontal canal, just medial to the short process of the incus. Here, a 4-mm diamond burr and copious irrigation are used to make wide strokes, starting at the incus superiorly and aimed toward the stylomastoid foramen inferiorly. Adequate irrigation prevents thermal injury to the nerve. The facial nerve should be visualized through thin bone but not completely exposed. As the facial nerve is traced inferiorly, the branch-point of the chorda tympani nerve will be found (Fig. 152.9A). The chorda can then be traced anteriorly and superiorly.

All of the cells within the mastoid tip may be exenterated. The posterior belly of the digastric muscle inserts medially on the mastoid tip. Identifying the muscle through eggshelled bone is referred to as the "digastric ridge," which is actually a surgically created landmark (Fig. 152.9A). Fascia enveloping the digastric muscle is continuous with the fibrous tissue surrounding the facial nerve at the stylomastoid foramen. The stylomastoid foramen enlarges as it exits the inferior portion of the temporal bone. Following the digastric ridge anteriorly in the mastoid tip is one technique used to find the facial nerve. Infralabyrinthine (retrofacial) air cells are those cells medial to the facial nerve, superior to the jugular bulb, and inferior to the posterior semicircular canal. They should be exenterated if disease is found within them or if either the jugular bulb or endolymphatic sac needs to be exposed.

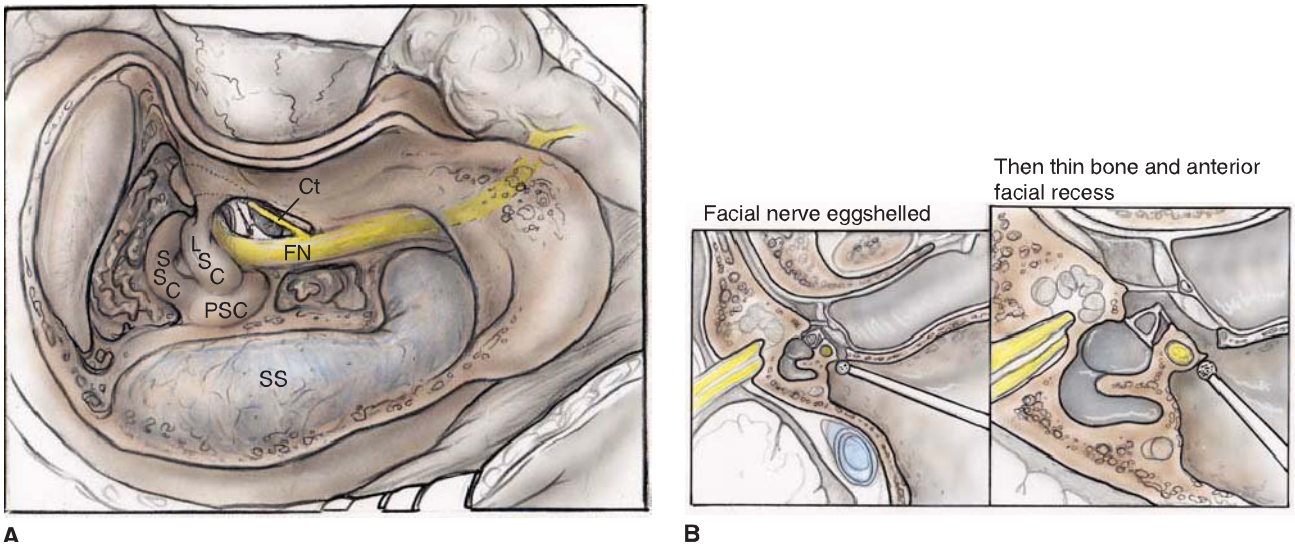

Figure 152.9 Facial recess approach. **A:** Surgical view. The bone over the mastoid portion of the facial nerve and the chorda tympani is thinned. The bone between these two landmarks is removed giving access to the middle ear. **B:** An axial depiction of the facial recess approach illustrates the thinning of bone over the fallopian canal and the opening made into the middle ear between the tympanic annulus and the facial nerve. Ct, corda tympani; SSC, superior semicircular canal; LSC, lateral semicircular canal; PSC, posterior semicircular canal; SS, sigmoid sinus; FN, facial nerve.

Following a complete mastoidectomy, the surgeon should thoroughly irrigate the cavity to remove bone dust, which may otherwise cause ossicular fixation. The complete mastoidectomy cavity should consist of a well-defined tegmen tympani and tegmen mastoideum superiorly, a clearly delineated sigmoid sinus posteriorly, an open sinodural angle, well-visualized semicircular canals, an intact posterior bony ear canal wall, and the facial nerve seen through thin bone.

Complete Mastoidectomy with a Facial Recess Approach

The facial recess is an aerated extension of the posterior–superior middle ear space. Medial to the tympanic annulus and lateral to the fallopian canal, it allows access to the middle ear from the mastoid cavity without disruption of the tympanic membrane. Some surgeons use the term "posterior tympanotomy" to describe a facial recess approach. The facial recess is a triangular opening bordered posteromedially by the facial nerve, anterolaterally by the chorda tympani nerve, and superiorly by the fossa incudis (Fig. 152.9). An open facial recess provides access to the ossicles, stapedius tendon, round window, tympanic segment of the facial canal, and cochleariform process (4). Dissection of the region of the facial recess should be performed with diamond burs and copious suction irrigation to avoid mechanical or thermal damage to the nerves.

There are numerous indications for performing a posterior tympanotomy. These include transmastoid cochlear implantation, middle ear electromechanical implantation (5), presence of cholesteatoma within both the middle ear and mastoid, chronic otomastoiditis with granulation tissue or cholesterol granuloma, and tumors within the middle ear and mastoid (6).

In the anterior epitympanum, a projection of bone extending inferiorly from the tegmen tympani (the cog) can obscure disease in the supratubal recess (7). The presence of granulation tissue, cholesteatoma, or tumor in the anterior epitympanum and supratubal recess may require removal of the incus, head of the malleus, and the cog for increased exposure. If removal of the incus is necessary, the incudostapedial joint must first be disarticulated through the facial recess before removing the incus and malleus head. Opening the facial recess can also improve aeration of the mastoid by providing an alternate route for air from the eustachian tube to enter the mastoid (other than the aditus ad antrum). Inadequate aeration or loculation of the mastoid cavity may result in recurrent retraction pocket formation, mucocele formation, or chronic otomastoiditis. One way to test for adequate aeration of the mastoid cavity is to fill the middle ear with saline and watch for flow into the mastoid. When the incus has been removed, rarely is a facial recess approach required for aeration.

When thinning the posterior bony canal wall, the facial recess is encountered medially. It is first noted as a color change (darker appearing bone) anterior to the facial nerve, just inferior to its second genu. The facial nerve lies medial and inferior to the tip of the short process of the incus. The second genu of the facial nerve usually forms an angle of 95 to 125 degrees; it usually makes a gentle curve rather than an abrupt turn. The nerve may descend directly through the mastoid in a caudal direction, or it may deviate from the vertical by 5 to 35 degrees. The facial nerve travels laterally as it moves inferiorly through its vertical segment and is located lateral to the posterior–inferior tympanic annulus in 65% of cases (8).

The surgeon should be aware of potential facial nerve anomalies. Dehiscence of the facial nerve is reported to occur in 55% to 57% of temporal bones (9). The facial nerve is dehiscent approximately 50% of the time just superior to the oval window, in its tympanic segment. Other areas of possible dehiscence include the geniculate ganglion, facial recess, tympanic sinus, and the retrofacial region. Bone erosion secondary to cholesteatoma may also create dehiscence in the fallopian canal. Before encountering the nerve, the vasa nervorum can be appreciated through the eggshelled bone overlying the nerve. The most common site of injury to the facial nerve in mastoid surgery is inferior to the lateral semicircular canal just beyond the second genu (9).

At a variable point along its descent toward the stylomastoid foramen, the facial nerve gives off the chorda tympani nerve. This nerve travels in an anterior, superior, and lateral direction. Facial nerve anomalies can include a chorda that branches from the facial nerve after it exits from the stylomastoid foramen, a bifid facial nerve (10), or a nerve coursing through the middle ear space just inferior to the oval window (11). Once the chorda tympani nerve is identified, the bone between the chorda and the facial nerve may be removed with a small diamond burr and copious irrigation. This opens the facial recess (Fig. 152.9A). If additional exposure is required, an extended facial recess approach can be performed, where the chorda is sacrificed and the facial recess extended inferiorly. Care must be taken to identify the fibrous annulus of the tympanic membrane and to avoid inadvertent injury to the tympanic membrane or medial ear canal.

Intact Canal Versus Canal-Wall-Down Mastoidectomy

Both the open (canal-wall-down) and the closed (intact canal with facial recess or posterior tympanotomy) procedures have advantages and disadvantages. Judgment as to which procedure to perform depends on the nature of the disease, the reliability of the patient, and the experience of the surgeon (Table 152.2).

The intact-canal-wall approach offers several advantages over open (canal-wall-down) techniques. First, postoperatively there is no mastoid cavity to care for. Patients

TABLE 152.2 OPEN VERSUS CLOSED TECHNIQUES FOR MASTOIDECTOMY

	Advantages	Disadvantages
Intact wall	Physiologic tympanic membrane position Deep middle ear No mastoid bowl	Residual cholesteatoma may be occult Recurrent cholesteatoma may occur in attic Delayed canal breakdown Incomplete exteriorization of facial recess Second stage often required
Canal-wall-down	Residual cholesteatoma visible on follow-up Recurrent cholesteatoma is rare Total exteriorization of facial recess	Mastoid bowl maintenance can be a lifelong problem Middle ear is shallow and difficult to reconstruct Position of pinna may be altered Second stage sometimes required

with cavities often require regular office debridement, may have a difficult time fitting hearing aids, need to adhere to water precautions, and have meatoplasties that may be cosmetically unappealing. An intact-canal procedure also allows for a more physiologic ossicular reconstruction with a deeper, better-aerated middle ear. Some authors, however, have found no significant benefit in hearing results for intact-canal-wall mastoidectomy compared with canal-wall-down procedures (12,13).

There are several potential disadvantages to the intact-canal-wall approach. First, there is an increased risk of residual or recurrent disease. Widely varying results using a canal-wall-up mastoidectomy have been reported in the literature. However, most of the larger series reveal residual cholesteatoma in 20% to 35% of cases and recurrent disease in 5% to 20% (14–17). This is in contrast to results for open procedures in which there is a 2% to 17% rate of residual disease and a 0% to 10% chance for recurrence (18,19). Although uncommon, a second potential problem with the intact-canal-wall procedures is delayed breakdown of the bone of the posterior canal wall. This is due to compromised blood supply from over-thinning the bone. A third disadvantage is an inability to see the mastoid cavity in the office for surveillance. Some surgeons routinely perform "second look" operations 6 to 12 months after the initial procedure. A staged ossicular reconstruction can also be accomplished at that time. Careful patient selection is vital. Intact-canal procedures should be performed in reliable patients who plan to follow-up regularly in the office.

Radical Mastoidectomy

The radical mastoidectomy is the most aggressive of the open cavity mastoid procedures. The classic radical mastoidectomy involves a canal-wall-down mastoidectomy combined with complete removal of the tympanic membrane, annulus, malleus, incus, and all middle ear mucosa. The eustachian tube is stripped of mucosa and obliterated with packing (fascia, muscle, or bone). The goal of radical mastoidectomy is to establish a dry, open cavity devoid of secretory epithelium. Before the advent of tympanoplasty, this radical procedure was by far the most common open procedure. However, it is rarely performed today. Most surgeons now prefer an MRM with reconstruction of a middle ear space and the sound conduction apparatus. If disease permits, a graft can be placed isolating the eustachian tube and round window from the middle ear, creating a cava minor reconstruction. However, there are still some indications for a radical mastoidectomy; these include unresectable cholesteatoma with extension into the eustachian tube, cholesteatoma with erosion into the cochlea or labyrinth, or patients who have had multiple failed MRMs.

The procedure involves performing a complete (intact bony canal) mastoidectomy with identification of all the landmarks discussed previously. The superior and posterior canal walls are then removed with a cutting burr and suction–irrigation. Prior to encountering the ossicles, the incudostapedial joint is separated and the head of the malleus as well as the incus are removed. The bone of the canal wall is lowered to the level of the mastoid portion of the fallopian canal, but the stapes is preserved. A diamond burr with copious irrigation is used to identify the facial nerve through thinned bone. All mucosa from the mastoid and middle ear is removed, and the eustachian tube is packed with fascia or bone. The mastoid tip is removed. Care should be taken to lower the facial ridge, remove overhanging edges, and lower the bone of the inferior canal wall so as to prevent creation of a dependent mastoid tip. To reduce the depth of the cavity, its perimeter is well saucerized.

Modified Radical Mastoidectomy

The radical mastoidectomy operation is termed "modified" when a middle ear space is reconstructed (Fig. 152.10). The MRM begins with a complete mastoidectomy. The decision to take the canal wall down is then based on the extent of disease (Table 152.2). Most of the bone lateral to incus can be removed quickly with a large cutting burr and the scutum made flush with the anterior canal wall. Because

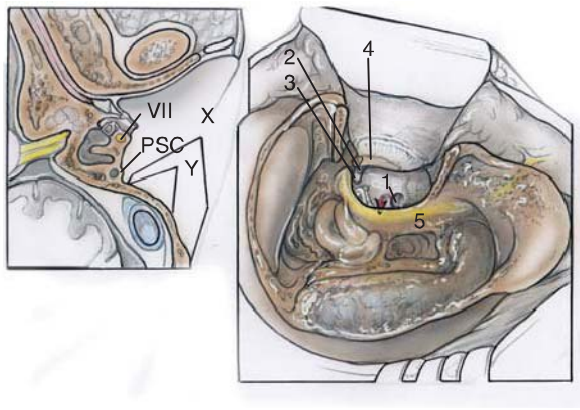

Figure 152.10 Completed canal-wall-down MRM. **Left:** Axial view demonstrating the complete removal of air cells of the mastoid and saucerization over the sigmoid sinus. X, Potential depth without saucerization; Y, Potential depth with saucerization. **Right:** Surgical view of a completed, canal-down mastoidectomy *1*, Round window; *2*, Tensor tympani tendon; *3*, Cochleariform process; *4*, Manubrium of malleus; *5*, Facial ridge. *Red arrow*—sinus tympani.

the facial nerve is medial to the incus, it is protected. The bone immediately lateral to the ossicles must be removed carefully with microinstruments rather than the drill. This avoids direct contact between the rotating burr and ossicular chain. Alternately, the incudostapedial joint may be separated and the incus and head of the malleus removed. The posterior and inferior portions of the remaining bony ear canal are then removed. The bone, lateral to the facial nerve, called the "facial ridge," is drilled down to the level of the fallopian canal, leaving a thin covering of bone over the facial nerve.

A few technical points deserve mention. Once the bulk of the posterior ear canal has been removed with cutting burrs, the vertical (mastoid) segment of the facial nerve is found by lowering the facial ridge with a diamond burr. The nerve should be seen through thinned bone. Actual exposure of the facial nerve should be avoided, however, because exposure puts the nerve at risk. With radical mastoidectomies and MRMs, the mastoid cortex must be well saucerized and the mastoid tip removed. This precludes a deep cavity with overhanging edges that can be difficult to cleanse. Saucerization makes the cavity shallow by allowing surrounding soft tissues to prolapse inward. The inferior portion of the tympanic ring should be lowered so it is flush with the hypotympanum. This prevents the formation of a dependent region in the hypotympanum that may collect debris postoperatively. An anterior canal wall canaloplasty should be performed when the prominence of the anterior wall obscures the anterior tympanic sulcus. An incision is made in the anterior canal wall just lateral to the tympanic annulus, the skin is raised in a retrograde manner back to the bony cartilaginous junction, and the bone sculpted as necessary. One should use a large diamond burr with constant suction–irrigation to avoid entering the glenoid fossa.

After mastoid surgery has been completed, the middle ear space is reconstructed. Commonly a fascia or cartilage graft is laid from the anterior annulus to and over the facial ridge. The graft must be well positioned as to not adhere to the promontory. Surgeons may elect to place Silastic over the promontory to prevent adhesions between the drum and middle ear mucosa. Although the middle ear is shallow in open techniques, there is usually sufficient space to perform an ossiculoplasty.

The Bondy Modified Radical Mastoidectomy

The Bondy procedure (20), first suggested by Körner (3) in 1899, is a variation of the MRM. It can be performed through either an endaural or postauricular incision. This operation is used in cases of large attic cholesteatomas in which the middle ear has been spared of disease. An atticotomy is performed first. The entire scutum is then removed to expose the epitympanum, to marsupialize the cholesteatoma, and to debride its keratin content. The medial wall of the cholesteatoma matrix is left in place over the body of the incus and head of the malleus in the epitympanum. This seals the middle ear space. If the cholesteatoma is seen extending around the ossicles, the surgeon must be prepared to perform a traditional MRM. If involvement of the middle ear is in question preoperatively, a high-resolution computed tomography (CT) scan of the temporal bone with axial and coronal views may help determine whether a Bondy procedure is indicated. This operation is reserved for those ears with large primary acquired cholesteatomas in which hearing is preserved and the ossicular chain is free of disease. A Bondy mastoidectomy is a particularly useful technique in cases with cholesteatoma and a labyrinthine fistula, especially in an only hearing ear. After the procedure, keratin can be debrided in the office while leaving the medial matrix of the cholesteatoma intact over the fistula. The surgeon must be vigilant, however, during each office examination. If cholesteatoma appears to extend into the middle ear, this finding should be verified with CT imaging and a traditional MRM would then become necessary.

MEATOPLASTY AND MASTOID OBLITERATION

The most important factors in avoiding a chronically draining cavity are thorough removal of disease during surgery, designing a properly shaped mastoid cavity, and creating a wide external auditory meatus.

Mastoid Obliteration

Following canal-wall-down mastoidectomy, the patient is left with an open mastoid cavity. The keratinizing squamous epithelium that lines the mastoid bowl is prone to collecting debris and should be cleaned on a regular basis. Many patients must adhere to lifelong water precautions to

minimize risk of infection. Some technical considerations help to limit postoperative complications in a canal-wall-down mastoidectomy. Wide saucerization of the mastoid bowl allows the surrounding soft tissues to prolapse into and partially obliterate the cavity. Lowering the bone lateral to the fallopian canal and performing a generous meatoplasty also helps. Avoiding a dependent mastoid tip prevents accumulation of debris in this difficult-to-clean area. Lowering the bony canal wall and inferior tympanic annulus flush with the hypotympanum facilitates in-office access to the dependent areas of the mastoid.

Muscle/tissue flaps. Some surgeons obliterate the mastoidectomy cavity in more formal ways. Originally described by Moser (21), the "Palva flap" has been used successfully in obliterating mastoid cavities (22,23). This flap is a laterally based postauricular musculoperiosteal flap that is rotated into cavity at the end of the procedure. Postmortem histologic examination of temporal bones from patients who underwent mastoid obliteration with the Palva flap has demonstrated viable muscle, fat, collagen, and richly vascularized tissue years after the procedure. There can be some atrophy, however, over the 5-year period after mastoidectomy. Some cavities widen as a consequence (24). Other flaps utilized for mastoid obliteration include an anteriorly based temporalis muscle flap or temporalis fascia flap based on a superficial temporal artery pedicle (the Hong Kong flap) (22). Such flaps provide bulk, cover exposed bone, recruit a blood supply, and provide a surface for epithelial migration. Palva (25) has advocated the use of bone pâté and bone chips for obliterating the mastoid defect. It is important to collect the bone pâté from cortical bone, before entering the diseased portions of the mastoid. This pâté is laid into the cavity at the end of the case and flaps rotated over it. All bone pâté must be completely covered by fascia or the Palva flap. Osteoneogenesis then results in further reduction of the size of the mastoid cavity (26) over time.

Replacement of the canal wall. Gantz et al. (27) have described carefully removing the posterior wall, exenterating disease as needed, replacing the wall, and filling the mastoid with bone chips.

Other techniques. Synthetic materials have been used for mastoid obliteration with mixed results (28,29). We recommend caution in the use of alloplastic materials for mastoid obliteration when infection is present as there have been reports of troublesome complications using hydroxyapatite preparations (30).

Meatoplasty

Enlarging the external auditory meatus is a necessary part of canal-wall-down procedures. It promotes aeration and epithelialization of the canal and cavity, facilitates effective postoperative care, and makes office debridement of the cavity much easier. An adequate meatoplasty also reduces the depth of the bowl. Several techniques to enlarge the external auditory meatus have been devised. Each involves removing some conchal cartilage and draping the posterior meatal skin into the mastoid bowl (Fig. 152.11). An excellent meatoplasty can be performed by connecting superior and inferior Lempert endaural incisions with the postauricular incision. The superior cut is brought out laterally into the tragal incisura while the inferior cut is curved just medial to the antitragus. This creates a laterally based composite flap containing conchal cartilage and meatal skin. Varying amounts of this cartilage can be removed (through the postauricular incision), leaving behind thin conchal skin that drapes into the mastoid bowl (Fig. 152.11B) (31). Adequate resection of cartilage and appropriate positioning of the posterior canal skin are vital (Fig. 152.11C). The meatus can be maintained open by placing absorbable sutures from the remaining conchal cartilage and perichondrium to the postauricular periosteum. Three sutures are usually placed: one posterosuperiorly, one directly posterior, and the third posteroinferiorly. The sutures are not tied until all three have been properly placed. These tacking sutures prevent postoperative protrusion of the auricle and collapse of the meatus. This meatoplasty technique can be adapted to individual reconstructive needs. Permanent sutures may be used in recalcitrant cases of meatal collapse. Some have advocated suturing the medial margin of the posterior canal skin to the subcutaneous tissue posterior to the mastoidectomy defect, thereby pulling the meatus open. While this maneuver does open the meatus, it usually results in a more voluminous mastoid cavity than desired.

ENDOSCOPY

Endoscopes often see where the microscope cannot. The surgeon's view through the operating microscope depends on a clear line of sight. A 1.7- to 2.8-mm, 30-degree rigid telescope, however, can look around a corner to visualize the facial recess, sinus tympani, or epitympanum and it can be inserted through a tiny incision. It can also be used to assess the depth of retraction pockets and determine the extent of cholesteatomas. Some authors have advocated the use of endoscopes for second-look procedures following intact-canal-wall tympanomastoidectomies (32). Rosenberg et al. (33) reported that endoscopic findings correlated well with open surgical exploration in 10 out of 10 patients. The role of endoscopy will continue to expand in the otologic and neurotologic applications as surgeons become more comfortable with their use and larger studies confirm their efficacy.

ENDOLYMPHATIC SHUNT

In 1927, Guild (34) proposed that endolymph in the inner ear may flow from the cochlea to the endolymphatic sac. It was near this time that Portmann (35) first incised the endolymphatic sac in the treatment of Ménière disease. Interestingly, it was not until a decade later that Hallpike and Cairns (36) demonstrate the histopathology of endolymphatic hydrops in patients with Ménière disease.

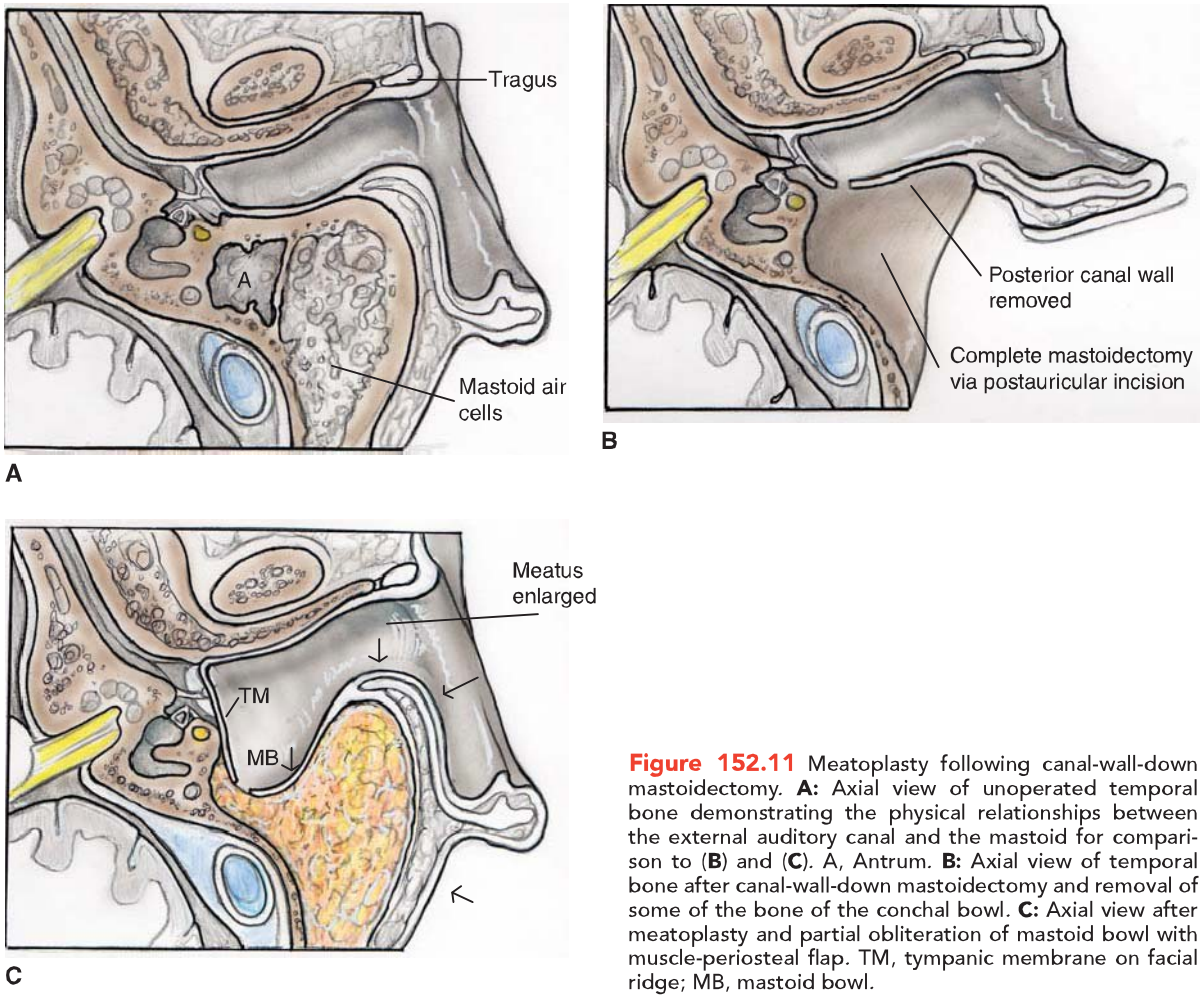

Figure 152.11 Meatoplasty following canal-wall-down mastoidectomy. **A:** Axial view of unoperated temporal bone demonstrating the physical relationships between the external auditory canal and the mastoid for comparison to (**B**) and (**C**). A, Antrum. **B:** Axial view of temporal bone after canal-wall-down mastoidectomy and removal of some of the bone of the conchal bowl. **C:** Axial view after meatoplasty and partial obliteration of mastoid bowl with muscle-periosteal flap. TM, tympanic membrane on facial ridge; MB, mastoid bowl.

Since then, multiple procedures have been designed to "shunt" or "decompress" endolymphatic sac for the treatment of intractable Ménière disease (37). Successful control of vertigo has been reported in a majority of patients regardless of the technique used, but some have questioned the efficacy of these procedures (38) (see Chapter 166).

Exposure of the endolymphatic sac requires a complete mastoidectomy. The facial nerve should be identified and traced from the second genu through its vertical segment. The otic capsule bone of the posterior semicircular canal is identified, and the posterior fossa plate between the sigmoid sinus and the posterior semicircular canal is thinned. The inferior crus of the posterior semicircular canal does not extend more than 12 mm inferior to the tip of the incus (39). The sigmoid sinus is followed inferiorly toward the jugular bulb. As the posterior fossa plate is thinned, the endolymphatic sac comes into view just posteroinferior to the posterior semicircular canal. This structure usually appears as a thickened, white area of dura. The bone overlying the sac must be removed, and its lateral wall is incised if desired (Fig. 152.12). Because the "lumen" of the endolymphatic sac is a labyrinth of small, interconnected lumina, space for the shunt is created by blunt dissection. The surgeon should place a sickle knife or similar instrument into the sac and palpate the operculum. An anterior margin of the sigmoid sinus may obscure a direct view of the endolymphatic sac. In such cases, the sinus can be decompressed and retracted posteriorly for visualization of the sac. One should be vigilant for the presence of a high

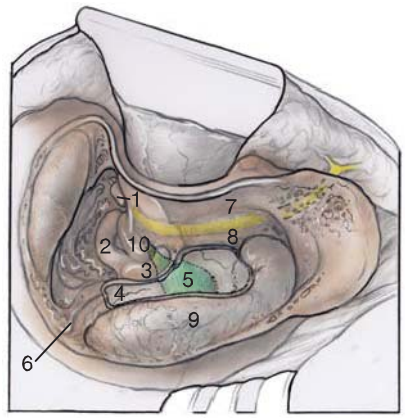

Figure 152.12 Transmastoid exposure of endolymphatic sac. The endolymphatic sac is within the posterior fossa dura generally inferior to the labyrinth and often in contact with the sigmoid sinus. *1*, Incus; *2*, SSC; *3*, PSC; *4*, Posterior fossa dura; *5*, ELS; *6*, SDA—sinodural angle; *7*, PCW—posterior canal wall; *8*, Retrofacial air cells; *9*, Sigmoid sinus skeletonized; *10*, LSC.

jugular bulb. This does not usually impair access to the sac, but its presence limits the amount of space available to the surgeon inferior to the posterior semicircular canal.

TRANSMASTOID BLOCKAGE OF THE SEMICIRCULAR CANALS

The posterior and superior semicircular canals can be obliterated through a mastoidectomy approach for the treatment of canalithiasis and the dehiscent superior semicircular canal syndrome. Obliteration of the posterior semicircular canal is indicated for intractable benign positional vertigo (40). With the recognition of the superior semicircular canal dehiscence (SSCD) syndrome (41), surgical approaches for its repair have been devised. Although most surgeons repair SSCD through the middle cranial fossa (42) many can be repaired by transmastoid obstruction of the superior semicircular canal (43).

Transmastoid obstruction of the semicircular canals can be achieved through a thorough mastoidectomy approach. As the bony capsule of the semicircular canals is approached, the bony trabeculae on the surface of the posterior or superior canals are removed. Once the bony labyrinth is identified, the perilymphatic space of the canal may be approached by gradually removing labyrinthine bone with a diamond burr and constant suction irrigation. The techniques to approach the posterior and superior canals vary.

In the case of canalithiasis of the posterior canal, the labyrinthine bone over the canal is thinned until a "gray line" is visible through the thinned overlying bone. This thin bone can be gently picked away to create a 1 × 3 mm opening into the perilymphatic space. Fine bone chips obtained while drilling are then placed into the canal, collapsing the contents of the canal and completely occluding it. Fibrin glue or bone wax may be used to hold the bone chips in place (40); hydroxyapatite cement may also be applied.

In the case of SSCD, the bony trabeculae between the bone of the lateral semicircular canal and the tegmen mastoideum are removed. As trabeculae are removed, the otic capsule bone of the superior semicircular canal is exposed (Fig. 152.13). The dura is often lying low, making retraction necessary. Once the bone of the anterior and posterior crus of the superior canal is identified, they can be "gray lined" as described above. There is no need to expose the middle fossa dehiscence since manipulation of the contents of the semicircular canal may damage that structure. After the bone over the anterior (ampulated) and posterior crura of the superior canal are identified by drilling with a 1 or 2 mm diamond burr, this bone may be chipped away with small picks (opening ~1 × 2 mm) and occluded with fine bone chips (see Fig. 152.13). The opening into the posterior crus of the superior canal should be performed above the junction of the posterior canal (common crus) as to avoid obstruction of the posterior semicircular canal. Fibrin glue, bone wax, or hydroxyapatite cement may be used for reinforcement (43).

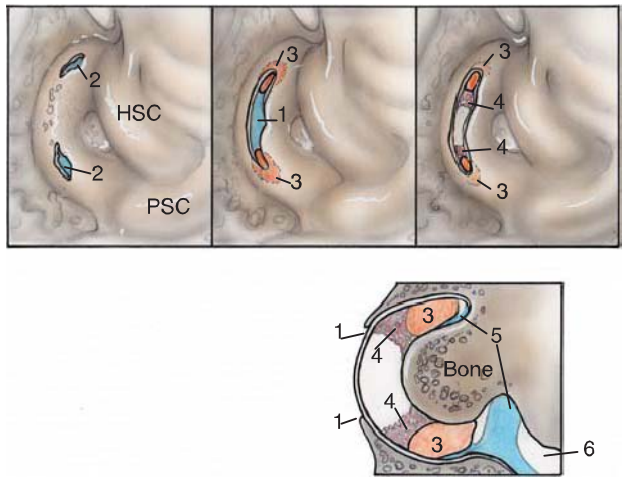

Figure 152.13 Transmastoid exposure and opening of the superior semicircular canal for obstruction of the canal. The bone over the anterior and posterior crura of the superior semicircular canal is first thinned to eggshell thickness. The canal is opened without disruption of endolymphatic membranes and both crura packed with fascia. Bone chips from drilling can be inserted over each graft to encourage osteogenesis (**lower inset**). *1*, Area of dehiscence; *2*, Eggshelled SSC; *3*, Fascia; *4*, Bone dust; *5*, Endolymph; *6*, Perilymph; HSC, horizontal semicircular canal; PSC, posterior semicircular canal.

PETROUS APICECTOMY

Infections of the mastoid and middle ear can spread to the anterior and medial segment of the temporal bone known as the petrous apex. Petrous apicitis is classically characterized by deep retro-orbital pain, abducens nerve palsy, and otorrhea (Gradenigo syndrome). Cranial nerves V, VI, and VII may become involved (44,45). Surgical access to the petrous apex becomes necessary for drainage of expanding cholesterol granulomas and mucosal cysts, exenteration of infected air cells, removal of cholesteatomas, and biopsy of various mass lesions.

The petrous apex takes the form of a truncated pyramid in the posterior skull base (Fig. 152.14A and B). It can be divided into anterior and posterior portions by a coronal plane through the internal auditory canal (Fig. 152.14C). Thirty percent of posterior petrous apices and 9% of anterior apices are pneumatized (46). The petrous tip is in close relation to Dorello canal and the trigeminal fossa anteriorly. Dorello canal, formed by the petrous apex, clivus, and petrosphenoidal (Gruber) ligament, contains the abducens nerve (Fig. 152.14B). The trigeminal fossa (Meckel cave), in the floor of the middle cranial fossa, houses the trigeminal (gasserian) ganglion (Fig. 152.14B). Given this anatomy, it is easy to see why diseases here can compromise cranial nerves V and VI.

The classic procedures designed to access the posterior petrous apex include the transmastoid infralabyrinthine approach and the translabyrinthine approach. Procedures used to access the anterior petrous apex include the

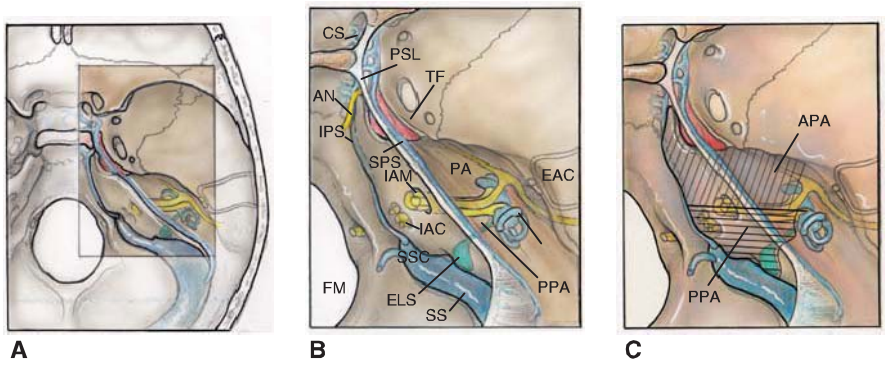

Figure 152.14 **A:** Superior view of base of skull indicating the position of the petrous apex in the skull base. **B:** The petrous apex with the relative location of the internal auditory canal, structures at the tip of the apex and labyrinth. **C:** Petrous apex divided into the anterior and posterior portions. IAC, internal auditory canal; IAM, internal auditory meatus; EAC, external auditory canal; SS, sigmoid sinus; SPS, superior petrosal sinus; IPS, inferior petrosal sinus; TF, trigeminal fossa; PSL, petrosphenoidal ligament; AN, abducens nerve; CS, cavernous sinus; ELS, endolymphatic sac; FM, foramen magnum; PPA, posterior petrous apex; APA, anterior petrous apex.

infracochlear approach, the transotic approach, the middle fossa approach, and an anterior approach through the glenoid fossa (Fig. 152.15). Other procedures including the transcanal anterior approach (47), endoscope-assisted approach (48), and an image-guided approach through the sphenoid sinus (49) have also been described. Sparing the otic capsule surgically is preferred in patients with serviceable hearing.

Fortunately, most lesions in the petrous apex require drainage rather than en bloc resection. An isolated middle cranial fossa approach can be used when the disease involves the anterior petrous apex but spares the middle ear and mastoid. Unfortunately, this approach does not allow for dependent drainage. In brief, a temporal craniotomy is performed, the temporal lobe of the brain is retracted superiorly, and an extradural dissection is carried out along the middle fossa floor. Key landmarks in this approach are the arcuate eminence, the geniculate ganglion, and the internal auditory canal. Bone anterior to the internal auditory canal and medial to the carotid artery is removed in order to approach the pathology.

The classic infracochlear approach provides direct surgical access to the anterior petrous apex. The ability to perform this approach depends upon aeration of the infracochlear air cell track between the cochlea and great vessels of the skull base (Fig. 152.15B–D). A postauricular incision is made and the ear retracted forward in the usual manner. A wide superiorly based tympanomeatal flap is elevated using canal incisions in the 10-o'clock and 2-o'clock positions. The flap should be relatively long so as to cover the enlarged tympanic ring created by the procedure. A canaloplasty is then performed, lowering both the inferior tympanic ring and the floor of the external auditory canal. The infracochlear air cell tract must be identified. It is initially bordered by the basal turn of the cochlea superiorly, the ascending segment of the internal carotid artery anteriorly, and the jugular bulb posteroinferiorly (Fig. 152.15B and D). A 1- or 2-mm diamond burr and suction irrigation are used to open the air cells of this tract. Once the biopsy or drainage procedure is complete, a silastic stent can be placed into the pathway to facilitate aeration. The tympanomeatal flap is returned to its anatomic position, and the ear is closed in the usual manner. A high-riding jugular may prohibit the use of this approach.

The transmastoid, infralabyrinthine approach to the petrous apex necessitates a complete mastoidectomy and precise delineation of the facial nerve. The canal wall may be maintained in patients with adequate mastoid development and pneumatization. The infralabyrinthine air cell tract is located inferior to the posterior semicircular canal, superior to the jugular bulb, and medial to the facial nerve (Fig. 152.15B). This tract is opened in an anterior and medial direction. The route passes inferior to the internal auditory canal and through the region of the cochlear aqueduct, which, if opened, must be plugged to prevent a postoperative cerebrospinal fluid (CSF) leak. The lesion in question should be exteriorized or biopsied, and a silastic stent placed. Adequate review of preoperative high-resolution CT scans will determine whether this tract is present and of reasonable caliber for access.

Patients with large lesions and no serviceable preoperative hearing are candidates for the transotic approach. This route provides superior access for complete removal of mass lesions such as cholesteatomas. The procedure begins with a radical mastoidectomy and labyrinthectomy in which semicircular canals and cochlea are removed. Great care is taken to delineate and protect the facial nerve (superior and posterior), petrous carotid (anterior), jugular bulb (inferior), and internal auditory canal. Thinned bone should be preserved over these structures. The surgeon

dissects in an anterior and medial direction. Should a patent cochlear aqueduct be encountered inferior to the basal turn of the cochlea, it must be plugged with bone chips, fascia, or bone wax at the end of the procedure. After removing the mass in question, most surgeons choose to obliterate the cavity with fat, plug the eustachian tube, and close off the external auditory canal.

Gerek et al. (47) describe a transcanal approach for drainage of limited lesions in the anterior petrous apex. Using cadaver dissections, they suggest elevation of a wide, superiorly based tympanomeatal flap followed by a generous anterior and inferior canaloplasty. The vertical segment of the petrous carotid is exposed and traced for 3 to 6 mm. The cortical bone anterior to the cochlea, between it and the internal carotid artery, is then drilled away with diamond burrs. If greater exposure of the anterior apex is required, the complete apicectomy of Ramadier and Lempert may be performed (46,50,51). In this approach, the glenoid fossa must be exposed and the mandibular condyle can either be removed or displaced anteriorly (Fig. 152.15C and D). This provides access to the medial wall of the glenoid fossa. In the classically described procedure, the anterior external auditory canal wall is removed; however, it can be preserved in most cases. The position of the petrous carotid must be kept in mind as the medial wall of the glenoid fossa is removed using diamond burrs and suction–irrigation. All bone between the carotid artery and the dura of the middle cranial fossa is removed (Fig. 152.15C). Complete exenteration of the anterior petrous apex is impossible without performing a labyrinthectomy, but, in most cases, drainage of infected cells is sufficient to reverse the suppurative process (Fig. 152.15D). Although typically referred to as an "apicectomy," these procedures would be more accurately described by the term "petrousotomy."

ADVANCES IN TEMPORAL BONE SURGERY

Otologic surgery has had a long history of surgical innovation. Currently, many creative surgeons are suggesting further advances in surgical techniques. Robotic surgery may offer more precise control of instruments in the most delicate portions of otologic surgery (52). Technical advances in endoscopes may allow techniques of minimally invasive surgery to the discipline of temporal bone surgery (53,54). Additionally, Labadie et al. (55) have provided proof of concept studies that show that microstereotactic surgery may be applicable to the temporal bone.

COMPLICATIONS AND EMERGENCIES

Facial Nerve Injury

The facial nerve is at risk in its labyrinthine, tympanic, and mastoid segments during otologic surgery (Table 152.3). The nerve not only takes a tortuous, sometimes-anomalous course through the temporal bone, but its canal may also be dehiscent. Heat generated by a diamond burr can injure the nerve without direct mechanical trauma. Constant suction–irrigation helps dissipate thermal energy and prevents this complication. Landmarks such as the antrum, horizontal semicircular canal, short process of the incus, fossa incudis, cochleariform process, oval window, pyramidal process, chorda tympani, and digastric ridge help to locate the nerve. However, such landmarks may be absent or altered during procedures for congenital atresia or cases requiring revision surgery. Intraoperative facial nerve monitoring may be helpful in reducing the risk of iatrogenic trauma.

If the facial nerve is traumatized during surgery, the extent of injury should be assessed both by direct observation and electrical testing. The region of the suspected injury should be examined by decompressing the nerve 3 to 6 mm proximal and distal to the site of injury. It should be exposed in a 180-degree fashion. If facial muscle contraction can be elicited by stimulation with 0.5 mA or less proximal to the injured area, further treatment is unnecessary. Systemic corticosteroids may be helpful in the postoperative period to minimize swelling. If facial movement can be elicited by stimulation of the nerve distally but not proximal to the injury, the extent of nerve disruption determines the next course of action. If only a few fibers are damaged, they may simply be returned to their anatomic position. Significant disruption of the nerve, however, requires direct reanastomosis or cable grafting. When greater than 50% of the facial nerve was disrupted, Green et al. (9) obtained a House-Brackmann Grade III recovery using direct reanastomosis and Grade IV with cable grafting. Direct end-to-end repair may require facial nerve rerouting, which itself may compromise nerve function.

Unexpected facial paralysis noted postoperatively requires prompt attention. Weakness without frank paralysis has a good prognosis and can be treated with a tapering course of steroids. However, complete facial paralysis in patients where the nerve was never formally identified presents a diagnostic dilemma. Local anesthetics administered preoperatively may be responsible for immediate postoperative facial palsy. Therefore, surgical exploration should be deferred for a few hours and the patient reassessed. If complete paralysis persists, early exploration is usually indicated. High-resolution CT scanning may give additional insight into the extent and nature of the injury. The nerve must be clearly identified, and, if traumatized, the surgeon should decompress it or perform the necessary repair.

TABLE 152.3 COMPLICATIONS MASTOID SURGERY

Perioperative complications
Facial nerve injury
Sensorineural hearing loss
Postoperative infection
Dysgeusia
Brain herniation
CSF leakage
Bleeding
Delayed complications
Posterior canal breakdown
Perichondritis
Blue-domed cyst
Mucosalization of mastoid bowl
Stenosis of external canal

Hearing Loss

Iatrogenic hearing loss may be conductive or sensorineural. Undetected disruptions of the tympanic membrane or ossicular chain may cause a conductive hearing loss. Sensorineural hearing loss can result from a variety of causes. Acoustic trauma from a high-speed drill (56) or suction squeal may cause hearing loss. Transmission of high-frequency mechanical energy from contact between the drill and the ossicular chain also causes sensorineural hearing loss. If such contact is unavoidable, the surgeon should first disarticulate the incudostapedial joint. Inadvertent entry into the inner ear (semicircular canal, oval or round window, cochlea, etc.) and loss of perilymph/endolymph may result in hearing loss. If faced with cholesteatoma matrix overlying a semicircular canal fistula, most surgeons advise meticulous removal of the matrix and subsequent grafting with bone dust or fascia (57,58). Some recommend leaving the keratinizing epithelial cholesteatoma matrix over the fistula and perform a second operation in 6 to 12 months. At that time, the residual cholesteatoma matrix (now a small pearl) can be removed. This second procedure may be safer because the field is less inflamed and visualization improved.

Vestibular Injury

Injury to the labyrinth during tympanomastoid surgery can result from direct trauma or from postoperative infection. Ears affected by serous labyrinthitis often recover function over time and may benefit initially from steroid therapy. Suppurative labyrinthitis, however, usually destroys vestibular function. Complete unilateral vestibulopathy usually results in acute vertigo which resolves over the next few days to weeks as central compensation occurs. Some patients are left with mild disequilibrium that improves slowly with vestibular rehabilitation. Chronic disequilibrium may occur in the elderly and in those patients who do not undergo successful central compensation. Some patients may also experience delayed benign positional vertigo, presumably due to the mobilization of otoconia within the labyrinth and migration into the posterior semicircular canal.

Infection

Surgical procedures of the mastoid and petrosa are often necessary because of chronic recurrent and persistent infections. In chronic otitis media (59) and cholesteatoma (60) there is evidence of chronic colonization/infection with bacterial biofilms. These established colonies are highly resistant to host defenses and antibiotics. Hence, procedures are often performed in the presence of bacteria and fungi. In the presence of bacterial colonization, postoperative infection continues to pose a threat to successful outcomes in otologic surgery. Immediate concerns include dehiscence of the postauricular incision, failure of the tympanoplasty grafts, and necrosis of the external auditory canal skin flaps. In extreme cases, the cartilaginous structures of the auricle become infected. Perichondritis requires debridement of necrotic cartilage and administration of parenteral antibiotics. Other potential complications include suppurative labyrinthitis, facial nerve palsy, epidural or subdural abscess, meningitis, sigmoid sinus thrombosis, otitic hydrocephalus, and brain abscess. If an ear is grossly infected preoperatively, antibiotics may be administered based on cultures and sensitivity data. Perioperative antibiotics are generally indicated for tympanomastoid procedures done for chronic otitis although specific evidence is lacking (61). However, the use of preoperative prophylactic antibiotic therapy is not established. In a recent Cochran review by Verschuur et al. (62), they concluded that there was no role for the use of prophylactic antibiotics in clean and clean-contaminated otologic procedures.

Dysgeusia

Dysgeusia resulting from injury to the chorda tympani nerve may be quite distressing to some patients. Symptoms such as a metallic taste in the mouth usually improve with time, but patients must be warned that these taste alterations may persist. This may be of particular concern for those needing a keen sense of taste or flavor in their professions. Traumatized chorda tympani nerves tend to result in more prolonged dysgeusia than cutting the nerve.

Cerebrospinal Fluid Leakage and Encephalocele

The terms meningocele, encephalocele, and meningoencephalocele refer to herniation of meninges, brain matter, or both outside their normal confines. In the course of thinning the tegmen tympani and tegmen mastoideum during tympanomastoid surgery, areas of dura may become exposed. Approaching the dura carefully using diamond burrs rather than cutting burrs helps to prevent complications. Generally minor dural exposures are of little consequence. However, if larger areas of dura are exposed or lacerated, CSF, meninges, and brain tissue may enter into the mastoid cavity. Elderly patients are at particular risk because the dura tends to thin with advancing age. These regions may later herniate into the mastoid or epitympanum leading to delayed complications.

Myeloencephaloceles usually present with CSF otorrhea, CSF rhinorrhea, a persistent clear effusion behind an intact tympanic membrane, hearing loss due to mass effect (fluid and brain matter), or infections such as meningitis and encephalitis. A CSF leak can occur, however, without herniation of meninges or brain matter. High-resolution CT scans with axial and coronal views help define bony defects in the tegmen or posterior fossa plate, and magnetic resonance imaging (MRI), with its excellent soft tissue resolution, distinguishes brain from fluid, cholesteatoma, or cholesterol granuloma. MRI is also useful in evaluating the integrity of the dura. If fluid can be obtained, β_2-transferrin assays may help in confirming the presence of CSF.

Conservative options for managing CSF leaks in the acute phase include bed rest, stool softeners, and placement of a lumbar drain for controlled CSF removal. When such measures fail or if the patient becomes infected, surgical options are necessary. Repairing an encephalocele requires resection of devitalized tissue followed by reconstruction of the defect. If the damage is recognized during the initial procedure, the defect can be repaired at that time. Dura is elevated in a circumferential manner around the defect and a fascia graft placed intracranially between the dura and bone. Other material forms of processed collagen may be suitable as well. If the CSF leak or encephalocele is recognized postoperatively, the precise location and size of the defect dictate the surgical approach. Options include transmastoid, middle fossa, or combination techniques. Small defects may be managed through the mastoidectomy itself; use of fascia with or without bone or cartilage reinforcement may be adequate. For larger defects, a middle fossa craniotomy can be used. An extradural approach is used with temporal lobe elevation. A sheet of temporalis fascia (or other collagen material) is placed between the bone of the mastoid and the dural defect. The window

of bone harvested in the craniotomy can then be thinned and inserted between the fascia and the floor of the middle cranial fossa. Use of auricular cartilage is an alternative.

Bleeding/Air Embolism

Most bleeding from the sigmoid sinus or jugular bulb can be controlled easily using gelatin foam, Surgicel pledgets covered by a small cottonoid. Hemostatic matrix preparations have also been used successfully in management of bleeds from the dural sinuses. However, a significant laceration places the patient at risk for secondary complications such as air embolism or thrombosis of the sigmoid sinus. Once the bleeding is controlled, the potential for air embolism must be entertained especially if the head is elevated. An air bubble in the venous system that becomes trapped within the right ventricle can result in cardiopulmonary arrest. The early signs of air embolism include increased end-expiratory carbon dioxide, hypotension, and abnormal cardiac sounds. The surgical field should be flooded with saline immediately and the patient should be placed in the Trendelenburg (head-down) position to minimize further ingress of air into the vascular system. Placement in the left lateral position can help to reposition the air bubble into the right atrium or vena cava. If cardiovascular compromise is still present after these maneuvers, the air must be aspirated from the vena cava using a central venous catheter.

Injury to the carotid artery during tympanomastoid surgery requires immediate hemostasis by direct compression. Once the bleeding is temporarily controlled, emergency angiography should be performed. In most cases, occlusion of the carotid artery within the temporal bone by the interventional radiologist is indicated. Occlusion of the carotid artery puts the patient at significant risk for stroke.

Delayed Complications

Other complications of mastoid surgery include delayed posterior external ear canal wall breakdown, perichondritis, cholesterol granulomas, mucosalization of the mastoid bowl, and external auditory canal stenosis.

HIGHLIGHTS

- Postauricular incisions allow excellent exposure of the mastoid cortex. The inferior portion of the incision must be placed more posteriorly in young children to avoid facial nerve injury.
- The mastoid antrum is located directly medial to Macewen triangle.
- The temporal line provides a topographic landmark for the tegmen and floor of the middle fossa.
- The surgeon must thoroughly saucerize the mastoid cavity during a canal-wall-down mastoidectomy.
- Facial nerve variations and anomalies are common within the temporal bone, especially in patients with congenital ear malformations.
- The posterior musculoperiosteal flap, known as the Palva flap (or more appropriately, the Moser flap), has been successful in obliterating mastoid cavities especially in conjunction with bone pâté.
- Saucerization, removal of the mastoid tip, obliteration techniques, and a large meatoplasty are vital to obtaining a clean, dry ear in canal-wall-down mastoidectomies.
- Disadvantages of intact-canal-wall procedures include an increased risk of occult residual and recurrent disease.
- The endolymphatic sac can be located inferiorly between the posterior semicircular canal and the sigmoid sinus.
- The anterior petrous apex can be opened through the anterior epitympanum, the hypotympanum, and the middle cranial fossa.

153 Reconstruction of the Tympanic Membrane and Ossicular Chain

John L. Dornhoffer *Michael B. Gluth*

Seeking knowledge and expertise in the art of tympanoplasty and ossiculoplasty can be a difficult task, in part due to the overwhelming number of techniques that have been described, but also because of the plethora of dogma and surgical tradition that circulates throughout the otologic surgery community. In the following chapter, the authors seek not to champion a particular set of techniques, but to provide a broad overview of this topic with a focus on fundamental principles that apply globally. This information is delivered under the assertion that it is wise for otologists to acquire a working mastery of several techniques that may be applied in a customized manner based on pathology and conditions at hand.

DEFINITION OF TERMS

Canalplasty refers to surgical modification of the bony external auditory canal. This is often used as an adjuvant procedure in tympanoplasty to improve surgical access.

Meatoplasty refers to surgical modification of the cartilaginous external auditory canal and external auditory meatus. This is often used as an adjuvant procedure in tympanoplasty to provide improved postoperative access or to attain consistent lateral-to-medial ear canal size matching following canalplasty.

Myringoplasty refers to surgical repair of the tympanic membrane that involves work confined to the drumhead only.

Ossiculoplasty refers to surgical modification of the ossicular chain, including reconstruction and mobilization.

Tympanoplasty refers to surgical repair of the tympanic membrane in combination with work within the tympanic cleft, such as ossiculoplasty, middle ear exploration, or lysis of tympanic adhesions. Traditionally, elevation of the annulus within a tympanomeatal flap has served as a practical boundary that differentiates tympanoplasty from myringoplasty.

TYPES OF TYMPANOPLASTY AND OSSICULAR RECONSTRUCTION

Tympanoplasty techniques were classically outlined by Zollner (1) and Wullstein (2). Subsequent modifications of Wullstein's classification have been based on the underlying properties of acoustic mechanics associated with each tympanoplasty type as opposed to classification based on underlying tympanic and ossicular pathology. Understanding this classification system is helpful not only for purposes of grasping a global and historical view of tympanic membrane and ossicular chain reconstruction, but also for understanding basic principles of middle ear acoustic mechanics.

Type I Tympanoplasty

This procedure involves repair of the tympanic membrane in the setting of an intact native ossicular chain. At most, manipulation of the ossicular chain is limited to interventions aimed at improving mobility, such as lysis of tympanic adhesions or removal of tympanosclerotic foci.

Type II Tympanoplasty

This procedure involves repair of the tympanic membrane in combination with any type of ossiculoplasty procedure that preserves the integrity of the malleoincudal lever mechanism. The most common example of this is repair of a dysfunctional (eroded) incudostapedial articulation. Tympanoplasty with delayed staged ossiculoplasty consisting of an incus-grip stapedotomy could also be considered a subgroup within this category. It is perhaps worth noting that these modern depictions of type II tympanoplasty differ somewhat from the classic description that was devised to deal with the uncommon scenario of isolated malleus erosion, wherein tympanic membrane grafting is applied directly upon the intact long process of the incus.

Type III Tympanoplasty

This procedure involves repair of the tympanic membrane in combination with any type of ossiculoplasty procedure that does not preserve the integrity of the malleoincudal lever mechanism. Type III tympanoplasty includes the vast majority of techniques described for routine ossicular chain reconstruction. Accordingly, type III tympanoplasty classification has been further subdivided according to ossiculoplasty technique.

Stapes Columella Subtype

This type III tympanoplasty involves placement of a tympanic membrane graft directly onto the superstructure of the stapes *without* the use of a prosthesis or any other substantial interpositional material.

Minor Columella Subtype

This involves the use of an interpositional graft or prosthesis to establish continuity between the tympanic membrane and the superstructure of the stapes. Examples of this include the use of a synthetic partial ossicular replacement prosthesis (PORP) or sculpted ossicular (incus or malleus head) autograft. Interpositional ossiculoplasty techniques that employ a lateral contact point with the malleus manubrium also fall within this subtype.

Major Columella Subtype

This procedure is exactly the same as the minor columella subtype except that the stapes superstructure is absent; thus, with a major columella subtype the interpositional graft or prosthesis is set upon the stapes footplate. An example of this is use of a synthetic total ossicular replacement prosthesis (TORP). Tympanoplasty with delayed staged ossiculoplasty that consists of a malleus-grip stapedotomy could also be considered to fall within this subtype.

Type IV Tympanoplasty

This procedure involves repair of the tympanic membrane in such a manner that the boundary between the mucosalized middle ear space and the epithelialized lateral compartment (external auditory canal, open mastoid cavity, epitympanum) is shifted in a way that renders the stapes footplate externalized as part of the latter. As a result, the tympanic cavity is divided into a smaller-than-normal aerated space in continuity with the eustachian tube, termed the cavum minor, in which the round window is acoustically shielded, and an external component in which the mobile stapes footplate is covered by a thin epithelial layer and is directly exposed to incoming sound energy.

Type V Tympanoplasty

This procedure is the same as the type IV tympanoplasty, except that it also includes the need to address an underlying immobile stapes footplate and, therefore, is generally performed in a staged manner once active infectious disease is controlled. Historically, fenestration of the lateral semicircular canal was described as part of this procedure to counteract stapes fixation; however, total footplate removal and a soft tissue seal have generally replaced fenestration.

PHYSIOLOGY: MECHANISMS OF GAIN

The modern view of middle ear acoustic science involves two basic pathways by which sound is able to stimulate the inner ear (3,4). The first involves transmission of sound pressure through the tympanic membrane and ossicular chain via the oval window. This is known as *ossicular coupling*. This mechanism is the primary means by which the state of impedance mismatch that exists between the air in the ear canal (low impedance) and the fluid within the cochlea (high impedance) is overcome. In such a state, sound pressure is deflected during passage through the air–fluid interface, resulting in a loss of gain in the realm of 30 dB. The coupling effect of the tympanic membrane and ossicles almost overcomes this loss.

Ossicular coupling has been attributed to the collective effect of three characteristics of the tympanoossicular mechanism traditionally known as the *acoustic transformer theory* (5). The first and most significant of these characteristics is the *hydraulic lever effect* that results from the difference between the surface area of the tympanic membrane relative to that of the oval window (usually a ratio of nearly 21:1). This effect results in compression of sound energy and increase in force at the oval window, equating to a theoretic approximate increase in gain of 26 dB. The second characteristic is the *malleoincudal lever effect* that results from the difference in length between the malleus manubrium relative to that of the long process of the incus along the axis of ossicular rotation (a ratio of 1.3:1). However, this effect only accounts for an additional 2 dB theoretical increase in gain. The final factor is the so-called *catenary lever effect* that is generated by the elastic stretching of the tympanic membrane from the annulus to the malleus manubrium—somewhat akin to the stretched strings across a tennis racquet. The specific degree of acoustic benefit derived from the catenary effect is not well understood but probably lies within a range similar to that of the malleoincudal lever.

It is important to recognize that, in reality, ossicular coupling is a much more complex phenomenon than what is suggested by these simplified traditional models as they do not account for factors such as variation in efficiency with changes in frequency or inefficiencies in sound transmission through the tympanic membrane and ossicular chain attributed to the inherent tension or laxity of the ossicular ligaments. Thus, it is perhaps not surprising that the 25 to 30 dB of gain that is predicted by the acoustic transformer theory does not equate well with experimental

measurements, which suggest an actual more modest increase in the realm of just over 20 dB (6–8).

The second pathway of sound stimulation of the inner ear involves direct passage of sound pressure via the oval and round windows without involvement of the tympanic membrane or ossicular chain. This is known as *acoustic coupling* (4). Given an intact tympanic membrane and functional ossicular chain, this pathway is of only minor importance. However, in the various conditions of a diseased ear, acoustic coupling can be important. This is why, for example, a conductive hearing loss will be greater in the case of ossicular discontinuity and an intact tympanic membrane (60 dB) compared with ossicular discontinuity and an absent tympanic membrane (40 to 50 dB). With the former, the intact tympanic membrane restricts the acoustic coupling pathway by blocking direct access of sound pressure to the oval and round window membranes.

A final relevant consideration in middle ear acoustic mechanics is that of *phase*. A sound stimulus to the inner ear is detected as the net difference in sound pressures applied to the round and oval windows that results in movement of intracochlear fluids. If these sound pressures are simultaneously applied to the round and oval windows with equal amplitude and phase, they will counteract each other and no resultant intracochlear fluid displacement will occur. In the normal situation, this does not occur due to the unbalanced selective effect of ossicular coupling upon the oval window, the acoustic shielding effect of the tympanic membrane upon the round window, and the uneven anatomical positioning of the round window versus the oval widow relative to incoming sound. However, when the tympano-ossicular mechanism is absent and acoustic coupling is primarily relied upon (as in the case of a type IV or V tympanoplasty), an unshielded round window can yield significant negative acoustic consequences due to phase cancellation (4).

A simplified chart depicting the theoretic ideal acoustic effects of various tympano-ossicular scenarios is shown in Table 153.1.

PREOPERATIVE EVALUATION

When a patient is considered for tympanoplasty or ossiculoplasty, a thorough history, examination, and audiometric evaluation should be performed on both ears. Otoscopy and pneumatic insufflation under the binocular microscope, following careful removal of debris, provide a wealth of information. The results of the audiogram should always be correlated with the physical exam, including Weber and Rinne tuning fork tests, especially when a masking dilemma is present. If the audiogram and tuning fork exam do not agree, surgery should not be performed until this is reconciled.

A preoperative audiogram can be helpful in suggesting underlying pathology. Generally, a perforation will cause a conductive hearing loss between 5 and 40 dB depending on its characteristics (9). Controversy exists as to whether or not the location of a perforation impacts the degree of hearing loss, yet perforation size and underlying middle ear volume do matter (an ear with a smaller volume tends to have worse hearing than one with a larger volume, even given identical perforations).

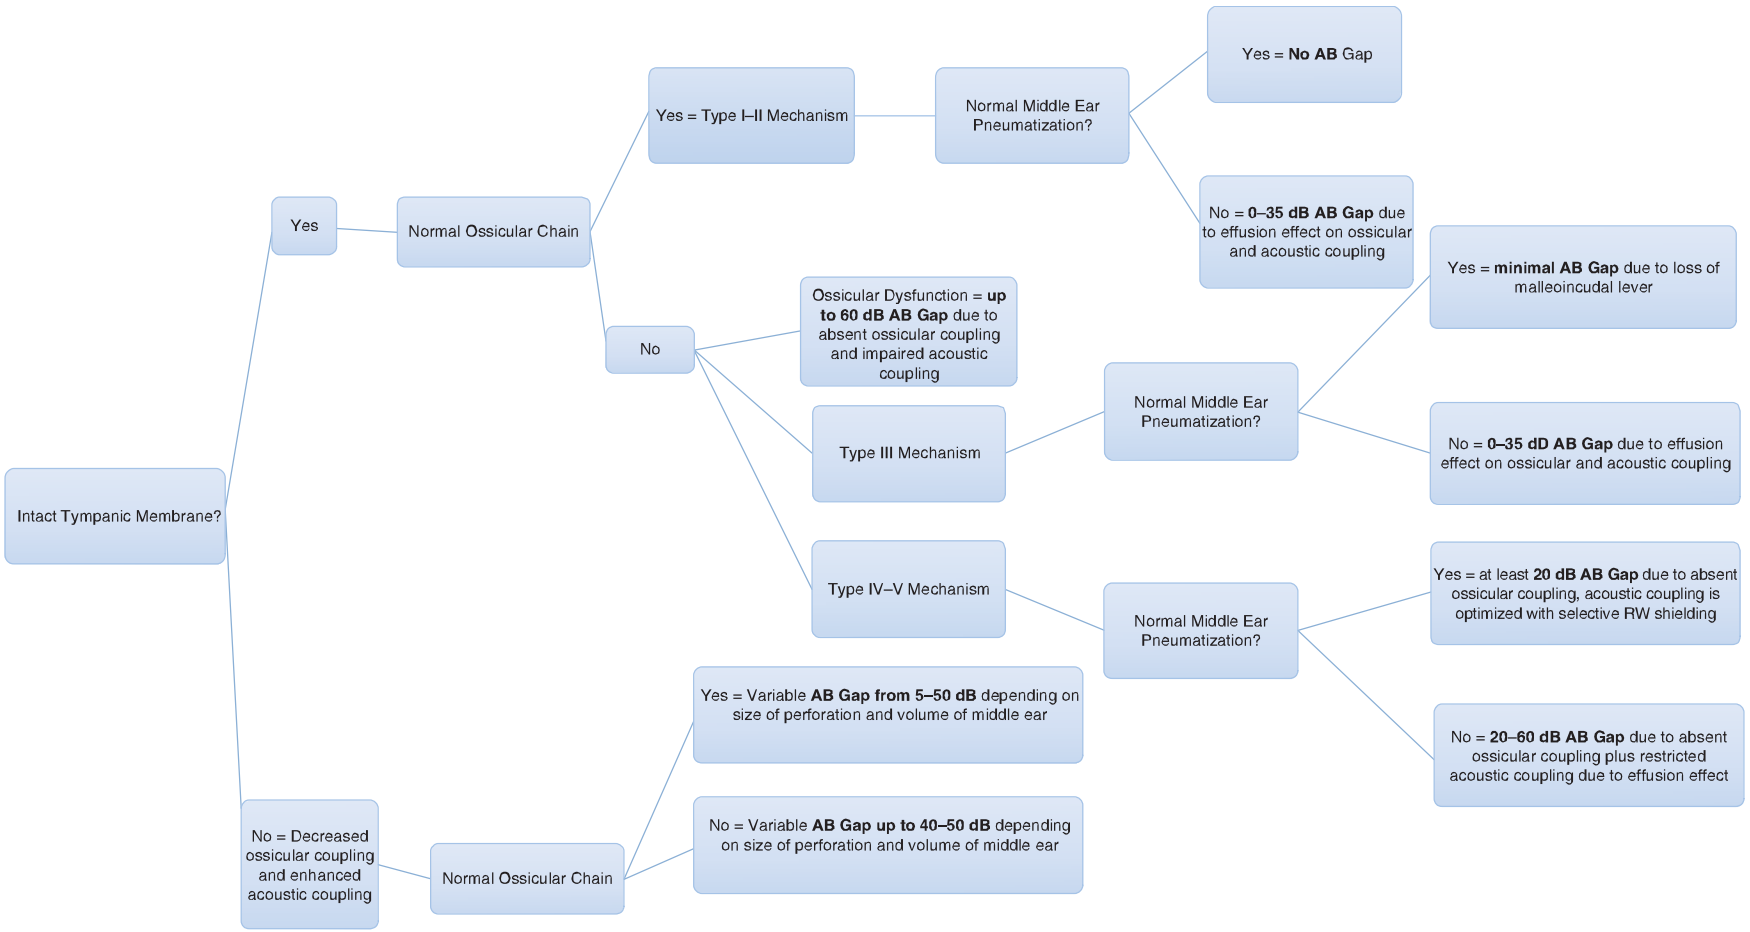
When the tympanic membrane is intact, a conductive hearing loss greater than 35 to 40 dB strongly suggests the possibility of ossicular chain dysfunction. Furthermore, the pattern of hearing loss may be typical of particular scenarios; for example, ossicular fixation generally causes a low-tone conductive hearing loss, the degree of which is related to the extent and location of the fixation. With malleus head fixation, the low-tone air–bone gap generally closes at the higher frequencies, whereas stapes fixation tends to affect the middle and high frequencies to a relatively greater degree (10).

The status of the eustachian tube will impact surgical outcomes, yet there is no consensus on the optimal way to reliably assess its function (11). Auto-inflation using the Valsalva or Toyenbee maneuver is helpful, albeit a nonphysiologic test of tubal patency. The clinical status of the contralateral ear likewise can provide insight into tubal maturity and function in the diseased ear (12). As part of the eustachian tube evaluation, the nose should be examined so that allergy, adenoiditis, and rhinosinusitis can be treated in an effort to promote optimized tubal function (13). Furthermore, aggressive medical treatment of infection involving the ear itself should be undertaken prior to surgery, including aural toilet and ototopical agent application. When an ear will not dry with medical therapy, culture acquisition may be useful in helping to identify antimicrobial-resistant pathogens.

Once patient assessment is complete, a few general rules should be applied to surgical candidacy. First, one should avoid elective surgery on an only-hearing ear as much as is reasonably possible. Exceptions to this would be situations where surgery is primarily confined to the tympanic membrane, and drilling or significant ossicular manipulation is unlikely, or when a perforation is contributing to difficulty with hearing aid usage. Also, cases that involve disease processes that impart risk of hearing loss, such as cholesteatoma, will generally warrant intervention. Second, when bilateral disease is present, surgery should be undertaken on the worse-hearing ear in the absence of any other compelling reason to do otherwise on account of underlying disease. Finally, special consideration should be given to the timing of surgery in the pediatric patient.

Age as a prognostic factor in tympanoplasty is controversial, with contradicting reports present in the literature (14,15). The authors' approach to pediatric patients is to avoid repairing the tympanic membrane during the otitis-prone years (≤3 years). If the contralateral ear is normal, routine tympanoplasty is considered at age 4 for an ear that is dry or only occasionally drains with water

TABLE 153.1 THEORETIC IDEAL ACOUSTIC EFFECTS OF VARIOUS TYMPANO-OSSICULAR SCENARIOS



contamination (16). However, if the contralateral ear is abnormal at this time, adenoidectomy is considered and tympanoplasty is deferred until the contralateral ear reaches stable quiescence or the patient reaches age 7. If contralateral disease is still present at this time, a more aggressive technique, such as cartilage tympanoplasty, is performed on the worse-hearing ear. The second ear is repaired several months later, but only after the first ear is documented to have a stable satisfactory outcome and is not expected to require further surgery.

TYMPANOPLASTY

General Principles

Modern tympanoplasty techniques all have common ground in that they endeavor to reconstruct the deficient middle fibrous layer of a tympanic membrane perforation with graft materials that then act as a scaffold for lateral epithelial growth. Although simplified myringoplasty techniques that utilize non-grafted temporary scaffold materials, such as a thin paper patch, can be used for small perforations, they are relatively limited in application and simple to learn. Thus, patch myringoplasty techniques are not a focus of this discussion.

The common goals of tympanic membrane repair are to

- Create a barrier between the dry lateral epithelialized compartment (drumhead, external auditory canal, open mastoid cavity) and the moist medial mucosalized compartment (middle ear, eustachian tube)
- Provide reinforcement to correct tympanic membrane weaknesses in order to resist future disease processes (atelectasis, perforation)
- Create an optimized sound-conducting platform for ossicular coupling or a round window shield for acoustic coupling depending on tympanoplasty type
- Create a contour favorable for outward keratin debris migration

Applied Tympanic Membrane Mechanics

The tympanic membrane is the major element of the middle ear transformer mechanism and acts as a barrier between the sound pressure of the ear canal and middle ear. Its motion, which has been studied with laser vibrometry and stroboscopic holography, is both complex and variable depending on the frequency of stimulation (17,18). At frequencies up to 1,000 Hz, the tympanic membrane tends to vibrate in one consolidated phase, but as frequency rises further, its vibration splits into a state of phase subdivision, with overall diminished efficiency.

While it is intellectually satisfying to assert that reconstruction of the tympanic membrane must endeavor to exactly recreate these native vibratory patterns, in truth it is unknown if this is possible or even necessary. Numerous tympanic membrane graft materials have been used that are quite dissimilar to the native drumhead in rigidity and thickness, yet excellent acoustic outcomes have been attained. For example, reconstruction with large cartilage grafts has been reported to result in hearing outcomes equal to those with more pliable temporalis fascia (15,19–21), including occurrences of *complete* air–bone gap closure in the speech frequencies. Further complicating the situation is uncertainty regarding the interplay between an aphysiologic reconstructed tympanic membrane and the underlying aphysiologic reconstructed ossicular chain in collectively providing acoustic gain (22). Gaps between observed clinical outcomes and predicted tympanoplasty outcomes based on tympanic membrane acoustic models highlight the fact that there is still much to be learned.

Surgical Exposure

The importance of assuring proper visualization and exposure in order to surgically manipulate the tympanic membrane and middle ear may seem obvious, but if taken for granted, surgical results can be compromised. Line-of-sight visualization in itself does not always signify adequate exposure. The surgeon must assure that instruments are allowed to enter the microscopic field at a sufficiently open lateral angle so as not to impede binocular vision or require awkward manipulation. Although minimally invasive approaches can be desirable, these should only be utilized if they provide equally sufficient access and exposure to the surgical target. The morbidity associated with even the widest tympanoplasty access route (postauricular with canalplasty) is generally not high. Table 153.2 provides a suggested guide for choosing appropriate access for tympanic membrane repair. One noteworthy consideration is that when a perforation involves the anterior drumhead, wide exposure via a postauricular incision and, when needed, a canalplasty may be helpful.

Canal Incisions

Numerous sites for canal incisions have been described to raise a tympanomeatal flap, and generally these are chosen according to the anticipated surgical plan. Many surgeons have traditionally insisted upon preservation of the posterior–superior "vascular strip" of canal skin or avoidance of transecting the tympanic annulus. However, many of these dictums seem to be routinely ignored by accomplished otologists with little if any apparent negative consequence. In reality, quality surgical execution and careful atraumatic handling of canal skin are probably the key factors to a successful outcome regardless of how this is done (see Fig. 153.1).

Preparing the Drumhead

Prior to graft placement, the tympanic membrane should be prepared to maximize the chances of graft take and rapid epithelialization. This typically involves

TABLE 153.2 SUGGESTED ROUTES OF ACCESS FOR TYMPANIC MEMBRANE REPAIR

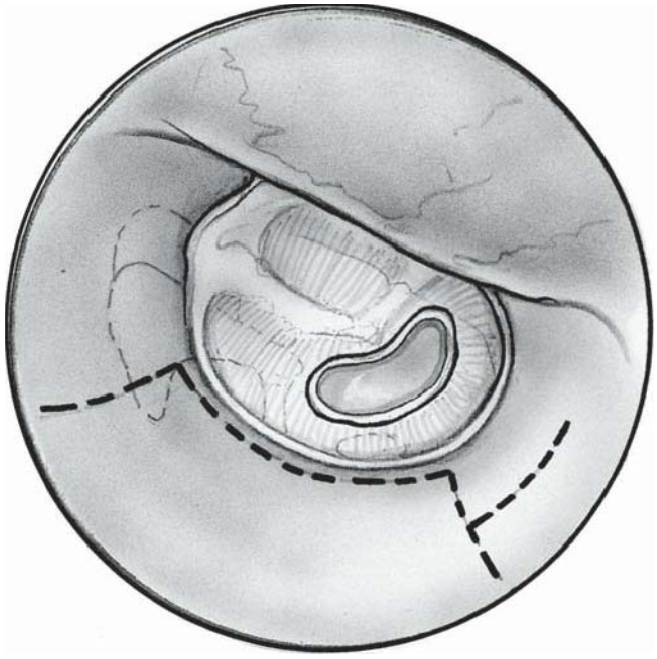
Transcanal	• Patch myringoplasty (office procedures) • Small posterior underlay tympanoplasty
Endaural	• Underlay tympanoplasty without significant anterior component
Postauricular	• Underlay tympanoplasty
Postauricular with Canalplasty	• Underlay tympanoplasty with large anterior component • Overlay tympanoplasty

freshening the margins of the perforation with cold knife rim resection or laser application in order to encourage sprouting of new microvasculature. As a general rule, it is better to be aggressive in completely removing unhealthy portions of the tympanic membrane than to attempt incorporation of them into the reconstruction process. This includes myringitis (particularly important), tympanosclerotic plaque, scar, and old graft material. Pathologic adhesions between the drumhead and middle ear should also be released.

Choosing, Preparing, and Shaping the Graft

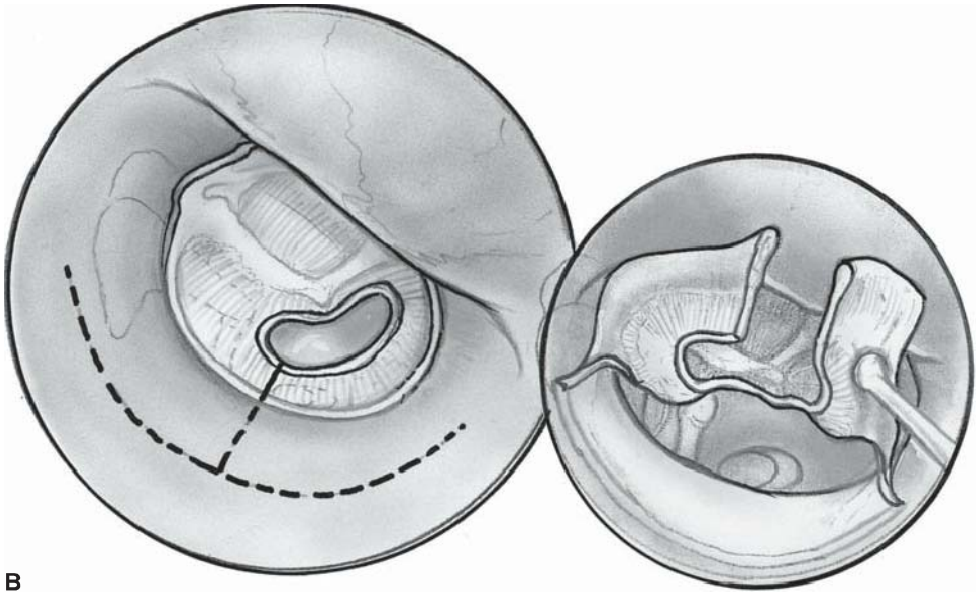
The most commonly used tympanic membrane grafting material is temporalis fascia, which is desired for its pliability. This is harvested, via either an endaural or postauricular incision, as the glistening whitish layer of fascia immediately overlying the temporalis muscle fibers. After harvest, this is generally pressed thin and set aside for drying, which may promote ease of trimming and placement. Readily available alternatives to temporalis fascia that are also thin and pliable include pressed perichondrium, periosteum, and muscle. Cadaveric acellular dermal matrix (AlloDerm, LifeCell Corp, Branchburg, NJ) (23) has also been used with success and may be particularly useful for simple in-office tympanoplasty procedures where harvest of a tissue graft is not desired.

Auricular cartilage grafts are very useful in tympanoplasty (24,25) and may be harvested from various sites, but are typically harvested from the tragus and the cymba with the overlying perichondrium intact. These can be applied with or without perichondrium or the concurrent use of fascia; however, the authors' bias is to apply cartilage grafts that have been stripped of perichondrium on the medial surface but have adherent perichondrium or overlying fascia on the lateral surface (26). In the authors' experience, such grafts tend to be much more resistant to involvement with postoperative middle ear adhesions than either fascia or perichondrium.

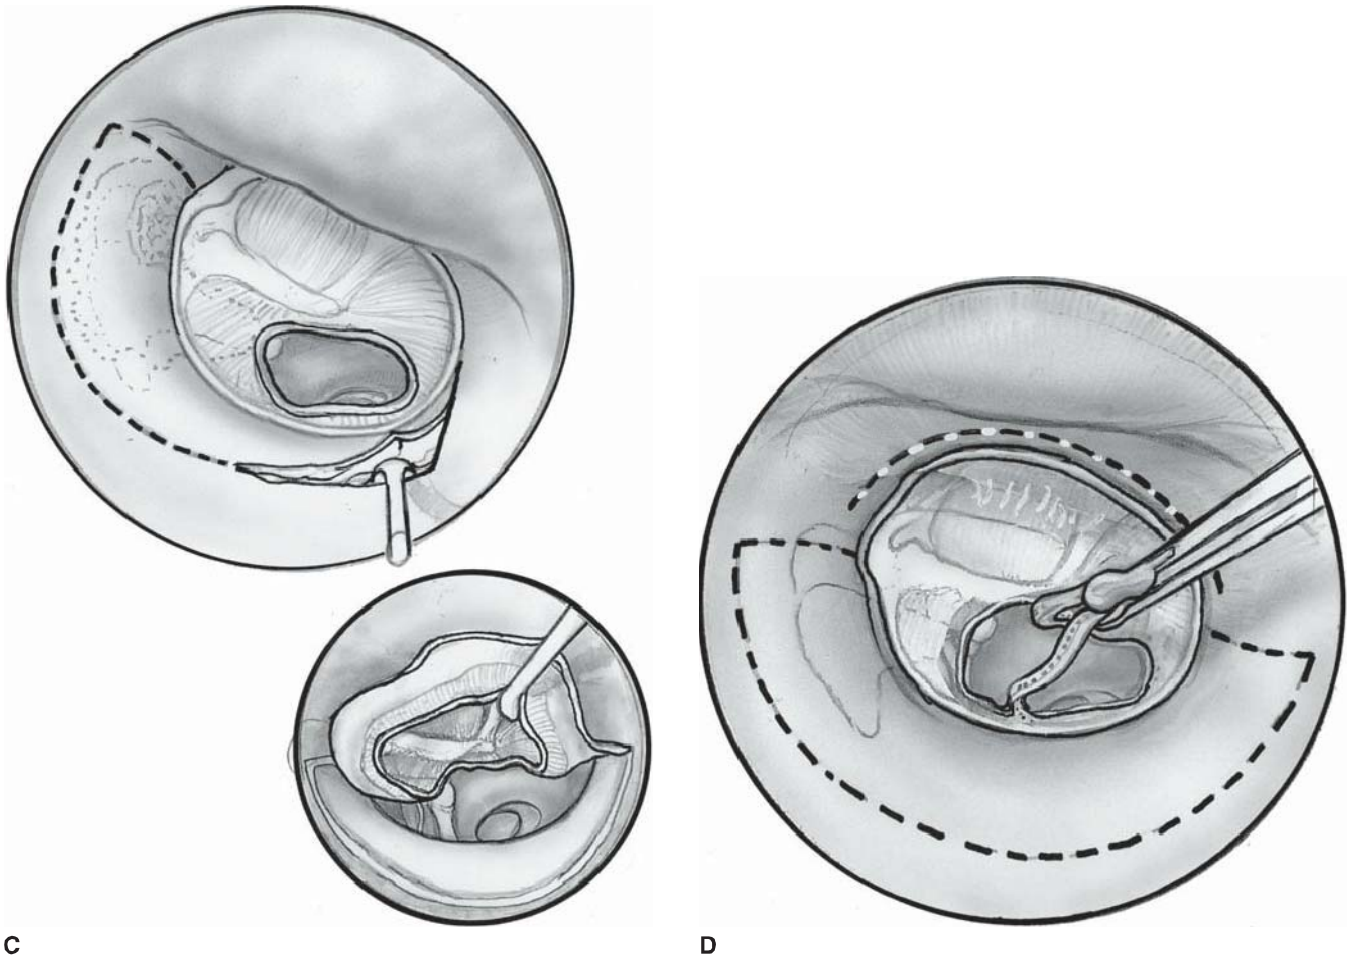


A

Figure 153.1 Canal incisions. **A:** The classic vascular strip incision involves preservation of the posterior canal skin to within a few millimeters of the annulus.

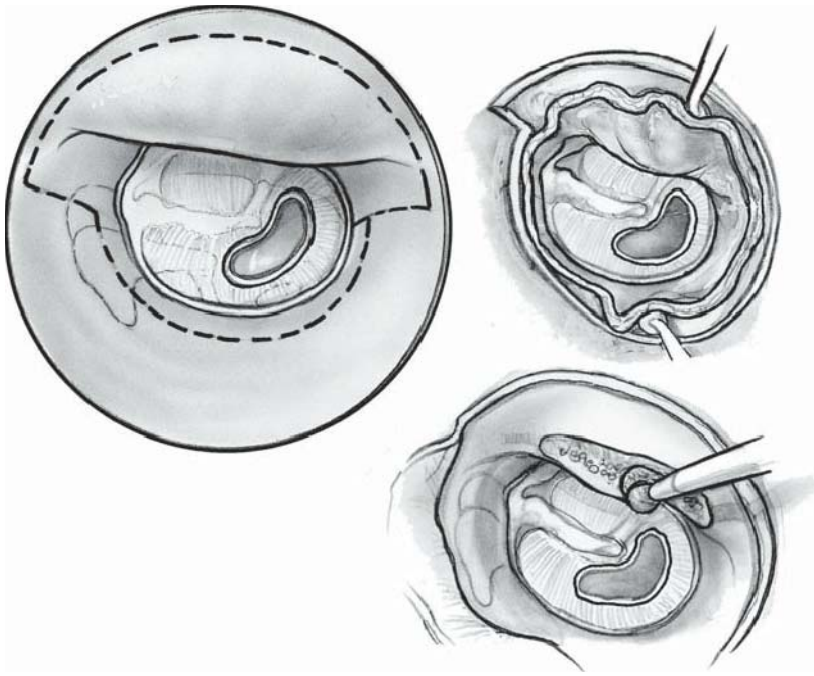


B

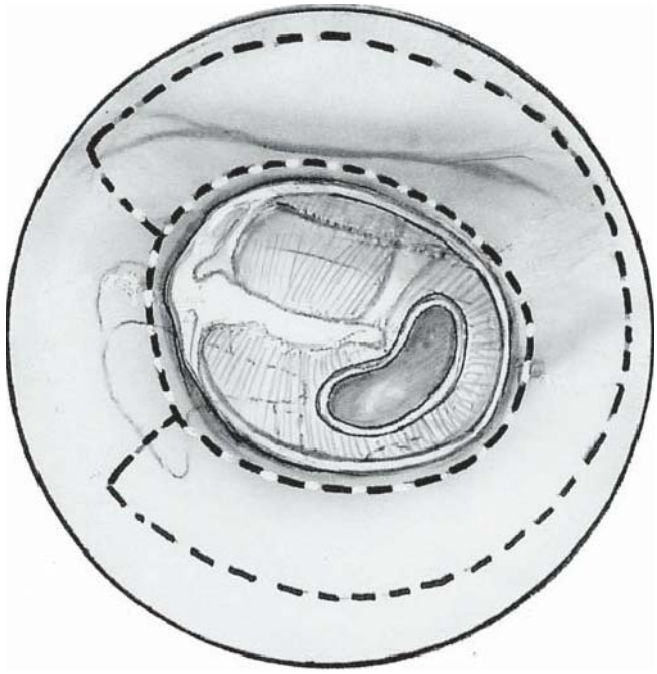


C D

Figure 153.1 (*Continued*) **B:** A "book page" flap provides particularly good access for graft placement by dividing the annulus with an incision through the canal skin and tympanic membrane into the perforation. **C:** A "ship sail" flap is larger at the superior aspect and is particularly useful when wide curettage of scutum bone results in the need for extra tympanomeatal flap length for coverage. **D:** Modified canal incisions for underlay tympanoplasty can incorporate both a standard tympanomeatal flap as well as a separate anterior canal incision to elevate the annulus and anchor the graft. *(Continued on next page)*



E



F

Figure 153.1 (*Continued*) **E:** Overlay tympanoplasty requires incisions that afford removal of the anterior canal wall skin to allow access for canalplasty. **F:** Overlay tympanoplasty incisions can be modified to allow wider removal of canal skin if desired.

When the use of a composite perichondrium–cartilage island graft is desired, perichondrium is usually stripped off of one side, and the remaining cartilage is cut to the desired shape as an "island" upon the preserved opposite side (see Fig. 153.2). If used for repair of a large perforation, a composite island graft is shaped into a thin circular disk 8 to 9 mm in diameter, with a notch cut to cradle the malleus manubrium and tails of perichondrium on the periphery that can be anchored on the external auditory canal wall under the annulus. For optimized acoustics, a cartilage graft thickness of 0.7 mm or less is preferable; however, if shaved too thin, undesirable curling of the graft may occur.

The choice of graft material is made based on the complexity of the reconstruction and the activity of any underlying chronic ear disease. In higher risk situations, cartilage tympanoplasty techniques may provide more durable results (27,28). A high-risk perforation might be considered one that is larger than 50%, an anterior perforation, a perforation draining at the time of surgery, a recurrent

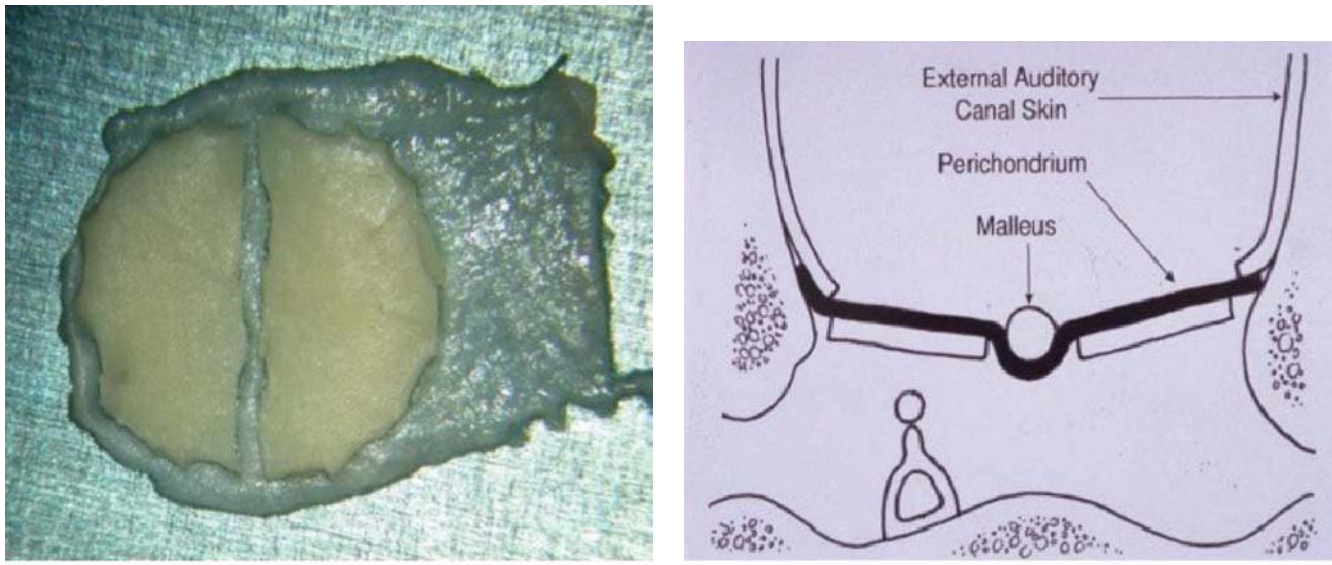


Figure 153.2 Composite perichondrium–cartilage island graft. **A:** A composite perichondrium–cartilage island graft is formed by stripping perichondrium off a single side of the graft. The cartilage is then cut to the desired shape and size without violating the remaining perichondrium. For total tympanic membrane reconstruction, the preferred diameter of the graft is 8 to 9 mm. A 1-mm central strip of cartilage is removed to accommodate the malleus handle and to allow posterior graft elevation for ossiculoplasty. The remaining peripheral perichondrial "apron" is set over the canal wall bone. **B:** Cross section of a perichondrium–cartilage island used as an underlay graft.

perforation (29,30), or a perforation in the setting of permanent absent eustachian tube function. Other situations where cartilage is useful are the atelectatic ear, retraction pockets, and cholesteatoma as re-atrophy and perforation are common over the long term when fascia is used solely in the reconstruction (31).

Mini split-thickness skin grafts may also be used as an adjuvant in tympanoplasty. Although it is generally not advisable to graft the entire reconstructed drumhead due to the potential for dysfunctional postoperative epithelial migration, small grafts (4 mm or less in any dimension) tend to incorporate well with adjacent native epithelium. When utilized, these grafts are best rendered very thin and positioned partially upon the intended tympanic graft target and at least partially upon adjacent healthy canal bone. Instances where mini split-thickness skin grafts may be particularly useful include correction of tympanic membrane blunting, repair of total tympanic membrane defects, removal of chronic granular myringitis, and treatment of tympanic slag injury.

Underlay Repair

Underlay tympanoplasty is the most widely used tympanic membrane repair technique and is suitable for perforations of all sizes and locations (see Fig. 153.3). The concept of underlay grafting involves placement of graft material immediately underneath the residual native drumhead in a manner that accounts for the entire defect and all perforation margins. Three forces typically support this graft. First, medial support is obtained via absorbable middle ear packing material. Second, adhesion occurs between the graft and the undersurface of the adjacent native drumhead and between the graft and lateral packing material through the perforation. Finally, the peripheral aspect of the graft is anchored in place between the tympanic annulus/canal skin and the underlying bone of the external auditory canal. Anchoring almost always involves the posterior canal wall and tympanomeatal flap but has also been described at various anterior points (32,33).

The advantages of underlay grafting include simplicity, rapid execution, and a high rate of reported success. However, failures do occur, and these are most often related to overreliance on middle ear packing materials. If peripheral annulus anchoring is insufficient, packing may fail to prevent medial (inward) graft displacement and point separation of the graft from the perforation edge. This seems to be a particular risk when repairing an anterior or near-total perforation. In the authors' experience, large rigid cartilage grafts are less likely than fascia or perichondrium to displace medially.

Another theoretic negative consequence of underlay grafting relates to development of postoperative middle ear adhesions and tympanosclerosis. When middle ear mucosa is denuded, the large volume of middle ear packing required for underlay graft support harbors the potential to increase scar formation between the walls of the middle ear cleft and the undersurface of the drumhead. Additionally, redundant margins of underlay graft that lie in contact with the ossicular chain have the potential to adhere and negatively affect ossicular mobility.

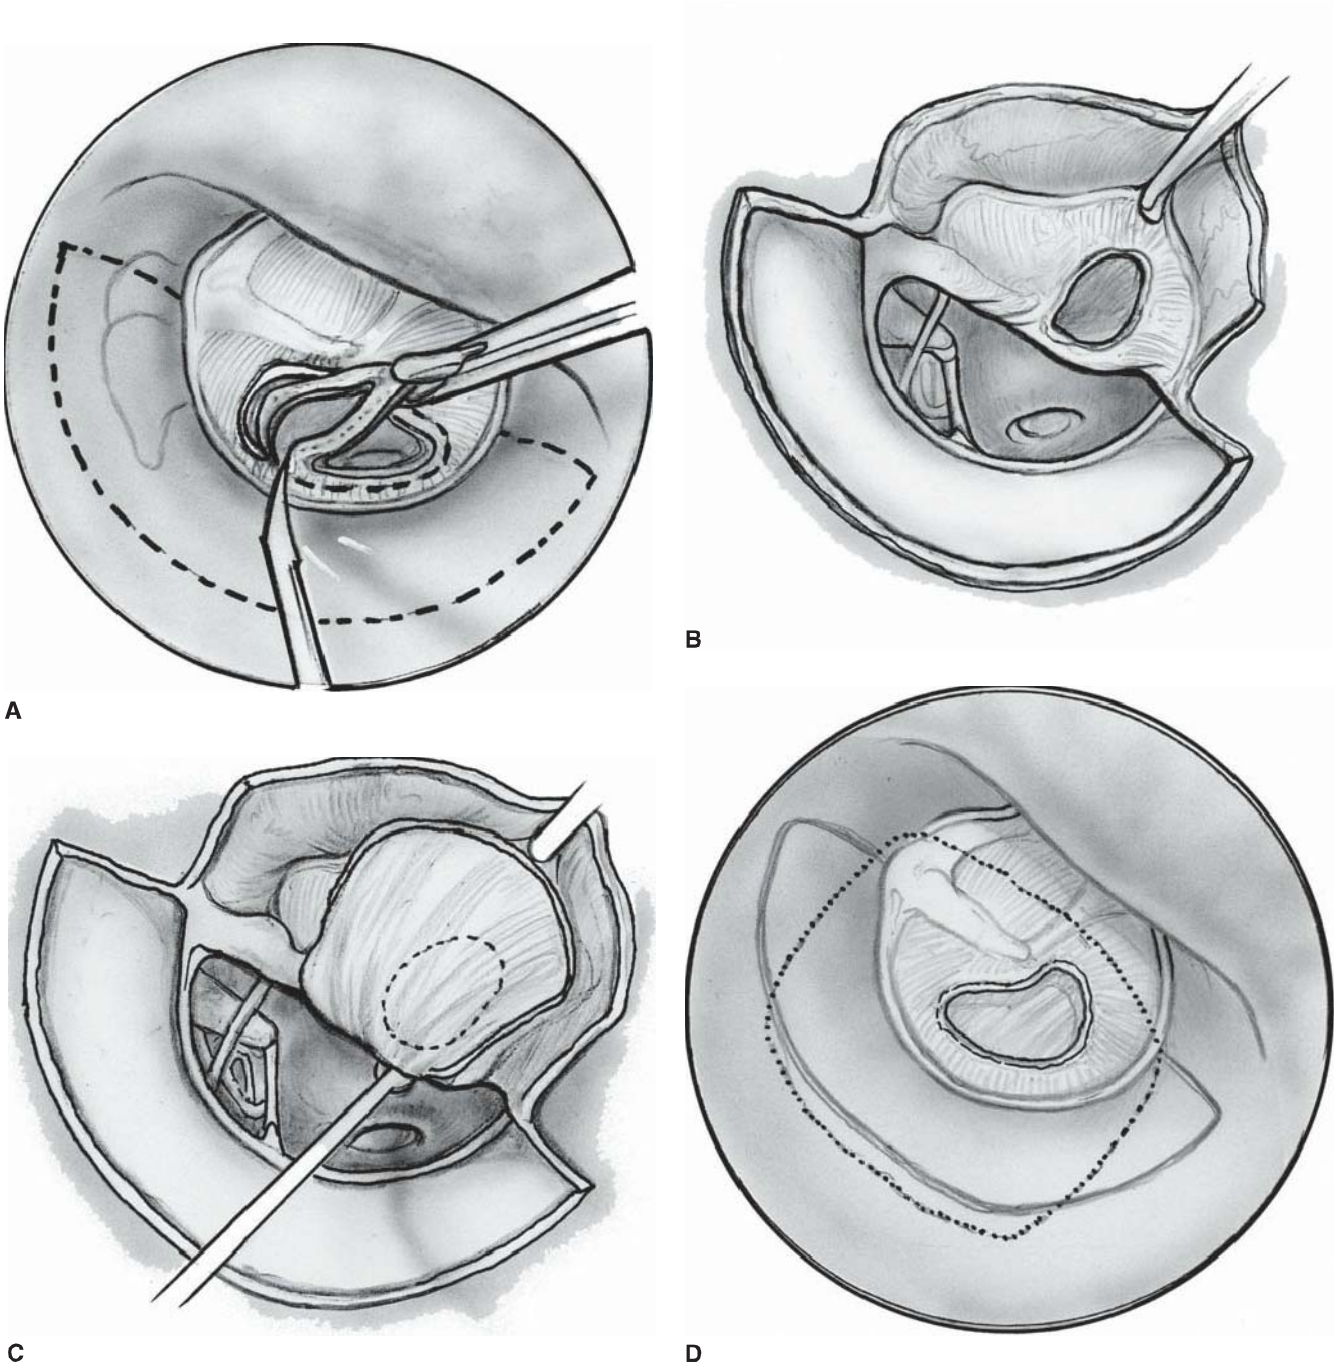

Figure 153.3 Underlay tympanoplasty. **A:** The rim of the perforation is freshened. **B:** The tympanomeatal flap is raised and middle ear work completed as needed, including palpation of the ossicular chain. **C:** The graft is set in an underlay fashion to account for all margins of the perforation. **D:** After application of middle ear packing to support the graft medially, the tympanomeatal flap is returned to the anatomical position, with perforation closure assured.

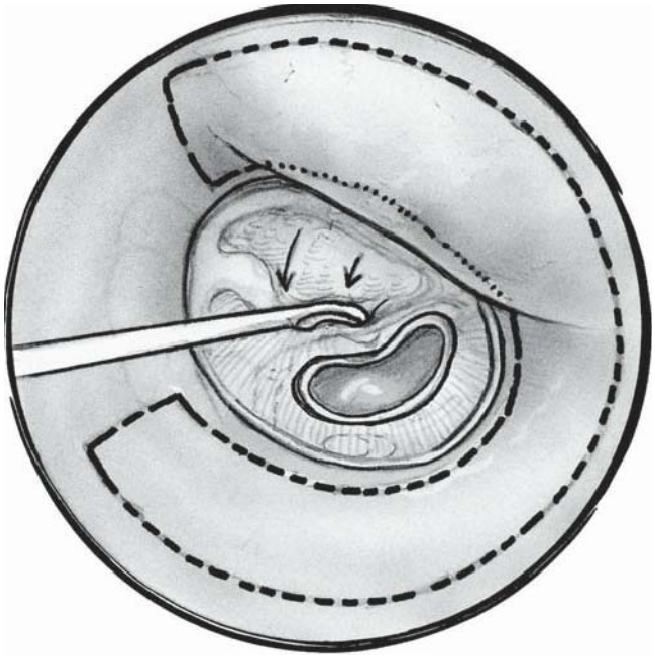
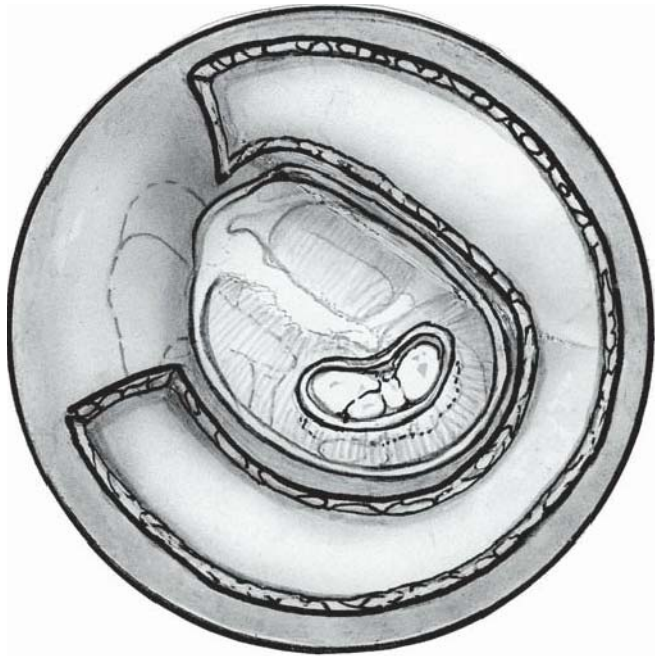
Overlay Repair

The basic concept of overlay or "lateral grafting" involves de-epithelialization of the tympanic membrane remnant while preserving what exists of the native middle fibrous layer. This preserved middle layer remnant is then used as partial medial support upon which grafting materials are set (see Fig. 153.4). Overlay techniques are robust and can be applied to all perforations, but they are especially useful in dealing with anterior and near total defects (34). They have the advantage of being relatively resistant to graft failure due to inadequate medial support and inward graft migration during the healing phase sometimes seen with underlay techniques.

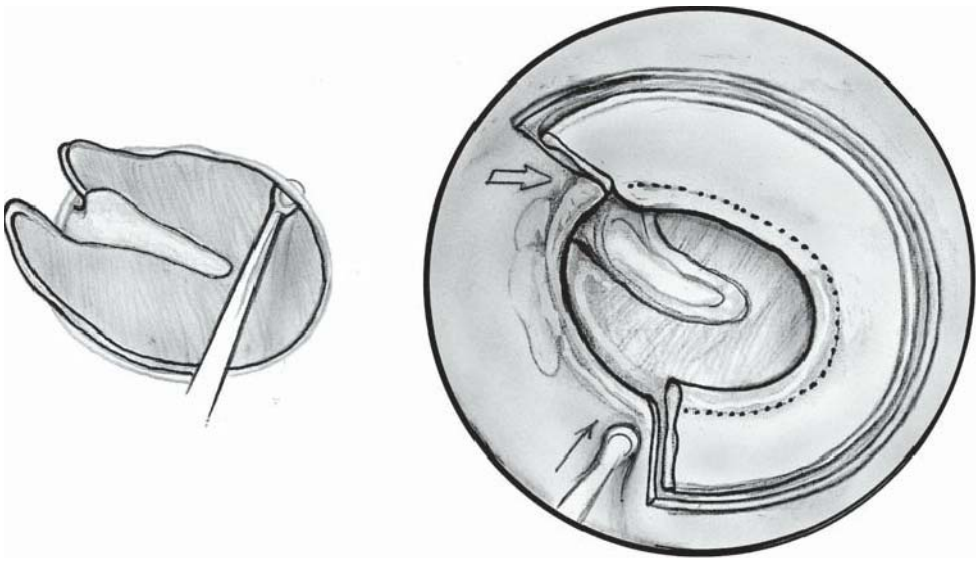
Most common overlay graft techniques are combined with canalplasty to remove the bulge of the anterior canal wall. De-epithelialization of the tympanic membrane is often undertaken as part of the process of exposing the



A

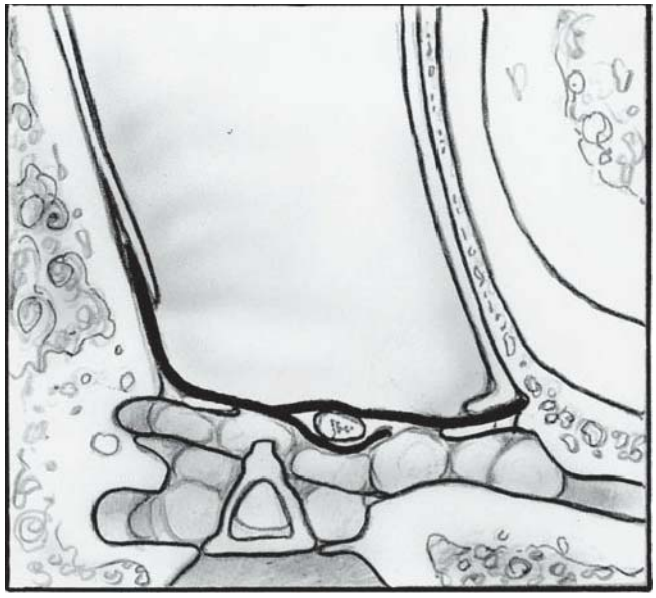


B

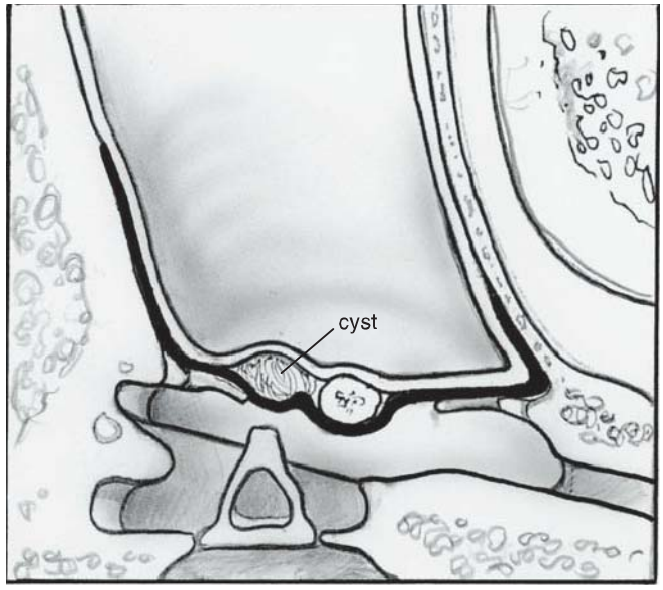


C

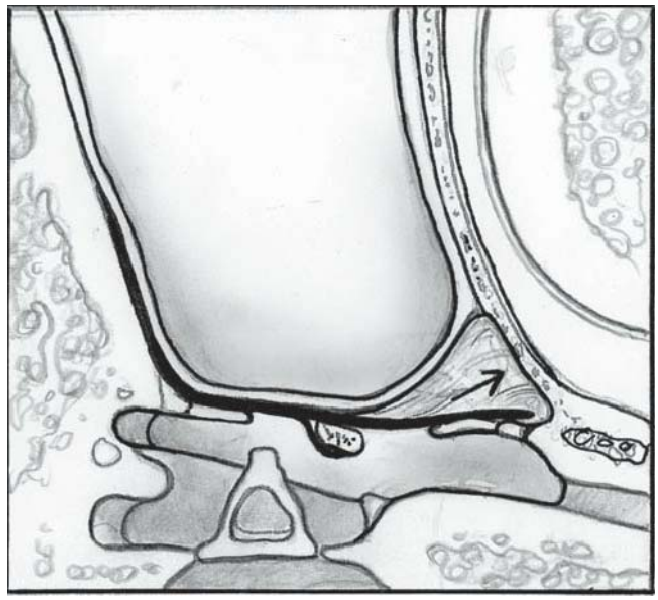
Figure 153.4 Overlay tympanoplasty. **A:** With exposure of the canal wall for canalplasty, all lateral epithelial components of the remnant tympanic membrane are dissected free. **B:** The graft is shaped with a notch for the malleus to account for the entire surface of the tympanic membrane. **C:** The graft is placed medial to the malleus handle to prevent lateralization and then draped over the canal wall on the periphery, lateral to the fibrous tympanic membrane remnant. *(Continued on next page)*



D Ledge drilled at anterior annulus



E



F

Figure 153.4 (*Continued*) **D:** Cross section of overlay graft in place. Of note, the anterior canal wall must be drilled with a groove to open the acute anterior tympanomeatal angle. This area is also tightly packed. **E:** If epithelium is left on the remnant tympanic membrane, an intratympanic keratin cyst may result. **F:** Inadequate packing or drilling of the anterior canal wall can result in blunting. Functionally, this becomes a problem when the malleus handle becomes fixed to the anterior canal wall by scar tissue.

bone of the anterior canal wall for drilling, wherein the canal skin is elevated in continuum with the epithelial remnants of the drumhead. Usually, this canal wall skin is removed and reset near the end of the surgery as a free graft. Care should be taken that all epithelial remnants have been removed prior to graft overlay in order to prevent development of intratympanic keratin inclusion cysts.

It is important to understand that canalplasty is performed with overlay grafting not only to provide adequate exposure to the anterior tympanic ring, but also to open the acute anterior tympanomeatal angle between the anterior canal wall and drumhead in an effort to prevent postoperative blunting of this area. Blunting can be functionally understood as dense scarring of the anterior tympanic membrane that results in reduction of the functional surface area of the drumhead and "pseudo-malleus fixation" caused by adhesion between the manubrium and the anterior canal wall. This risk can be minimized not only by canalplasty, but also by strategically packing this area after graft placement.

Unique Situations

Atelectasis

Tympanic membrane atelectasis may require augmentation with an underlay graft (usually cartilage) or, rarely, drum replacement (14). As a general rule, when atelectasis is limited and has not resulted in the need for ossiculoplasty, medical management to promote eustachian tube function or tympanostomy tube placement is sufficient.

Surprisingly, even some cases of severe atelectasis will correct with the combination of nitrous oxide induction anesthesia, microsuction manipulation, tympanic intubation, and time. However, when these measures have failed and ossiculoplasty is inevitable, or when cholesteatoma risk is high due to incompletely visualized retraction pockets, tympanoplasty is generally required. One challenge unique to this scenario is that long-standing severe retractions can be quite difficult to evert and completely remove from areas such as the sinus tympani, hypotympanum, or the ossicular chain. The laser can be a useful tool for removal of disease from an intact and mobile ossicular chain in these cases. If hearing is reasonable, some surgeons prefer to watch these patients closely rather than risk generating a cholesteatoma by failing to remove all adherent tympanic membrane epithelial remnants.

Lateralized Tympanic Membrane

As a complication of tympanoplasty, it is possible for the tympanic membrane to undergo unfavorable healing and scar formation that may result in postoperative lateralization of the tympanic membrane. When this occurs, the drumhead is typically not coupled to the underlying ossicular chain, thereby resulting in a large-volume conductive hearing loss. Lateralization is particularly a concern when tympanic membrane reconstruction does not involve graft placement medial to an intact stable malleus handle or when there is a prominence of circumferential bare external auditory canal bone. Aside from anchoring the tympanic membrane graft to the malleus handle with an underlay placement, other techniques helpful in dealing with lateralization include secure underlay anchoring of the graft under the tympanic annulus. Cartilage tympanoplasty techniques have proven particularly useful in this situation as the rigid material allows precise fixation medial to the bony annulus (35). Bringing the lateralized tympanic membrane to a more normal position often involves removal of the lateralized membrane, reestablishment of a new graft using underlay techniques, and the use of small full- or split-thickness skin grafts to cover exposed external canal bone in order to promote rapid healing and minimize the scar formation that leads to lateralization.

Open Mastoid Cavity

Successful tympanic membrane repair in the setting of a canal wall–down mastoid procedure requires attention to a few unique considerations. When an open mastoid cavity is created, the epitympanum is exteriorized; thus, the anchored boundary of the tympanic membrane margin is shifted medially in the posterior and superior aspects where the bony canal wall and tympanic ring have been removed. Typically, the bony canal of the tympanic and mastoid segments of the facial nerve form convenient new marginal boundaries for the neo-tympanic membrane in these superior and posterior aspects, respectively. Ideally, this should be achieved by complete lowering of the facial ridge of bone overlying the second genu and mastoid segment.

One oft-neglected aspect of neo-tympanic membrane creation in a canal wall–down situation is that exteriorization of the epitympanum usually involves opening the anterior supralabyrinthine communication with the supratubal recess. If this opening, located anterior to the tensor tympani tendon, is not recognized and accounted for with graft material, barrier separation between the moist middle ear mucosa and the epithelialized open mastoid cavity will not occur, and a source of moisture that acts as a *de facto* tympanic membrane perforation will lead to future open cavity instability.

A final consideration in canal wall–down neo-tympanic membrane repair relates to the resultant diminished middle ear volume, wherein much of the undersurface of the new drumhead is brought into relative proximity with the promontory and other middle ear structures. As such, postoperative negative middle ear pressure and retraction are much less well tolerated than in an intact canal wall situation as there is very little open space to buffer contact and adhesion formation. The use of cartilage grafts to resist retraction is particularly helpful in this situation. The authors favor the use of a large composite perichondrium–cartilage island graft such that residual perichondrial edges drape over the facial ridge and seal the middle ear space as part of a type III tympanoplasty with a direct stapes columella (36) or a synthetic prosthesis.

OSSICULOPLASTY

General Principles

While it is generally possible to ascertain the need for ossiculoplasty during the preoperative evaluation based on the audiogram and physical exam, one should be prepared for this contingency in every middle ear case. In addition, it should be considered routine practice to inspect the ossicular chain visually and mechanically every time the middle ear is entered. This can be performed with gentle palpation of the malleus, taking note of concomitant movement of the stapes and visualization of the round window reflex (movement of the membrane and fluid in the niche with palpation of the chain).

The goal of ossiculoplasty is to reconstruct the sound-conducting connection between the inner ear and tympanic membrane. This reconstruction should have immediate stability and long-term durability. It should also comply with as many of the gain-benefit principles of ossicular acoustic mechanics as is practical. The durability of ossiculoplasty is difficult to predict and is influenced heavily by the quality of the middle ear environment and activity of any related underlying disease process.

The timing of ossiculoplasty is controversial with respect to whether or not it should be performed primarily alongside repair of the tympanic membrane or as part

of a staged process. The benefit of staged surgery is that ossicular reconstruction can be applied to a favorable environment in which the dimensions of the tympanic membrane relative to the middle ear are stable and a quiet middle ear mucosal envelope is present. When a second stage is planned after canal wall–up cholesteatoma surgery or when the middle ear environment is particularly hostile (active infection, fibrotic mucosa, revision surgery), a staged approach is logical. In such instances, temporary silastic sheeting is placed within the middle ear during primary tympanic membrane repair to prevent adhesions between the undersurface of the drumhead and the medial aspect of the middle ear. Theoretical benefits notwithstanding, the authors' preference is to perform primary ossiculoplasty alongside tympanic membrane repair in most cases. In doing so, excellent results are still typical while avoiding the cost and inconvenience of further surgery. In the rare instance of an unacceptable hearing result after primary ossiculoplasty, revision surgery can still be easily performed while utilizing the original ossicular prosthesis.

Ossiculoplasty Materials

A variety of autograft, homograft, and synthetic ossiculoplasty materials are currently used or have been tried in the past. Autologous ossicular grafting techniques have been used extensively, are the most biocompatible, and tend to maintain their configuration over time through bone substitution (37). Cortical bone grafts show good biocompatibility, but in the authors' experience, are more likely than ossicular grafts to undergo absorption over the long term, especially in a hostile middle ear environment. Autologous cartilage is biocompatible and has been used in cases when the space to be reconstructed is small; for example, this material can be used as a stapes height extender in a canal wall–down reconstruction. However, concerns about graft acquisition of chondromalacia over the long term have limited the authors' use of autologous cartilage for major reconstructions between the stapes and malleus. Homologous cadaveric bone and cartilage grafts have also been used successfully in middle ear surgery, but the cost of preparation and risk of disease transmission have made these materials progressively less popular.

Numerous synthetic materials have been used in ossicular implants (38,39). Porous high-density polyethylene was used in several early implants; however, these implants were frequently associated with processes that have negative implications, such as micro-degradation and giant cell formation. Thus, other implants have been developed using plastics, bioactive glass, stainless steel, gold, titanium, and hydroxylapatite (the last two currently being most common in the United States and Europe). Promising short-term results continue to be published for most of these materials (40–43), but the long-term histological fate is uncertain in many instances. The extrusion rates of synthetic implants are generally higher than autologous materials (44).

Applied Middle Ear Mechanics

As discussed previously, by far the most important mechanism of acoustic gain will come from reestablishment of the hydraulic lever, derived from the surface area ratio of the tympanic membrane to the oval window, by coupling the reconstructed tympanic membrane to the stapes footplate. Reestablishment of the catenary lever is also often possible by utilizing the manubrium of the malleus in the reconstruction of both the tympanic membrane and ossicular chain. Recent basic science research using infrared laser vibrometry as well as retrospective clinical studies on ossiculoplasty suggest that incorporating the malleus in the reconstruction provides increased acoustic gain (45). However, since gain derived from catenary effects is severalfold less than that derived from the hydraulic lever, these theoretic benefits should be kept in proper perspective during surgical planning. Similarly, the malleoincudal lever provides such a small theoretical increase in gain (2 to 3 dB) that it does not constitute a compelling reason to favor a type II reconstructive mechanism over one of the type III subtypes.

Specific Situations

Incus Erosion

Due to its location relative to the common pathways of development of cholesteatoma and tympanic membrane atelectasis, as well as its rather tenuous blood supply suspended between the stapes and malleus, erosion of the incus long process is the most common ossicular defect. It can be encountered in roughly one-third of cases involving a chronic posterior tympanic membrane perforation due to a variety of factors, such as pressure necrosis, inflammation, and hydrolytic enzymes produced by cholesteatoma matrix.

While an eroded incus is usually obvious during middle ear exploration, in some cases palpation is required to uncover the presence of a more subtle fibrous union between the stapes and incus. The key factor in this situation is the degree of bony contact remaining, which, if present to some reasonable degree, may compel the surgeon to leave the incus untouched. However, if contact is deficient and movement with palpation is incomplete, reconstruction is recommended.

There are basically two options for reconstruction when incus erosion is present. The first involves an attempt to reconstruct the incudostapedial joint with a type II tympanoplasty. If the defect between the incus and stapes is very small, this can be accomplished by wedging a piece of cartilage or bone between the incus and malleus. Alternatively, various cements composed of materials such as ionomer and hydroxylapatite have shown promise in small-defect joint reconstruction (46,47); however, these cements have thus far been met with somewhat limited acceptance due to concerns of toxicity (ionomer) and of excessive brittleness that may result in a tendency to dislocate or fracture (hydroxylapatite).

For larger defects, various prostheses can be utilized. The prosthesis that has been in use for the longest duration, the Applebaum prosthesis (Gyrus ENT, Bartlett, TN), is made of dense hydroxylapatite and is shaped like a block, with two divots oriented at 90 degrees from each other to engage both the stapes capitulum and the eroded lenticular process. Other metallic prostheses have been developed that tend to be similar in concept in so far as they combine an extension that heat shrinks (nitinol) or crimps (titanium) to the remnant of the long process, with a cradle that engages the stapes capitulum.

All of these type II reconstructive techniques share many of the same theoretical advantages and disadvantages. On the positive side, they reestablish the natural malleoincudal lever with minimal disruption of the normal anatomical relationships and native ossicular connections. The primary disadvantages relate to uncertain long-term durability. Little is known about the pathophysiology and natural history of incus necrosis. If erosion is related to avascular necrosis, one may speculate that the remnant of the lenticular process, if used in ossicular reconstruction, may be subject to future loss.

The second reconstructive option for incus necrosis involves removal of the incus remnant and reconstruction between the stapes and malleus (or tympanic membrane), generally as a type III minor columella mechanism. The fundamental anatomic principles governing this reconstruction are the same regardless of the graft or prostheses used. Some key relationships include the vertical height from the stapes capitulum to the plane of the neck of the malleus (2 to 2.5 mm) and the horizontal or translational distance from the capitulum to the neck of the malleus (3 to 3.5 mm) (see Fig. 153.5). Although the malleus manubrium can become rotated medially as an effect of middle ear disease processes, especially along its distal aspect, in the authors' experience, the malleus neck is spared from rotational variation and can be used in ossicular reconstruction with these distances remaining fairly consistent. This is due to the fact that the axis of malleus medial rotation lies close to the neck as the malleus is supported at the anterior malleolar spine by the fan-shaped anterior malleolar ligament and medially at the cochleariform process by the tensor tympani tendon. However, if the malleus is medially or anteriorly rotated to an extreme degree, it may be necessary to pull it laterally with a small hook, to stretch or cut the tensor tendon, or rarely, to detach it from the drumhead and translocate the manubrium while keeping ligamentous attachments intact.

If the body of the incus is not significantly eroded or at risk of harboring microscopic cholesteatoma, it can be sculpted with a drill burr and used as an incus interposition autologous graft to fit the above-noted dimensions (see Fig. 153.6). If properly executed, this technique will generate a stable, durable reconstruction that has been described extensively in the literature as having favorable hearing

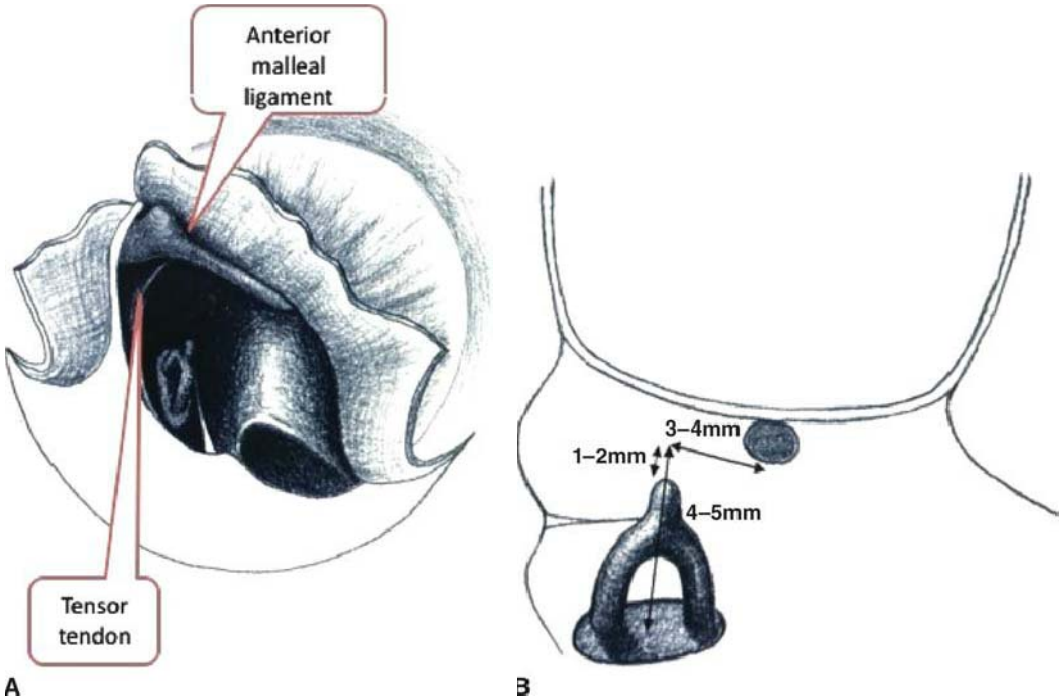


Figure 153.5 Middle ear anatomy relevant to ossiculoplasty. **A:** The tensor tympani tendon and the anterior malleal ligament anchor the malleus neck at the cochleariform process and anterior tympanic spine, respectively. These structures provide stability for tympanoplasty and ossiculoplasty procedures and should not be violated unless necessary. **B:** The stapes capitulum is typically 2 mm in height below the undersurface of the neck of the malleus, which is the proper target for the ossicular reconstruction interface. This same site is approximately 3 mm in the lateral dimension from the capitulum; thus, 3 mm of reach is generally required for a sculpted ossicular graft or synthetic prosthesis.

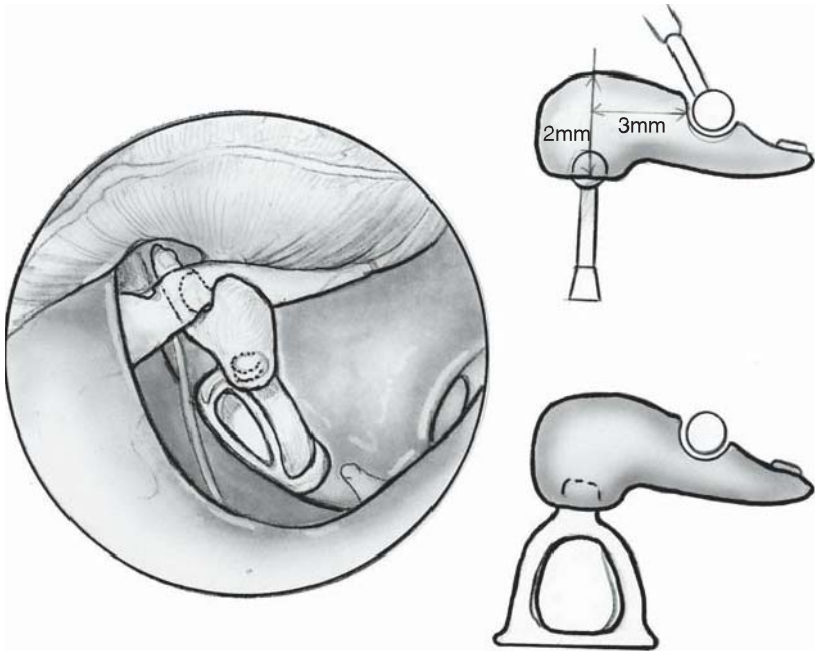

Figure 153.6 Incus interposition. Sculpted incus interposition grafts may be used to bridge the malleus handle and stapes capitulum. These should have an approximate height of 2 mm and an offset groove for the malleus interface at 3 mm.

outcomes (48). The main advantages of this technique are that it is inexpensive and there are no biocompatibility concerns. The disadvantages are that there is a low possibility of continued necrosis, the incus may not be available in all cases, and autologous ossicular grafts tend to fuse strongly to engaged native ossicles or to other adjacent structures such that revision surgery can be challenging.

If the incus is deemed unusable or if the time and work involved with autograft preparation are not embraced, most surgeons opt for the use of a synthetic PORP (49). The recommended surgical technique utilizing a PORP as a minor columella is quite similar to that described for incus interposition, keeping in mind that the vertical height should be 2 to 2.5 mm and the horizontal reach distance 3 to 3.5 mm. While many commercially prepared prostheses are produced with a wide range of lengths or are adjustable, if reconstruction is made to the malleus neck, adjustments are not often necessary. It has been the authors' experience that similar consistency in measurements to what is encountered in stapes surgery is seen in incus replacement if the proper site at the malleus neck is utilized. Thus, although it is sensible to confirm by measuring, a prosthesis with a vertical height of 2 to 2.5 mm and a horizontal reach of 3 mm can be used in almost every case as long as it is designed to engage the malleus handle and there is no stapes capitulum erosion or exaggerated inferior rotation onto the promontory.

Another important point to consider when using a PORP is that many of them have broad heads that make contact with the tympanic membrane in addition to the malleus (in contrast to the "strut-like" structure of a sculpted incus autograft that spares tympanic membrane contact). Since the tympanic membrane is a conical structure and not a flat disk, it is desirable to use a prosthesis that can be bent approximately 30 degrees at the junction of the shaft and head to facilitate this shape (see Fig. 153.7). Doing so will encourage the superior edge of the prosthesis head under the malleus neck to become "locked" by the tensor tympani tendon.

To combat synthetic prosthesis extrusion, a cartilage graft cap is recommended at the interface between the tympanic membrane and the adjacent prosthesis head. Although it has been suggested that this barrier may be optional with a prosthesis that features a hydroxylapatite head with smooth edges, cartilage is essential with sharper titanium prosthesis heads. As opposed to host incompatibility and lateral prosthesis migration beyond the tympanic membrane, the pathophysiology of prosthesis extrusion with an appropriate-length prosthesis more often seems to involve postoperative medial retraction of the tympanic membrane around the prosthesis. Cartilage can be placed in conjunction with reconstruction of the posterior half of the tympanic membrane in order to prevent retractions or cholesteatoma formation. When the cartilage graft is reconstructed exactly in piecemeal fashion, it is known as the mosaic technique (see Fig. 153.8).

The numerous apparent benefits of incorporating the malleus into ossiculoplasty notwithstanding (45,50), some surgeons achieve favorable hearing results without engaging the malleus. Even if the malleus is not included in the reconstruction, making provisions for the conical shape of the tympanic membrane is desirable. In the end, no matter which technique is used, the goal is to create a freestanding reconstruction that fixes to the tympanic membrane and stapes head, but not to other structures, such as the tympanic ring or cochlear promontory. A limited amount of absorbable packing can be used to achieve this end, but it should be noted that its use has been implicated with postoperative middle ear fibrosis, especially when denuded mucosa is present.

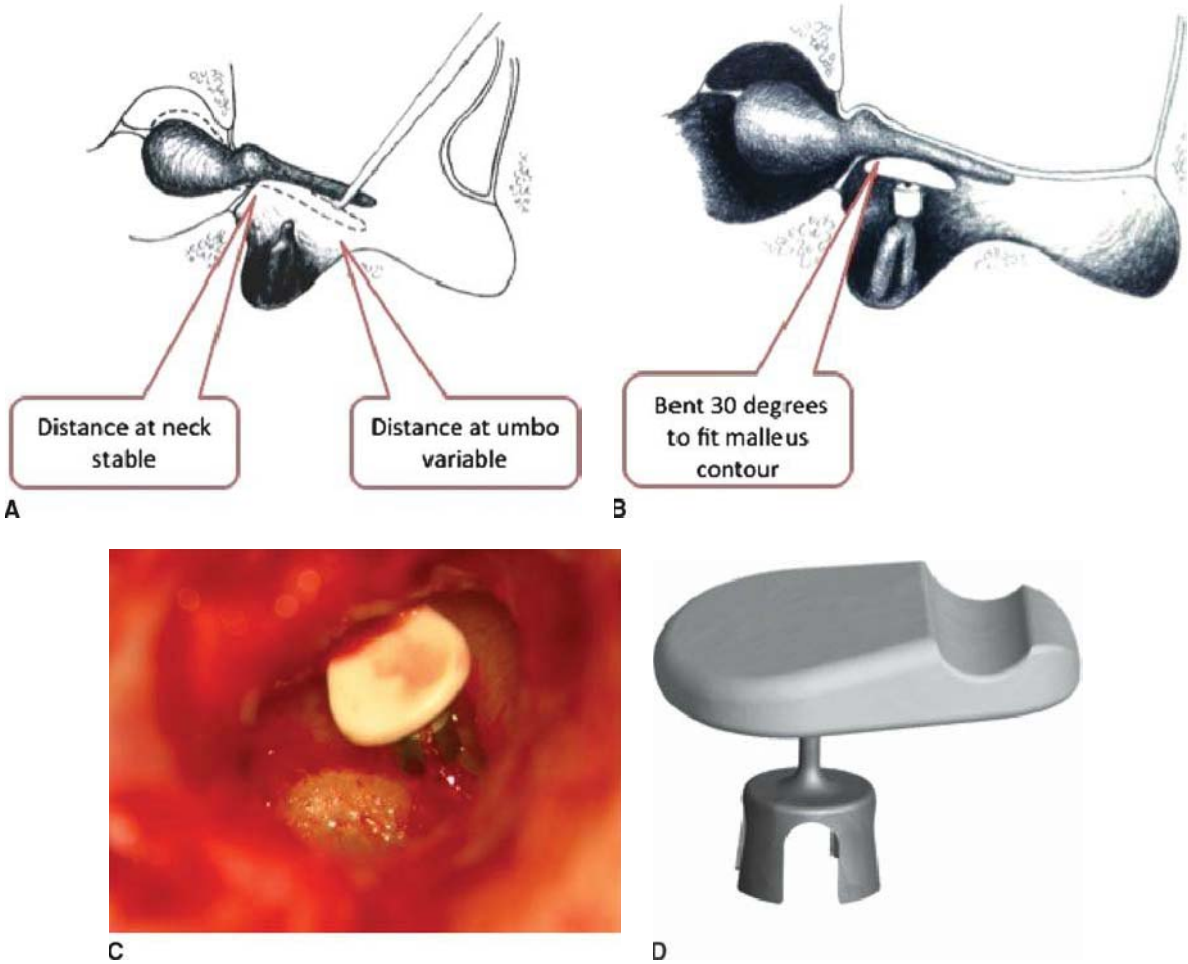

Figure 153.7 Contour of prosthesis to malleus handle. **A:** Although retraction can result in medial displacement of the umbo, the malleus neck orientation is relatively stable due to adjacent supporting ligaments. Thus, the malleus neck, not the handle, is the most constant target for ossiculoplasty. If required, the umbo can be lateralized with a blunt hook. **B:** The prosthesis is manually contoured with a bend of 30 degrees at the interface of the shaft and head to fit properly under the malleus handle and tympanic membrane curvature. **C:** Appearance of contoured PORP in proper stable position between the stapes capitulum and malleus neck. **D:** Dornhoffer PORP with hydroxylapatite head and titanium shaft (Grace Medical, Memphis, TN). The authors assert that, if properly shaped and applied, a prosthesis 2 mm in height can be used in nearly every single case.

Incus and Stapes Absent

When both the incus and stapes superstructure are absent, common options for reconstruction include a type III major columella mechanism or a type IV tympanoplasty, the latter being suitable only in certain cases involving a canal wall–down mastoidectomy. Ossicular or cortical bone grafts are generally not ideal for use in this situation because the long process of the incus is usually eroded to less than the length required for sculpting, while cortical bone grafts tend to fix to the adjacent fallopian canal. Thus, a synthetic TORP is typically what is used as a major columella. The same basic principles of reconstruction and recognition of anatomical consistencies discussed with the use of a PORP apply to a TORP. To account for the absence of the stapes superstructure, an additional 2 to 2.5 mm is added to the vertical height recommendation. Thus, the desired TORP dimensions will be approximately 4.5 mm in height, with 3 mm of reach in order to reconstruct to the malleus neck while maintaining the shaft oriented 90 degrees to the footplate.

One of the real challenges in this type of reconstruction relates to the lack of stability at the level of the footplate. Although the presence of the stapes superstructure offers no mechanism for acoustic gain, it does provide a convenient point for stable prosthesis fixation. The literature often shows superior hearing outcomes with a PORP versus a TORP, which is likely due to this difference in stability. The same 30-degree angled interface with the neck of the malleus and tympanic membrane is utilized for lateral stability, as described earlier. However, this alone does not ensure a stable centered footplate contact point because the forces exerted by the tympanic membrane and malleus onto the TORP head encourage the shaft to displace posteriorly. Several devices have been introduced to

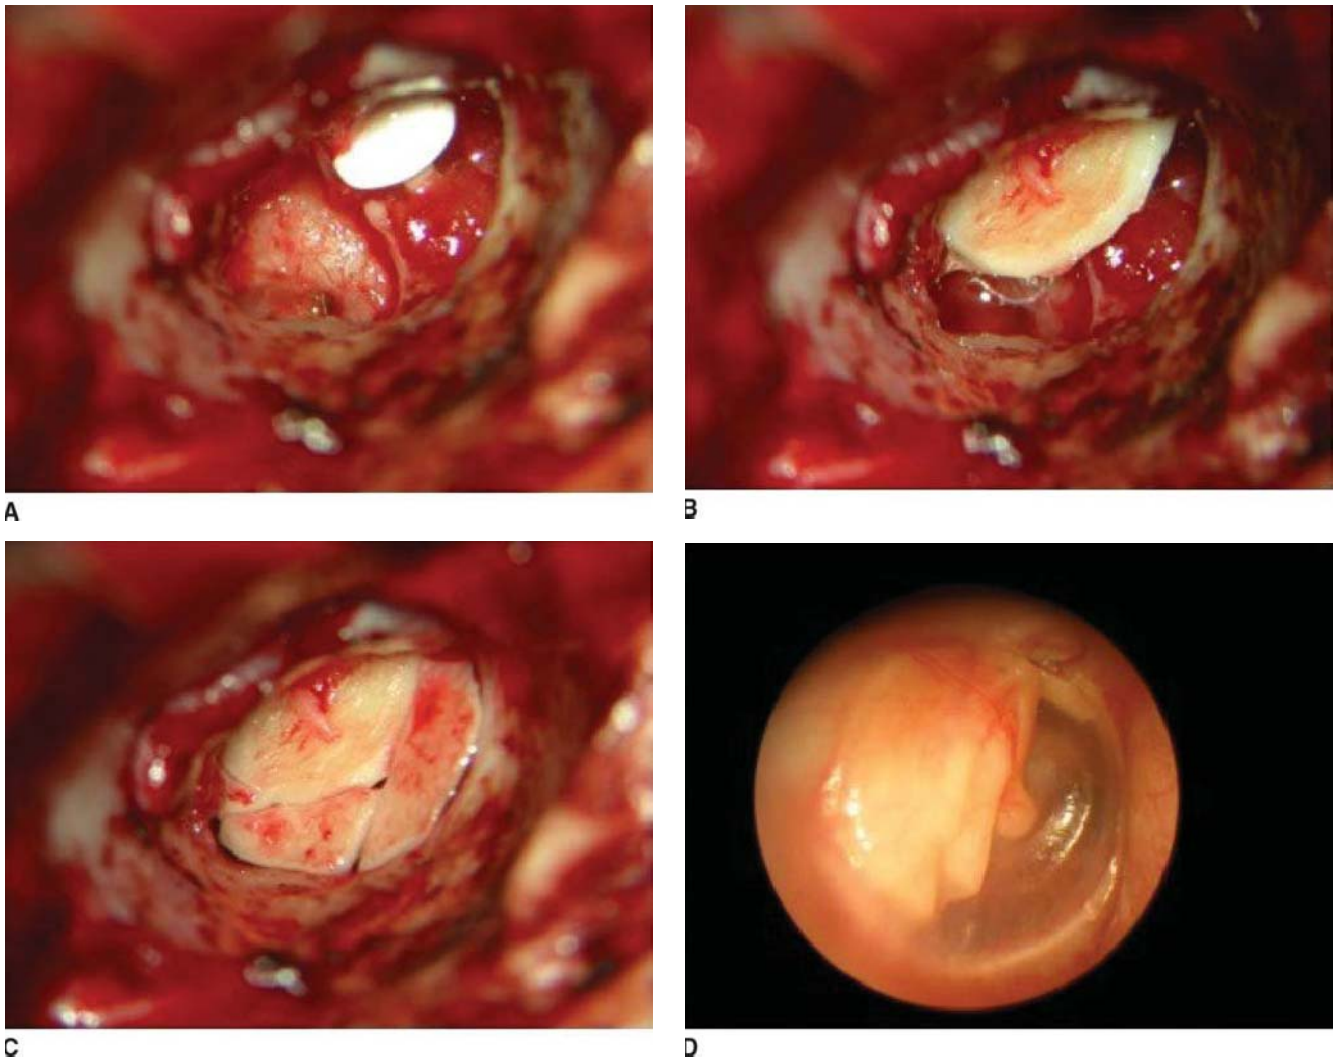

Figure 153.8 Mosaic cartilage tympanoplasty with ossiculoplasty. **A:** The PORP is set between the malleus neck and stapes capitulum. **B:** A large crescent-shaped piece of cartilage is set directly upon the prosthesis. **C:** Smaller crescent-shaped cartilage pieces are placed to form a "mosaic" of cartilage. **D:** Postoperative appearance following cartilage mosaic underlay tympanoplasty (right ear).

counteract this phenomenon, including both titanium and hydroxylapatite footplate "shoes" (see Fig. 153.9). Related techniques that utilize small oval-shaped pieces of cartilage with a central hole have also been described (51).

While it is advisable to utilize the stapes superstructure when present, inferior rotation toward the promontory due to disease or previous surgery can make a minor columella reconstruction unsuitable. In such instances, a PORP or incus interposition may produce rocking of the stapes toward the promontory instead of the desired piston motion. Therefore, a TORP placed on the footplate superior to the superstructure is a more suitable alternative that tends to rotate the stapes superiorly into a more favorable position (52).

Malleus Absent

The techniques previously described emphasize the use of the malleus for prosthesis stability and as an anatomical landmark for consistent length measurements; however, the malleus manubrium is not always present. Some otologists believe that the malleus is such a tremendous benefit in ossiculoplasty that techniques have been developed to create a "neo-malleus" from a piece of bone or a synthetic implant that is grafted into the tympanic membrane to be used later in staged ossicular reconstruction (53). Nonetheless, several options do exist for single-stage tympano-ossicular reconstruction in the absence of a malleus manubrium (52).

The most simple of these single-stage techniques is reconstruction directly between the drumhead and stapes superstructure with a type III stapes columella mechanism (especially in a canal wall–down procedure). It is acoustically favorable to perform this type of reconstruction in combination with tympanic membrane cartilage grafting, wherein the capitulum of the stapes is in contact with a piece of cartilage that is at least 4 mm in diameter, as opposed to a stapes/drumhead interface with fascia or native drumhead only. Although it is possible to achieve

Figure 153.9 TORP with footplate shoe for rotated stapes. When unfavorable inferior rotation of the stapes superstructure is present, a TORP is often preferable to maintain an approximate perpendicular orientation between the tympanic membrane and prosthesis shaft. In this case, the TORP is stabilized at the level of the footplate by a titanium shoe. The stapes capitulum is indicated by the *asterisk*.

excellent air–bone gap closure with the stapes columella subtype of type III reconstruction (36), actual outcomes can be inconsistent or lag behind what is predicted. Various other simple modifications of type III tympanoplasty that result in a minor columella can be made when direct contact between the drumhead and stapes is not possible but only a small gap exists. These include placement of some type of autologous interposition graft, such as a sculpted malleus head or stacked disk(s) of cartilage.

When a wider gap between the stapes and drumhead is present or when the superstructure is absent, the use of a PORP or TORP that directly contacts the drumhead (with or without the cartilage cap, depending on the prosthesis material used) is generally required. These techniques can be effective, but great care should be exercised in measuring the correct prosthesis length. It is recommended that the reconstructed drumhead be slightly tented by the prosthesis; however, a major reason for prosthesis extrusion, regardless of material, is excessive length. Because these cases involving an absent malleus harbor the potential for graft/prosthesis adherence to the undersurface of the reconstructed tympanic membrane and ossiculoplasty failure due to delayed lateralization of the capitulum or footplate as the reconstructed tympanic membrane heals and matures, many surgeons favor staged ossiculoplasty. One innovative way to accomplish this during the second stage is via the facial recess so that elevation of a tympanomeatal flap is avoided and a stable tympanic membrane measurement is afforded (54).

Finally, an alternative single-stage technique involves creation of a "pseudo-malleus" by reconstructing the tympanic membrane with a composite perichondrium–cartilage island graft that forms a creased midline ridge to act in place of the manubrium (see Fig. 153.10). This is achieved

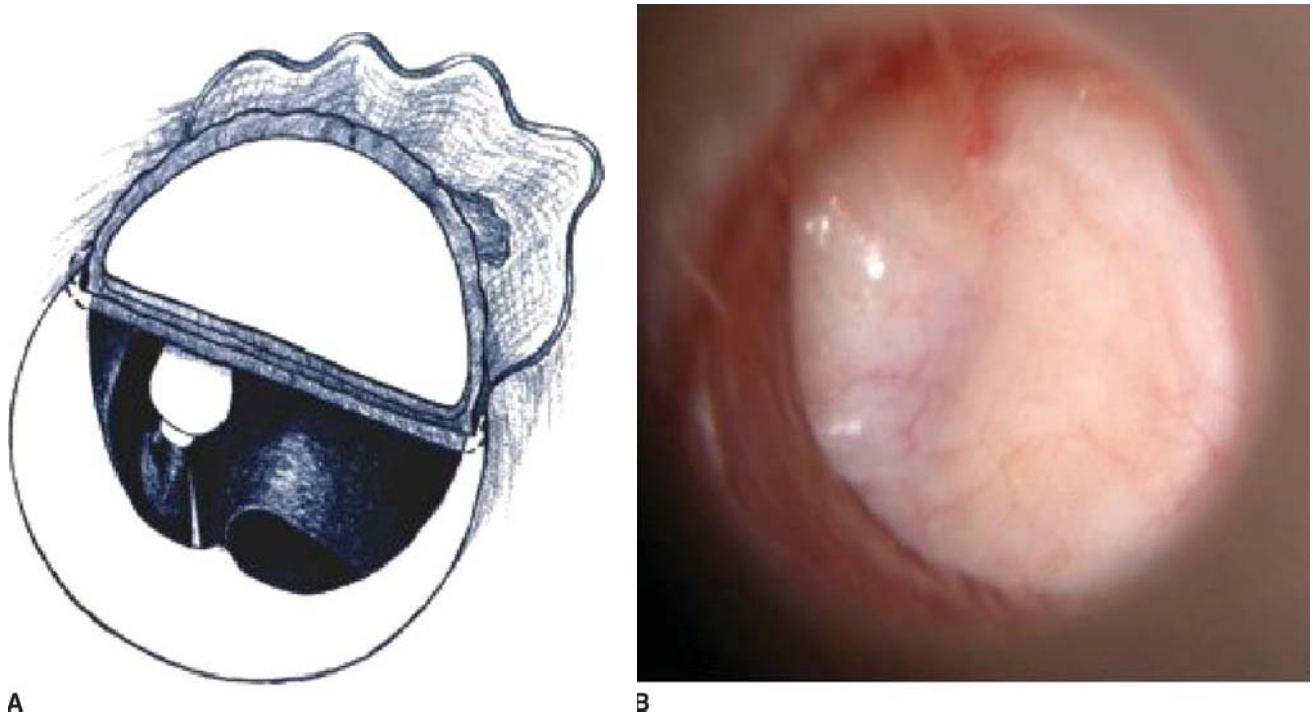

Figure 153.10 Tympano-ossicular reconstruction without malleus. **A:** When the malleus handle is absent, the folded ridge generated by opposing edges of a composite perichondrium–cartilage island graft can be used as a pseudo-malleus to support a prosthesis that has a notch intended for the malleus handle. **B:** Postoperative appearance of tympanic membrane after total drum reconstruction using a composite perichondrium–cartilage island graft.

by creating a circular cartilage island graft measuring 8 to 9 mm in diameter, with a 1-mm midline strip of cartilage removed from the perichondrium, bisecting the island into two half-circles. The anterior half-circle is inserted as an underlay below the tympanic ring inferiorly and anterior tympanic spine superiorly while supported medially with absorbable packing in the anterior mesotympanum. The posterior half-circle is then lifted to expose the posterior edge of the anterior island, which is placed near the position of the absent malleus handle. This pseudo-malleus ridge can then be used for ossicular reconstruction using the same lengths of prostheses described earlier.

Fixed Ossicular Chain

Tympanosclerosis involving the tympanic membrane and middle ear is common when significant otitis media has been present. When these chalky white plaques involve the tympanic membrane, little or no conductive loss is expected unless the ossicular chain is also affected. Hearing loss due to tympanosclerotic fixation can occur secondary to involvement with any component of the ossicular chain.

An isolated malleus head or incus fixation with a mobile stapes can be dealt with in two ways (10). The most common technique involves disarticulation of the incudostapedial joint followed by removal of the incus and amputation of the malleus head just above the insertion of the tensor tympani. Rarely, the malleus head is so fixed that it must be left in place; thus, a 1-mm gap is drilled between the fixed head and the mobile remnant to prevent re-fixation. Reconstruction is then accomplished with a type III minor columella as described previously.

The second technique for correcting malleus fixation involves mobilization through an atticotomy by carefully releasing the point of fixation with a diamond drill bur. While good results have been reported with this technique, great care must be taken not to contact the ossicular chain with the bur as high-frequency sensorineural hearing loss can result. Due to this and the risk of re-fixation with new bone growth, mobilization techniques are only recommended for low-complexity ossicular fixation.

Stapes fixation from tympanosclerosis represents a more complicated problem that often requires a staged approach. If fixation is secondary to a limited amount of soft tympanosclerotic plaque, it is usually possible to remove this in layers until mobilization is achieved. Unlike stapes mobilization in otosclerosis, where re-fixation is frequent, long-term mobility can be achieved with limited tympanosclerosis if otitis media is quiescent. However, if stapedial tympanosclerosis is extensive, a staged stapedotomy or the use of amplification *in lieu* of surgery is required. For stapedotomy to be considered in the setting of quiescent chronic otitis media, several criteria must be satisfied, including a healthy healed tympanic membrane, complete absence of middle ear disease and effusion for several months, and apparent eustachian tube patency (55).

During second-stage surgery standard incus-grip stapedotomy can be performed if the lateral ossicular chain is mobile although, similar to obliterative otosclerosis, this may require removal of plaque from the footplate with a laser or mechanical drill. If the lateral ossicular chain is fixed, the incus and head of the malleus can be removed so that an incus-replacement malleostapedotomy procedure can be performed. It should be noted that this is a technically challenging procedure that should be attempted only by the highly experienced otologic surgeon (56). A technically challenging alternative involves creation of a larger stapedotomy followed by placement of a tissue seal over the oval window and overlying reconstruction with a TORP (57). One must always consider that the hearing results with stapes surgery for extensive tympanosclerosis are generally not as good as for otosclerosis; thus, amplification should always be considered as an alternative to ossicular reconstruction in these instances.

RESULTS

Experienced surgeons should expect durable closure of the tympanic membrane in 85% to 95% of tympanoplasty procedures. Furthermore, although hearing results may vary, one should expect only a small air–bone gap in 90% of type I tympanoplasty cases (49). Risk factors for failure of type I tympanoplasty are not definitively understood or universally accepted; yet when viewed through the lenses of experience, common sense, and published tympanoplasty outcome data, certain themes can be recognized. First, underlying host tissue factors that negatively affect graft viability, capillary ingrowth, and nutrient supply, such as diabetes, smoking (58,59), severe malnutrition, active infection, past slag injury, or past radiation therapy, may be expected to increase the risk of failure to some degree. Furthermore, factors that increase the odds of graft displacement or migration during the healing phase, such as eustachian tube dysfunction, chronic cough, obstructive sleep apnea, or an unwillingness to adhere to recommended postoperative lifestyle guidelines, may have similar negative effects. Finally, other factors, such as the experience and skill of the surgeon, the merits and execution of the technique utilized, the size and location of the perforation, the condition of the tympanic membrane and middle ear, the presence of scar tissue or revision surgery, and the quality of the operating environment (bloodless, hypotensive), likely affect outcome.

Hearing outcomes with ossiculoplasty are more variable compared with type I tympanoplasty, and long-term results are, on average, worse than short-term results (60,61). This is likely because these procedures are more skill and technique dependent, are influenced by the inherent qualities of the prosthesis, and, on average, are associated with more advanced chronic ear disease. Traditionally, ossiculoplasty "success" has been roughly judged to be a pure tone average air–bone gap less than 30 dB for a major columella (TORP), less than 20 dB for a minor columella (PORP),

and less than 10 dB for a stapedotomy (62). However, in the authors' opinion, these benchmarks are only indicative of what is minimally acceptable without the need for revision and do not necessarily portray excellence in ossiculoplasty.

Much has been discussed about the inherent qualities of a theoretically ideal ossicular replacement prosthesis (39), but assuming the material is biocompatible and is correctly placed, the qualities of the underlying middle ear environment have a far greater impact on hearing outcomes. The importance of underlying risk factor stratification has been recognized since Wullstein first reported his classification scheme. Subsequently, Bellucci (16) introduced a classification scheme based on the degree of preoperative drainage, followed by Austin (63), who introduced a classification scheme based on the ossicular defect. Kartush (64) has modified Austin's classification by adding aspects of the patient history to the surgical findings in order to develop the widely used Middle Ear Severity Index. Other modern statistics-based classification systems have since been reported by Black (65) (Surgical Prosthetic Infection Tissue Eustachian), Dornhoffer (66) (Ossiculoplasty Outcome Parameter System), and others.

As with type I tympanoplasty, there is no agreement as to which factors are most important for success in ossiculoplasty; however, review of these classification schemes does reveal certain trends (49,64–68). Specifically, revision surgery, middle ear fibrosis, mucosal disease with drainage, smoking, absence of the stapes superstructure, absence of the malleus handle, and a shallow (69) or poorly aerated middle ear cleft (7) have been cited in the majority of studies as leading to worse hearing outcomes. From a practical standpoint, understanding these factors can be helpful in predicting which patients are at risk of having a poor hearing outcome and, therefore, are perhaps more suitable for staged tympano-ossicular reconstruction.

HIGHLIGHTS

- The goal of reconstruction of the tympanic membrane and ossicular chain is to provide a stable barrier between the moist middle ear and dry lateral epithelialized compartments while optimizing the ossicular coupling properties of the tympano-ossicular mechanism.
- Cartilage grafts are especially useful in reconstructing the tympanic membrane when the risk of graft failure or reacquisition of retraction is high.
- Ossiculoplasty utilizing the malleus neck can result in prosthesis stability and may afford additional acoustic benefits.
- Underlying factors related to the middle ear environment will greatly influence ossiculoplasty outcomes, no matter which techniques are utilized.

Otosclerosis 154

Brandon Isaacson *Joe Walter Kutz Jr.* *Peter S. Roland*

Otosclerosis (OS) is a fibrous osteodystrophy of the human otic capsule. Its clinical manifestations are primarily conductive hearing loss (CHL), although sensorineural hearing loss (SNHL) and mixed hearing loss (MHL) can also occur. The disease process causes abnormal resorption and deposition of bone. OS is noted clinically in 1% of the Caucasian population; it is transmitted in an autosomal dominant fashion but with incomplete penetrance. Females appear to be affected twice as often as males (1).

In 1873, Schwartze described a reddish hue medial to an intact tympanic membrane (TM), which was secondary to the increased vascularity of the cochlear promontory in active OS lesions (the phase known as otospongiosis). This finding is named after him and is known as Schwartze sign. It is seen in 10% of patients with OS. In 1881, von Troltsch noted abnormalities of the middle ear mucosa in this disease and was the first to use the term OS. In 1893, Politzer described OS as a primary disease of the otic capsule, rather than a condition related to previous episodes of inflammatory ear disease, as originally thought (2).

The clinical entity of OS was further described by Bezold in 1908, when he discussed its historical, physical, and audiometric findings. In 1912, Siebenmann discussed the possibility of OS causing SNHL. Since that time, numerous etiologies of OS have been suggested, including hereditary, endocrine, biochemical, metabolic, infectious (e.g., measles), traumatic, vascular, and even autoimmune factors (3). In fact, Lopez-Gonzalez and Delgado (4) suggested that oral vaccination with type II collagen may mitigate the autoimmune reaction in those susceptible to OS through hyposensitization. It is also possible that interplay of these different factors exist and vary from individual to individual, while causing the same pathologic and clinical findings. In other words, OS may be the common, final pathway of a clinically and genetically heterogeneous group of disorders (5).

EMBRYOLOGY

The maturation of the bony labyrinth plays a role in the pathogenesis of OS. The otic capsule arises from mesenchyme surrounding the otic vesicle at 4 weeks of embryologic development. At 8 weeks, the cartilaginous framework is initiated. At 16 weeks, endochondral osseous replacement of this framework begins in 14 identifiable centers. In some people, complete bony replacement does not occur and leaves cartilage in certain locations. One of these regions, the fissula ante fenestram, is anterior to the oval window (OW) and is usually the last area of endochondral bone formation in the labyrinth. According to temporal bone studies, this region is affected in 80% to 90% of patients with OS (6). In 1985, Schuknecht and Barber (7) reported other areas of predilection for otosclerotic lesions, such as the border of the round window (RW), the apical medial wall of the cochlea, the area posterior to the cochlear aqueduct, the region adjacent to the semicircular canals, and the stapes footplate itself (which is derived from otic capsule, as opposed to the superstructure, which is a branchial arch derivative).

HISTOLOGY

There are three forms of otosclerotic lesions: otospongiosis (early phase), transitional phase, and OS (late phase). The early, active phase lesions consist of histiocytes, osteoblasts, and the most active cell group, the osteocytes. The osteocytes resorb bone around preexisting blood vessels, which causes widening of the vascular channels and dilation of the microcirculation. Otoscopic or microscopic exam can reveal the reddish hue caused by these lesions (Schwartze sign if seen on clinical examination). As osteocytes become more involved, these areas grow rich in amorphous ground substance and deficient in mature collagen, resulting in

formation of new spongy bone. With hematoxylin–eosin (H&E) staining, this new spongy bone appears densely blue. This was described in 1914 by Manasse and is known as the blue mantles of Manasse. Interestingly, mantles are found in up to 20% of normal temporal bones. On electron microscopy, the foci of perivascular bony invasion coalesce as the lesions enlarge within the otic capsule (7).

The predominant finding in the late phase of OS is the formation of sclerotic, dense bone in areas of previous osseous resorption. The vascular spaces that were once dilated are narrowed due to bony deposition. Within each temporal bone containing OS, lesions can be found in early, transitional, and late phases, although the overall histologic status of the developing lesions is fairly uniform. Although OS begins in endochondral bone, as the spongiosis and sclerosis continue, the endosteal and periosteal layers also become involved (8).

BASIC SCIENCE

A number of mechanisms including autoimmune, genetic, and infectious have all been described as potential causative factors for the development of OS. Definitive evidence for an autoimmune etiology for OS is currently lacking. Conflicting evidence exists for increased levels of type II and IX collagen antibodies in patients with OS. Animal models of type II collagen autoimmunity were found to have lesions similar to OS in contrast to another nearly identical study where autoimmune mice were found to have no lesions (5).

OS has a significant genetic component with seven distinct loci reported to date. Autosomal dominant transmission with incomplete penetrance is the predominant mode of inheritance. The OS loci identified include genes that regulate growth regulation, intercellular communication; cartilage, bone, and collagen homeostasis and metabolism. Additional work is needed to identify potential candidate genes involved in the pathogenesis of OS (9).

A number of findings point toward a viral etiology for OS. Measles antigens and RNA, as well as nucleocapsid structures identical to measles virus have all been identified in otosclerotic lesions. Increased levels of measles-specific IgG have also been detected in the perilymph of OS patients undergoing stapedectomy. It is not yet certain that the measles virus is involved in the development of OS, and the pathogenesis has yet to be elucidated (9).

A more in-depth understanding of the molecular biology of bone remodeling has shed additional light on the pathogenesis of OS. The otic capsule is unique compared to the rest of the skeleton in that after the age of one, no further osseous remodeling occurs. Bone remodeling is rigorously regulated via a balance between the cytokines and receptor: osteoprotegerin (OPG), receptor activator of nuclear factor kB (RANK), and RANK ligand (RANKL). RANKL is present on the surface of osteoblasts and binds to RANK receptors on the surface of osteoclast precursor cells, which results in osteoclast differentiation, activation, and subsequent bone remodeling. Soluble OPG competes with RANKL in binding to the RANK receptor on the surface of osteoclast precursor cells and results in decreased bone remodeling. A fine balance exists between RANKL and OPG, which regulates skeletal remodeling including the otic capsule. High levels of OPG (reduced predilection for bone turnover) have been detected in the inner ear and are secreted into perilymph by type I fibrocytes located within the spiral ligament. It has been postulated that genetic, infectious, and autoimmune mechanisms likely alter this pathway, which eventually results in OS (9).

PATHOPHYSIOLOGY

The areas of OS involvement dictate the clinical presentation. The most common type involves the stapes and accounts for those cases in which CHL is the presenting symptom. The CHL is due to fixation of the stapes footplate, usually beginning at the fissula ante fenestram (Fig. 154.1). Progressive involvement of the footplate can create a thick focus of OS that fills the OW niche (obliterative OS) (5).

If OS involves only the footplate and spares the annular ligament, minimal fixation may occur. Such a thickened footplate is called a biscuit footplate. Because of minimal fixation, biscuit footplates can become mobilized inadvertently during a stapes procedure, placing the patient at a higher risk of postoperative SNHL. The RW is involved in 30% of all clinical cases of OS; complete closure of this niche is uncommon (10).

SNHL as a result of OS is an ongoing controversial subject. Some patients with OS have a greater amount of SNHL than expected considering their age and history of noise exposure. The mechanism for the SNHL is possibly the liberation of toxic metabolites into the inner ear with resultant injury to neuroepithelium, vascular compromise, or direct extension of lesions into the cochlea, causing

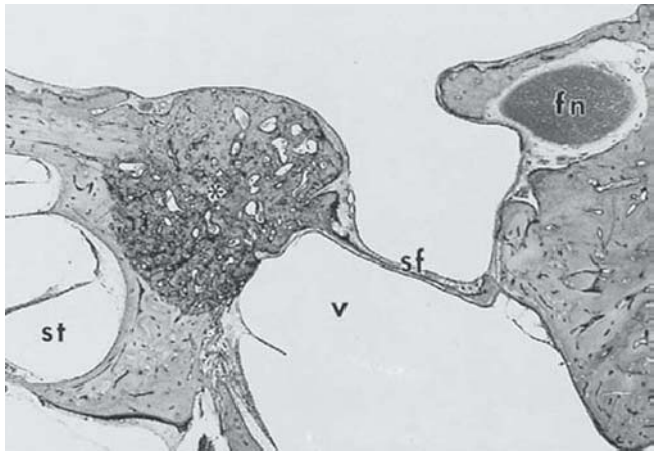

Figure 154.1 Photomicrograph of temporal bone section in a 79-year-old Caucasian male demonstrating a mature otosclerotic focus (*) involving the promontory and anterior stapes footplate (sf). st, scala tympani; v, vestibule; fn, facial nerve. (×20) (Courtesy of M.M. Paparella, director, and S. Lamey, coordinator, Otopathology Laboratory, University of Minnesota).

disruption of electrolytes and changes in basilar membrane mechanics. SNHL is usually associated with significant stapedial OS, although some otologists contend that isolated pure SNHL can be seen without associated CHL. The latter presentation is also known as cochlear OS (11).

Shambaugh (11) has suggested seven criteria to identify patients suffering from SNHL due to OS:

1. Schwartze sign in either ear
2. Family history of OS
3. Unilateral CHL consistent with OS and bilateral, symmetric SNHL
4. Audiogram with a flat or "cookie-bite" curve with excellent discrimination
5. Progressive pure cochlear loss beginning at the usual age of onset for OS
6. Computed tomography (CT) scan showing demineralization of the cochlea typical for OS
7. Stapedial reflex demonstrating the biphasic "on–off effect" seen before stapedial fixation

Vestibular symptoms occur in up to 40% of patients with OS. OS lesions have been described in the lateral semicircular canal during fenestration procedures (which have been replaced by the stapedectomy/stapedotomy). The vestibular symptoms are usually not severe, but objective evidence can be obtained with electronystagmography testing. Non-Ménière-type vertigo or disequilibrium associated with OS has been termed OS inner ear syndrome. It is important to differentiate this disorder from Ménière disease or superior semicircular canal dehiscence (SSCD). Ménière disease is an absolute contraindication for stapedectomy/stapedotomy. When the endolymphatic space is dilated (endolymphatic hydrops), the saccule may be enlarged to the point that it adheres to the undersurface of the stapes footplate. A stapes procedure can injure the saccule and result in profound SNHL. The distinction between OS inner ear syndrome and other causes of dizziness is based on differences in clinical presentation. Rarely does the inner ear syndrome of OS cause well-defined episodes of severe rotational vertigo, nausea, vomiting, and fluctuating SNHL. Dizziness in OS inner ear syndrome is milder but more persistent; low-frequency SNHL is generally not present (12).

In 2004, Mikulec et al. (13) reported on eight patients with presumed OS/unilateral CHL that did not improve after a stapes procedure. These patients were ultimately found to have SSCD. In contrast to typical SSCD patients, these patients had only CHL and no vestibular symptoms. One should keep this entity in mind, especially in a patient with CHL and pressure or sound-induced vertiginous symptoms. Intact acoustic reflexes in the setting of CHL should prompt further imaging to evaluate for an inner ear third window. SSCD, posterior and lateral semicircular canal dehiscence, enlarged vestibular aqueduct, and modiolar deficiencies (i.e., X-linked stapes gusher) can all present with a CHL or MHL with intact acoustic reflexes (13).

EPIDEMIOLOGY

OS is transmitted in an autosomal dominant fashion with incomplete penetrance (25% to 40%). The degree of penetrance is related to the distribution of lesions in the otic capsule. Some lesions are located where they cannot cause clinical symptoms. About 10% of Caucasians have histologic findings of OS. However, of those with histologic changes, only 12% have clinical symptoms; thus, overall, this represents about 1% of the Caucasian population. In the Japanese and South American populations, the incidence is 50% of that in Caucasians. The African American population has fewer cases of OS; only 1% demonstrate histologic findings of the disease. In all races, when one ear is affected, the contralateral ear shows histologic involvement 80% of the time. Generally, the lesions occur in similar anatomic locations and at similar histologic phases. The age at which symptoms become apparent is variable due to the insidious progression of hearing loss, but hearing loss often begins between the ages of 15 and 45 years. The average age at presentation is 33 years (14).

About 60% of patients with clinical OS report a family history of this condition. The remaining 40%, as suggested by Morrison and Bundey (14), make up a collection of cases that fall into one of the following categories:

1. Autosomal dominant inherited cases with failure of penetrance in other family members
2. Phenocopies (an individual expressing a trait that is environmentally as opposed to genetically induced)
3. New mutations
4. Those rare cases transmitted by alternate modes of inheritance (i.e., autosomal recessive)

OS has been reported to advance more rapidly in females than males, although no difference has been noted in age at onset. A recent study by Clayton et al. (15) examined the relationship in elderly women between osteoporosis and OS; both diseases show some similarities, including an association with the *COL1A1* gene. The study showed that a much higher percentage of women with OS also had osteoporosis as compared with a similar aged group with only presbycusis ($P < 0.007$). Juvenile OS may progress more rapidly than the adult form. Hormonal factors may play a role; some females with OS appear to have their condition worsen during pregnancy. Estrogen receptors have been noted in the OS plaques. However, more recent data minimize the association between pregnancy and worsening of OS (9).

HISTORY AND PHYSICAL EXAMINATION

Patients with OS usually present with a slowly progressive hearing loss over a period of years. Patients may describe hearing speech more easily in noisy situations. The CHL improves the signal to noise ratio by subduing background noise (paracusis of Willis). Tinnitus is present in 75% of patients. A complete head and neck examination

is performed to rule out concurrent otolaryngologic abnormalities. Otomicroscopic examination with pneumatic insufflations is done of the external auditory canal (EAC) and TM to asses for the presence of a middle ear effusion or mass, cholesteatoma, or TM retraction. The physical appearance of the TM is normal in most patients with OS. A Schwartze sign (a red to pink appearance of the cochlear promontory occasionally seen in active OS through the TM) may be present.

The primary purpose of performing a tuning fork exam is to confirm the findings of the audiogram. The Rinne test should demonstrate bone conduction to be better than air conduction (Rinne negative) in patients contemplating a stapes procedure. In the initial phases of the disease, CHL may be limited to the 256-Hz tuning fork. As footplate fixation progresses, the 512- and 1,024-Hz tuning forks will "reverse" as well. The amount of air–bone gap required to reverse the tuning forks are about 10 to 15 dB for the 256-Hz tuning fork and 20 to 25 dB for the 512-Hz tuning fork. The Weber test should lateralize to the ear with the greater degree of CHL, although this test is also affected by concurrent SNHL. If the tuning fork exam does not correlate with the audiogram, repeat testing is recommended since inadequate masking may falsely lead the clinician to believe a conductive loss is present in the setting of anacusis (16).

AUDIOLOGIC TESTING

The main objective measurement in OS is the audiogram (Fig. 154.2). On the audiogram, OS is seen as a widening air–bone gap that usually begins in the low frequencies. Variable degrees of SNHL may also be present. Bone conduction may show a 20-dB loss at 2,000 Hz and a 5-dB loss at 500 and 4,000 Hz. Such an apparent depression of bone conduction at 2,000 Hz is known as Carhart notch, which is most commonly seen in OS but can be seen in other types of CHL. This notch is an artifact of the audiogram and disappears after a stapedectomy. It is secondary to stapes fixation and a resultant change in the resonance of the otic capsule (17).

Word recognition scores are usually excellent in patients with OS even in the later stages of the disease process. Impedance can show reduced TM compliance (type A or As). Stapedial reflexes are characteristically absent in the setting of CHL. Intact stapedial reflexes can occasionally be observed in the earliest stages of OS depending on the degree of fixation. With early stapes fixation, a characteristic abnormal decrease in impedance may be noted at the onset and offset of the eliciting signal. This is the on–off effect of OS. The presence of stapedial reflexes with a significant CHL warrants evaluation for an inner ear third window (i.e., SSCD). Vestibular testing should be included when dizziness is present. Although there are not characteristic findings for OS inner ear syndrome, findings or a clinical history suggestive of SSCD or Ménière disease will alter treatment planning (17).

High-resolution CT scans can help identify or confirm patients with OS. Radiolucent areas in and around the cochlea are noted early in the course of the disease, creating the "halo sign." Diffuse sclerosis is found in mature cases (Fig. 154.3). Negative results on the CT scan are not diagnostic because some patients have disease below the capabilities of scanning protocols. The CT can rule out middle ear masses, vascular anomalies, or facial nerve abnormalities but is not an essential part of the workup. These scans can also assess the ossicular chain in addition to the osseous labyrinth (cochlea, semicircular canals) (18).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis should include other causes of CHL or MHL. A history of progressive CHL or MHL in the absence of history of trauma or infection but with the presence of a normal TM limits the possibilities. However, a definitive diagnosis can only be made during exploratory tympanotomy. The most common conditions that mimic OS are those that result in ossicular discontinuity or exert a mass effect on the TM or ossicles. A history of recurrent chronic otitis media suggests an ossicular discontinuity due to incus necrosis. The TM may be normal or thickened or atrophic in cases of chronic infection. The TM in these ears is sometimes abnormally compliant, which can be manifested as a type Ad tympanogram. Fibrous union of the incudostapedial (IS) joint can produce an air–bone gap wider in the high frequencies than in the lower frequencies (16).

Fractures or displacement of the ossicular chain is not uncommon in the setting of temporal bone trauma. Hemotympanum or otorrhea is frequently encountered in the immediate period following the injury. A follow-up examination with audiometry is typically recommended in patients with temporal bone fractures to allow for resolution of hemotympanum and spontaneous healing of TM perforation. In cases of traumatic ossicular chain displacement, a fibrous union often forms with resultant resolution of CHL. Distorted TM surface landmarks occasionally provide evidence of prior temporal bone trauma that has resulted in CHL or MHL. A fracture of the stapes superstructure or incus long process may have a similar audiometric configuration as OS.

Congenital stapedial footplate fixation presents at an earlier age than does juvenile OS. De la Cruz noted in his series that congenital footplate fixation was detectable at age 3, whereas juvenile OS was not detectable until about age 10 (19). In the setting of lateral ossicular chain fixation, the malleus and/or incus become fixed in the epitympanum (usually at the superior malleolar ligament), resulting in immobility of all the ossicles; this can occur congenitally or may be acquired through tympanosclerosis. The entire ossicular chain must be examined with

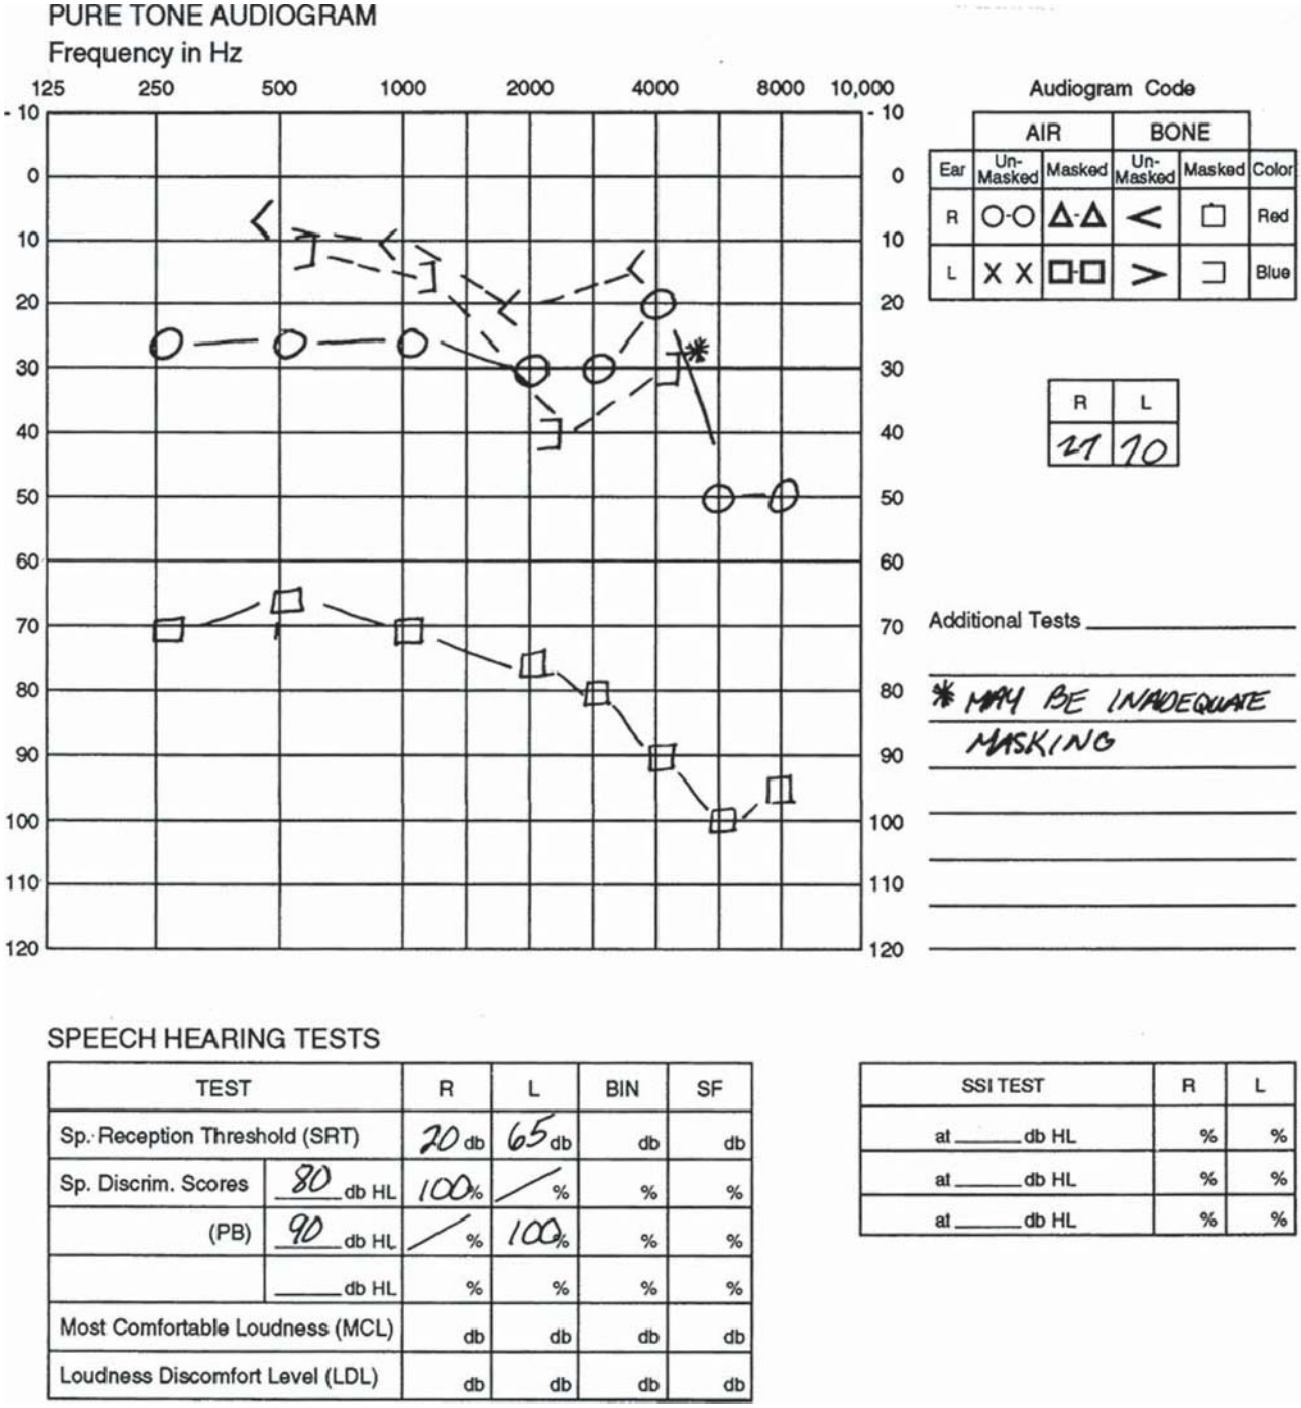

Figure 154.2 An audiogram of a 27-year-old Caucasian woman with OS demonstrating a near-maximum CHL in the left ear and a Carhart notch at 2,000 Hz in both ears. Notice that discrimination remains at 100% in both ears.

every exploratory tympanotomy to avoid overlooking this lesion. Tympanosclerosis can mimic OS, but a history of recurrent otitis media or tympanostomy tubes is usually present. In addition, the TM is often thickened with associated myringosclerosis. Persistent middle ear effusion, neoplasms of the middle ear and EAC (such as glomus tumors or facial nerve tumors), and chronic suppurative otitis media with and without cholesteatoma can also cause CHL. Audiometry and physical examination should help make the diagnosis apparent (16).

Paget disease (osteitis deformans) is a disease with diffuse bony involvement that is histologically similar to OS. In contrast to OS, Paget disease begins in the periosteal layer and involves the endochondral bone last. Temporal

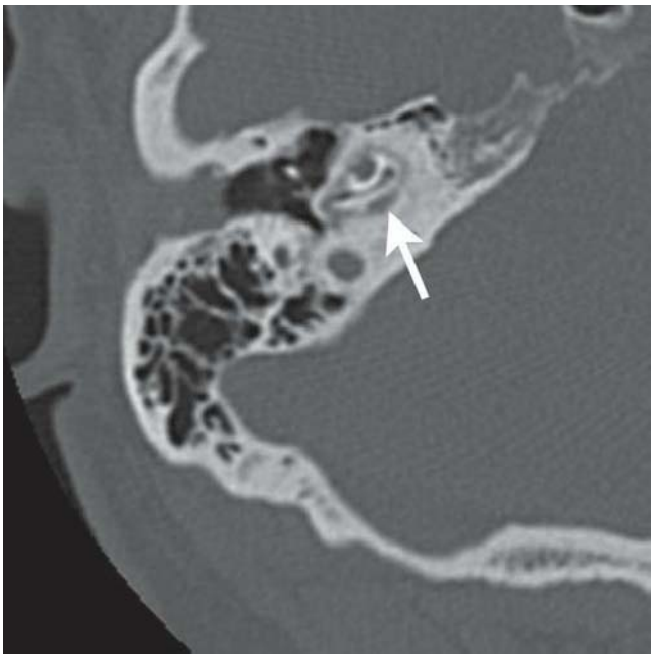

Figure 154.3 High-resolution axial temporal bone CT scan demonstrates extensive OS involving the right cochlea. A classic "halo" sign (*arrow*) surrounds the cochlea.

bone involvement can produce SNHL, but stapes involvement or fixation rarely occurs (20).

Osteogenesis imperfect (van der Hoeve-de-Kleyn syndrome) is an autosomal dominant defect of osteoblast activity resulting in multiple fractures. Stapes fixation and unique blue sclera are also found in 40% to 50% of affected patients. Stapes surgery can be performed in these patients, usually with results similar to those in patients with OS (Table 154.1) (21).

TABLE 154.1 DIAGNOSIS OTOSCLEROSIS

History
- Progressive hearing loss
- Family history of OS
- Tinnitus
- Possible vestibular symptoms (rule our Ménière or SSCD)
- Otitis media/otorrhea (absent)
- Head trauma (absent)

Physical examination
- Tympanic membrane (normal)
- Schwartze sign
- Rinne test (negative at 256 and 512 Hz)
- Weber test (lateralizes to side with greater CHL)

Ancillary studies
- Audiogram (assess for CHL, mixed HL, SNHL, Carhart notch)
- Tympanometry (type A or As; absent or on–off stapedial reflex)
- Imaging (CT scan showing radiolucent areas around bony labyrinth)

CHL, conductive hearing loss; CT, computed tomography; HL, hearing loss; SNHL, sensorineural hearing loss; SSCD, superior semicircular canal dehiscence.

MANAGEMENT

Ninety percent of patients with histologic evidence of OS are asymptomatic; active lesions usually mature without stapedial fixation or cochlear loss. In the symptomatic patient, slowly progressive CHL and SNHL usually begins between the ages of 30 and 50 years with a peak incidence in the 40s (22).The disease may advance more rapidly at times, possibly depending on environmental factors. Periods of progress may be followed by periods of quiescence. The CHL stabilizes at a maximum of 50 to 60 dB.

AMPLIFICATION

Patients with hearing loss secondary to OS should be offered the option of amplification with typical hearing aids as an alternative to observation or surgery. Unilateral or bilateral hearing aids may provide effective treatment. Some patients may not be suitable candidates for surgery, making amplification the only reasonable option. Another option is to use bone conduction hearing aid. A bone anchored hearing aid (BAHA) is another option for patients with CHL or MHL secondary to OS who cannot wear a hearing aid. Two BAHA systems are currently available in the United States (BAHA, Cochlear Corporation; PONTO, Oticon). A BAHA bypasses the ossicular chain and amplifies sound that stimulates the cochlea directly through bone conduction. McLarnon et al. (23) reported that satisfaction levels for three groups of patients receiving a BAHA was highest in patients with congenital aural atresia, followed by patients with OS, and was lowest in patients with single-sided deafness (e.g., acoustic neuroma patients).

Although amplification avoids potential risk of profound hearing loss that could occur from surgery, it is not capable of providing many of the benefits or patient satisfaction of successful stapes surgery. Hearing aids are usually not used at night. The canal occlusion effect, difficulties with feedback, and the physical sensation of the device within the EAC are disagreeable and have a negative impact on patient satisfaction. In addition, in the United States most insurance companies cover the costs of surgery but few cover the cost of hearing aids, which include batteries and a finite lifespan of 3 to 5 years.

For those with severe to profound SNHL bilaterally due to OS, cochlear implantation is an option. However, Rotteveel et al. (24) reported that partial electrode insertions, misplacement of the electrode, and inadvertent facial nerve stimulation are more likely than in patients without OS and normal cochlear anatomy.

MEDICAL MANAGEMENT

Medical therapy can be considered for all patients with OS, whether they are managed by observation, amplification, or surgery. In 1923, Escot was the first to suggest the use of

TABLE 154.2 COMPLICATIONS OTOSCLEROSIS SURGERY

Intraoperative
- Bleeding (high jugular bulb, tympanomeatal flap, persistent stapedial artery, mucoperiosteum)
- Facial nerve injury (<1%)
- Perilymph gusher
- Fracture/dislocation of incus
- Floating footplate

Postoperative
- Acute otitis media
- TM perforation
- CHL (middle ear effusion, displaced prosthesis, incus erosion)
- SNHL, vertigo, tinnitus (due to intraoperative trauma, labyrinthitis, reparative granuloma, perilymph fistula)
- Facial nerve palsy (local anesthetic, intraoperative trauma, delayed Bell palsy)

CHL, conductive hearing loss; OS, otosclerosis; SNHL, sensorineural hearing loss; TM, tympanic membrane.

calcium fluoride for the treatment of OS (25). Shambaugh (11) predicted stabilization of OS lesions with the use of sodium fluoride. Fluoride ions replace the usual hydroxyl radical, forming a more stable fluorapatite complex instead of hydroxyapatite crystal. The fluorapatite complex resists osteoclastic degradation that has been confirmed with histology. The effect of fluoride on OS remains to be elucidated, but many otologists prescribe it to stabilize active OS in an attempt to prevent progression of CHL, SNHL, and dizziness (25).

The recommended dosage of sodium fluoride is 20 to 120 mg/d. Evaluation of efficacy may be based on the disappearance of Schwartze sign (if it was present), stabilization of hearing, and improvement in the CT appearance of the otic capsule. Side effects of this therapy are usually minor. Gastrointestinal side effects (nausea) may affect patient compliance, but these effects can be minimized by lowering the dose or using enteric-coated tablets. Bone, muscle, or joint pain occasionally occurs with fluoride therapy, which usually resolves with temporary discontinuation of therapy. Rarely, fluid retention, cutaneous eruptions, and eye problems occur. Using this treatment regimen, patients may improve or show no progression of their symptoms (Table 154.2) (25).

SURGICAL MANAGEMENT

Although Rosen (8) introduced the stapes mobilization procedure in 1953, most otologists replace the stapes superstructure with a prosthesis (due to reduced risk of recurrent fixation). The stapedectomy was popularized by John Shea in the late 1950s (26). He removed the entire footplate and placed a vein graft to close off the vestibule. The stapes superstructure was reconstructed with a polyethylene prosthesis (26). This procedure has since been modified by using a wire prosthesis with an attached piece of fat, connective tissue, or gelatin material. The use of gelatin material in replacement of the footplate is no longer advocated secondary to the increased risk of reparative granuloma formation. Partial stapedectomy and stapedotomy have also been performed (instead of a total stapedectomy). Further modifications of these procedures have been described, but the essential principles have remained the same (27).

PATIENT SELECTION AND CONTRAINDICATIONS

The clinical circumstances favoring successful stapes surgery include unacceptable CHL, reversal of the Rinne 512-Hz tuning fork exam (bone conduction greater than air conduction), and good word recognition. When maximal CHL due to OS coexists with significant SNHL, detection of the bone line and conductive component can be difficult due to the limits of the audiometer. The situation is worse with bilateral MHL. Air-conduction thresholds may be present at very low levels (90 to 100 dB) or entirely absent. A history of progressive hearing loss should raise suspicion that OS may be involved. Suspicion should be heightened if discrimination scores or the ability to function appears much better than one would expect with such a significant degree of hearing loss. The presence of As tympanograms, abnormalities of stapedial reflex, or a family history of OS should raise suspicion even further. Use of the tuning forks may also separate advanced OS from SNHL of other causes (28).

A CT scan will sometimes permit a diagnosis of advanced OS when audiometry is inconclusive. If advanced OS is suspected, exploratory tympanotomy should be considered. Stapedectomy in such a setting can produce meaningful results. Air-conduction thresholds and discrimination scores can be improved enough to allow more effective amplification (29).

Age is an important consideration when contemplating stapes surgery. A temporal bone CT scan is recommended in any patient presenting with a normal otoscopic exam and conductive or MHL present since childhood. Inner ear malformations are occasionally identified in the pediatric age group and can present with mixed or CHL. Amplification is typically recommended when an inner ear malformation is identified in patients with conductive or MHL (30). The very young patient has a higher incidence of OW reclosure after a successful initial procedure. Although revision can be performed, a secondary procedure in any patient has a reduced success rate and a greater risk for postoperative SNHL. De la Cruz noted that in addition to being manifest at an earlier age, congenital footplate fixation is less likely to have a positive family history (19). Half of the children with juvenile OS have a positive family history, but only 10% of children with congenital footplate fixation have other family members with CHL. Patients with X-linked CHL have a high incidence of poststapedectomy

profound SNHL due to a perilymph (cerebrospinal fluid [CSF] leak) gusher. The incidence of congenital anomalies of the malleus and incus is substantially higher in children with congenital footplate fixation (25%) than in children with juvenile OS (3%). This difference in abnormalities of the remainder of the ossicular chain probably accounts for the poorer results. Eighty-two percent of the children with juvenile OS had closure of the air–bone gap to within 10 dB. This is in contrast to children who had congenital footplate fixation: only 44% had closure within 10 dB. Very young children with OS are also at greater risk postoperatively due to their increased incidence of otitis media and eustachian tube dysfunction (27).

Age is an important variable for surgical outcome; poorer results in the high-frequency range have been seen in older patients who have undergone stapes surgery. However, Meyer and Lambert (30) reviewed the recent literature and reported that primary and revision stapedectomy is still a reasonable option in elderly patients. Lifestyle and occupation are important factors in selecting patients for stapedectomy. Persons whose activities include repeated exposure to barometric pressure changes (e.g., scuba diver) may be at greater risk for postoperative fistula and prosthesis dislocation. Patients whose work or hobbies dictate excellent balance should be considered questionable candidates for surgery. Amplification instead of surgery is recommended in individuals whom taste is of the utmost importance (e.g., chefs, vintners), secondary to the risk of stretching or cutting the chorda tympani nerve with resultant dysgeusia (31).

Patients with otologic complaints not attributed to their OS must be carefully evaluated. For example, patients with Ménière disease and OS have a greater risk of cochlear hearing loss after stapedectomy. Patients with TM perforations and OS should have their perforations successfully repaired before attempted stapedectomy (i.e., staging of the ear). The incidence of severe to profound SNHL is much greater if stapedectomy is performed in an ear with a perforation. Patients with a history of severe eustachian tube dysfunction or a history of cholesteatoma are not good candidates for stapedectomy. Those with canal exostoses that are obstructing surgical access should have them removed before the stapedectomy. Relative contraindications for stapes surgery include the presence of an external or middle ear infection or effusion, suspected endolymphatic hydrops, active OS (positive Schwartze sign, pregnancy, and TM atelectasis). Patients with external ear infections or otitis media can undergo stapes surgery once the process has resolved. Patients presenting with OS and endolymphatic hydrops can undergo stapes surgery if they have been symptom free from their Ménière disease for at least 6 months. An absolute contraindication for stapes surgery is OS in an only hearing ear (27).

Stapes surgery should initially commence with the poorer hearing ear in patients with bilateral OS. The likelihood of achieving serviceable hearing in a unilateral MHL is an important consideration. Improved communication in such a patient may not be achieved after elimination of the CHL due to the continued SNHL. Some surgeons believe that significant high-frequency SNHL after stapedectomy in the first ear contraindicates attempting the second. A minimum of approximately 6 months should elapse before attempting surgery on the second ear due to the small but present risk of delayed postoperative hearing loss (32).

PATIENT COUNSELING

Observation, fluoride use, and a trial of hearing aid use are discussed with every patient, whether they have CHL or MHL. The patient must understand the elective nature of the procedure. The patient must be candidly informed of the risk of stapedectomy (postoperative deafness of less than 2%).

Stretching or contusion of the chorda tympani nerve is quite common and can produce alteration of taste (or rarely, dryness of the mouth). When these symptoms occur, they are usually self-limited and disappear in a few weeks or months. A severely stretched or contused chorda tympani nerve may produce more symptoms than one that is divided. Dehiscence of the fallopian canal over the OW can permit exposure or prolapse of the facial nerve. If the nerve is traumatized or injured during the stapes procedure, facial nerve palsy can result. Fortunately iatrogenic facial nerve paralysis is quite rare in the setting of stapes surgery (less than 1:1,000) (33). Facial nerve paralysis occurs less than 0.5% of the time and most commonly presents 7 to 10 days after surgery secondary to reactivation of the herpes simplex virus. Delayed facial paralysis is managed with oral prednisone, antivirals, and appropriate eye care (34).

A postoperative TM perforation may occur 2% of the time as a consequence of trauma or vascular injury to the TM flap. Acute balance disturbance is common after stapedectomy. It usually resolves in 3 to 7 days. Long-term balance disturbances or vertigo rarely occur. Sparano et al. (35) reported that 85% of patients with tinnitus improved after stapedectomy (with 52.5% reporting complete resolution, 12.5% reporting no change, and 2.5% reporting worsening of their tinnitus).

SURGICAL TECHNIQUE

A well-performed stapes procedure is gratifying for both surgeon and patient; however, stapes surgery is one of the most technically challenging procedures performed by an otologist. One concern about current resident training is the paucity of stapes surgery being performed. Prior to graduation, the average number of cases a resident performs as the operating surgeon is three. Vrabec and Coker (36) proposed that the number of surgical OS cases per surgeon could be decreasing due to the use of measles vaccination and because the number of surgeons able to perform the surgery has increased significantly over the past 30 years. The pros and cons of local versus general

anesthesia must be presented to the patient. Although general anesthesia is often easier for the patient and surgeon, local anesthesia may be safer to the patient (systemically) and to hearing preservation. Local anesthesia allows the patient to provide feedback about whether any dizziness is occurring during the procedure, allowing the surgeon to terminate the procedure momentarily or permanently. The patient can also let the surgeon know about the status of hearing improvement or loss intraoperatively.

Two keys to stapes surgery are adequate exposure and hemostasis. Preoperatively, the ear canal and TM are carefully inspected for evidence of inflammation or infection that would dictate postponement of the procedure. The patient can also be consented for use of endaural or postauricular approaches if the ear canal is too small for a transcanal approach. Ear canal vibrissae may be trimmed to improved operative exposure. Trauma to the drum or the ear canal from the preparation can occur, making the procedure more difficult. The ear canal is injected with local (1% lidocaine with 1:100,000 epinephrine) for both anesthetic and vasoconstrictive effect with care being taken to avoid blebbing of the osseous canal skin. The ear is then prepped and draped in the usual sterile fashion. The largest speculum that can be placed is used; in adults, a 7-mm speculum can usually be placed. Some surgeons prefer to use a black speculum as opposed to a silver speculum; the black color absorbs light and is less likely to reflect light from the microscope back to the surgeon. It is often possible to dilate the ear canal during the procedure with progressively larger speculums. A speculum holder is used by some surgeons to reduce the technical demands of stapes surgery. A tympanomeatal flap is elevated from the 6 o'clock to 12 o'clock position superior to the level of the lateral process of the malleus. The superior exposure is important to allow inspection of the epitympanum and lateral ossicular chain if necessary. The flap is approximately 6 mm wide, as measured from the fibrous annulus. This flap must be sufficient to cover any osseous defect created by curetting the scutum (Fig. 154.4).

The TM is elevated with the fibrous annulus (Fig. 154.5). The chorda tympani nerve is identified and preserved if possible. Enough scutum (the medial most posterior–superior EAC wall) is removed to visualize the OW, pyramidal process, and the tympanic facial nerve (Fig. 154.6). The scutum may be removed either with a sharp curette or drill. Care is taken to assess whether the facial nerve has an aberrant course or if the nerve is dehiscent or herniating too much to allow the procedure to continue. Prior to assessing stapes movement, the lateral ossicular chain is assessed for normal motion; one needs to rule out other causes of preoperative CHL. The stapes superstructure and footplate are palpated. A RW reflex can also be assessed.

A stapes mobilization instead of a stapedectomy or stapedotomy can be performed in selected cases. Stapes mobilization may be performed in a select group of patients, in whom a small point of fixation from OS can be seen and where improved stapes mobility can be clearly demonstrated. This technique can also be used in cases of tympanosclerosis. Poe (37) described a minimally invasive mobilization using an endoscope and the argon laser to potentially avoid the placement of a prosthesis; he called the procedure a stapedioplasty. Long-term follow-up of patients undergoing stapes mobilization frequently demonstrate refixation (38).

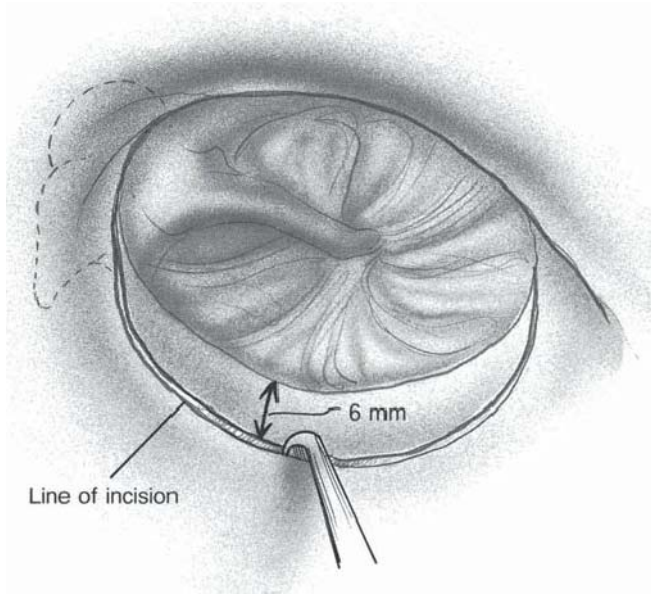

Figure 154.4 Typical design for a tympanomeatal flap.

Anterior crurotomy with partial stapedectomy, as described by Hough in 1960, requires removal of only the anterior footplate and crus (39). This procedure is helpful in a patient with isolated anterior fixation at the fissula ante fenestram. The footplate is fractured in its midportion, and only the anterior half is removed. A

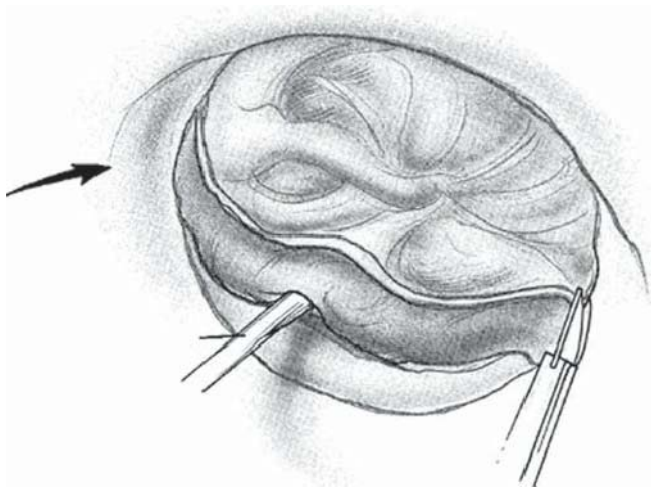

Figure 154.5 Technique for tympanomeatal flap elevation. The skin is elevated to the tympanic sulcus, and then the annulus is elevated from the sulcus.

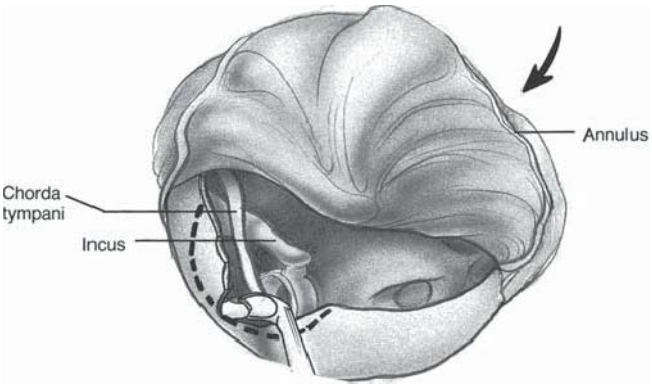

Figure 154.6 The tympanomeatal flap is now elevated. The *dotted line* indicates the area of bone removal for exposure to the OW.

connective tissue graft is then placed over the exposed area. The IS joint is not disturbed. The stapedial tendon is not divided, which makes this technique of potential benefit to patients working in a noisy environment (39). This technique has been further modified with the introduction of the laser that facilitates removal of the anterior crus and footplate (38).

Introduction of the laser has significantly reduced the technical demands of stapes surgery especially in revision cases. Perkins (40) was the first to use the laser in the treatment of OS in 1980. Since his original description, several types of lasers have been used: argon, potassium–titanyl–phosphate (KTP), erbium–YAG, and carbon dioxide. A laser provides the surgeon with a "no touch" means of transecting the stapes crura and fenestrating the stapes footplate. A CO_2 laser allows for rapid vaporization of bone and soft tissue and is the least traumatic to the membranous labyrinth medial to the stapes footplate. KTP and argon have a more favorable hemostasis profile as compared to a CO_2 laser and up until recently had the advantage of using a handheld probe as opposed to a micromanipulator. No difference has been shown between different types of lasers in terms of safety and efficacy or between lasers and the use of a drill or microinstruments. Surgeons using the laser should become very familiar with individual laser properties and settings (power, pulse duration, pulse interval) so as to reduce the risk of thermal injuries to the facial nerve and inner ear. Irrigation, short pulse durations, and clustering laser shots all serve to reduce heat in the operative site, thus reducing the risk of thermal injuries. A retrospective study of patients undergoing argon laser or carbon dioxide laser stapedotomy (~60 patients in each group) demonstrated no difference in the incidence of postoperative complications, hearing improvement, or speech discrimination (41). The surgeon's operative experience and skill are considered the most important factors in determining the success and incidence of complications.

Surgeon preference often dictates the whether one should perform a total stapedectomy, partial stapedectomy, or stapedotomy with the current practice trending toward partial preservation of the footplate. In patients undergoing stapedectomy or stapedotomy, a measuring tool is used to assess the distance between the footplate and the distal incus long process. Placing a control hole in the stapes footplate is sometimes performed to reduce the risk of injuring the membranous labyrinth in the event that the footplate subluxes from the OW while manipulating the stapes (Fig. 154.7). Dividing the IS joint prior to transecting the stapedial tendon provides additional stability to the stapes thus reducing the chance of floating or fracturing the footplate. A laser or otologic scissors are used to divide the stapedius tendon allowing visualization of the posterior crus of the stapes. Transecting the posterior crus of the stapes with a laser reduces the chance of a floating or fractured stapes footplate. The anterior crus of the stapes, in some cases, can also be transected with a laser. The stapes superstructure is then down-fractured toward

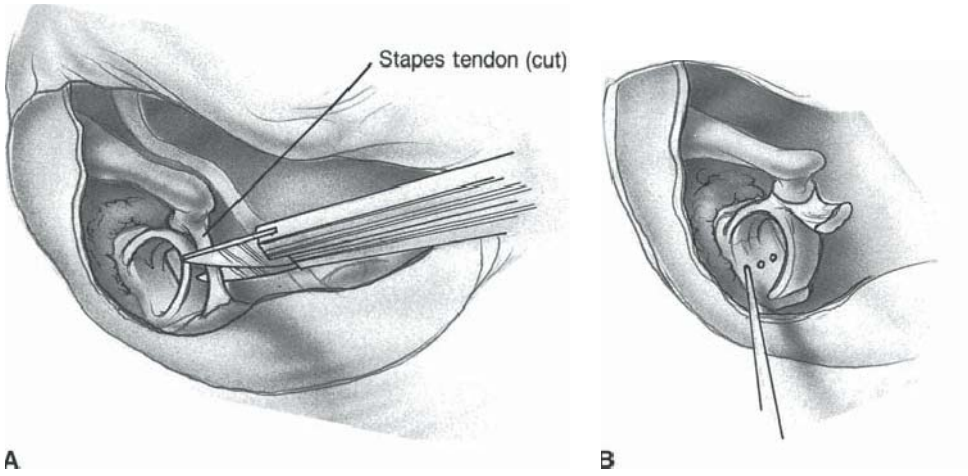

Figure 154.7 **A:** The tympanomeatal flap is now elevated, and bone has been removed. The stapedial tendon is divided by a pair of microscissors. **B:** Control holes are placed in the stapedial footplate.

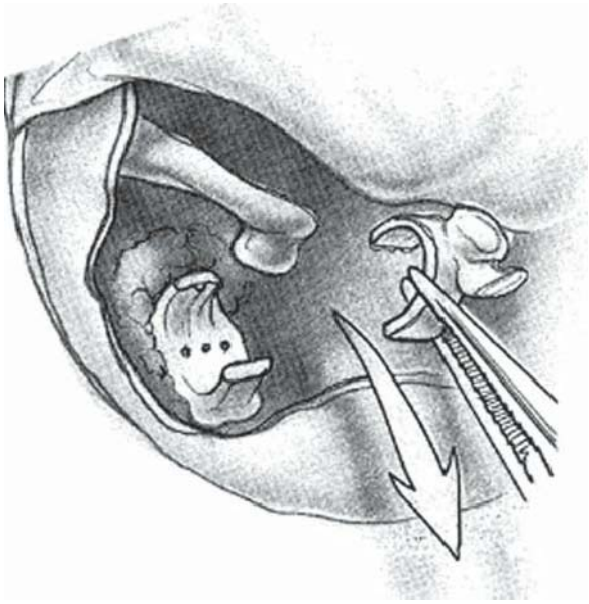

Figure 154.8 The stapedial superstructure is removed after fracturing of the anterior and posterior crus.

the promontory and is extracted (Fig. 154.8). The entire footplate is then removed in a piecemeal fashion using small right angle hooks of varying sizes for a stapedectomy (Fig. 154.9). Care is taken to avoid injuring the inner ear now that the vestibule has been exposed. Perilymph may be suctioned in an area away from the vestibule. However, one must avoid direct suctioning in the vestibule and a resultant dry vestibule, which has a risk of postoperative deafness. The OW is sealed with a graft, and the prosthesis is placed (Fig. 154.10). The most common tissue types used for grafting are the dorsal hand vein, tragal perichondrium, or fascia. Schmerber et al. (42) recently reported that use of a vein graft (as opposed to perichondrium) showed better postoperative air–bone gap closure and a lower incidence of postoperative SNHL.

Some cases of OS have formation of exuberant sclerotic bone that fills and obliterates the OW niche. Obliterative OS is encountered less commonly now than previously. When present in one ear, obliterative OS is present in the contralateral ear in 50% of cases. Obliterative OS requires thinning of the thickened footplate before creation of a fenestration and prosthesis placement. Thinning is usually accomplished with a small electrical or hand drill, which can also be used to perform the fenestration. The fenestra is usually 0.4 to 0.6 mm in diameter. A prosthesis is then placed through the fenestra into the vestibule. The vestibule is sealed by placing soft tissue around the prosthesis. However, some surgeons use just a blood seal with the stapedotomy approach. Ayache et al. (43) demonstrated a 62% success rate (with closure of the air–bone gap to 10 dB or less) in the drill-out procedure. As experience grew with the drill-out procedure for obliterative OS, some otologists began using the stapedotomy technique in all their patients with OS. The surgical technique involves creating a fenestra in the midportion of the stapes using a drill, picks, laser, or a combination thereof. The steps of a stapedotomy are identical to stapedectomy up until footplate work is initiated. A rosette pattern is created in the midportion of the footplate with a laser (Fig. 154.11). A Micropick or Skeeter drill is then used to complete the stapedotomy (Fig. 154.12). After a stapedotomy is performed, a prosthesis is then positioned over a tissue graft or the graft is positioned around the stapedotomy (Fig. 154.13). An autologous blood patch or hyaluronic acid gel can also be used to seal the OW in place of a tissue graft (43,44).

Longstanding results of the stapedotomy procedure have been comparable to a total stapedectomy. Some reports suggest a decrease in postoperative cochlear deafness and improvement in the air–bone gap closure above 2,000 Hz with stapedotomy. Stapedotomy and partial stapedectomy may show better postoperative hearing at higher frequencies (4,000 Hz) than total stapedectomy;

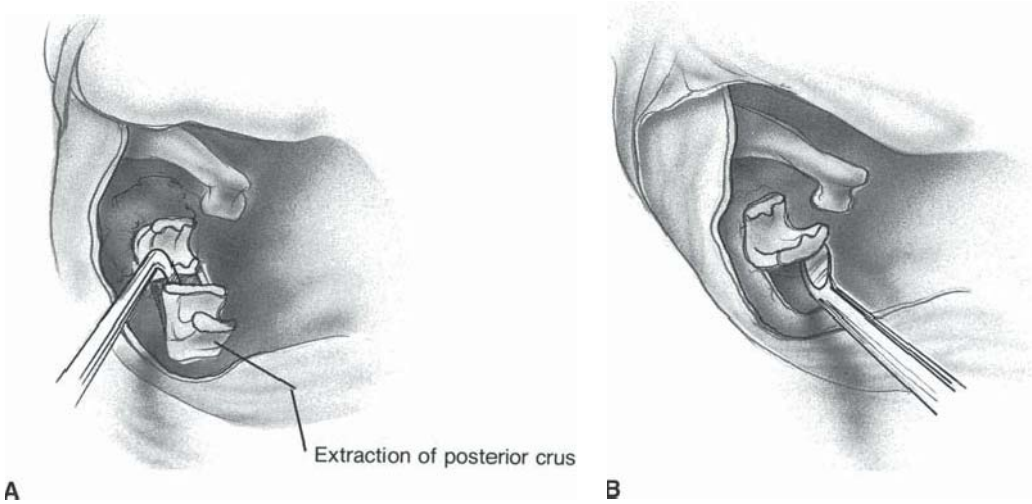

Figure 154.9 **A:** The posterior half of the stapedial footplate is removed with a sharp pick. **B:** The anterior half of the stapedial footplate is removed by a joint knife or Hough hoe.

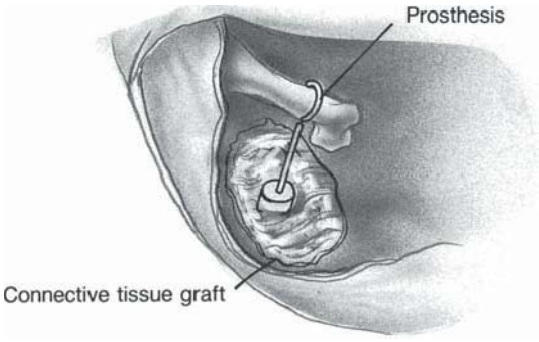

Figure 154.10 Prosthesis in place.

however, total stapedectomy may result in improved gains at lower frequencies (250 and 500 Hz) (44).

Numerous stapes prostheses have been developed since John Shea popularized the stapedectomy procedure. Early prostheses with a sharp or beveled end were found to cause a prohibitive number of postoperative fistulae. The designs that have proved most effective include a connective tissue OW graft and piston prosthesis. Tissue can be obtained from tragal perichondrium, dorsal hand vein graft, or temporalis fascia. The graft is combined with a variety of prosthetic designs, such as a wire Teflon piston or a Robinson-type bucket-handle prosthesis, which has a wire loop that is placed over the lenticular process of the incus. If the stapedotomy procedure is performed, the prosthesis is positioned, and connective tissue is placed around the prosthesis base to seal the vestibule or autologous blood is used to fill the middle ear space (Fig. 154.9). A recent addition to the variety of available stapes prostheses is a heat-activated self-crimping prosthesis, thus eliminating the crimping step necessitated by prior piston type implants. The heat-activated nitinol stapes prostheses also allow for a more uniform crimp around the incus thus reducing the risk of a loose prosthesis (45).

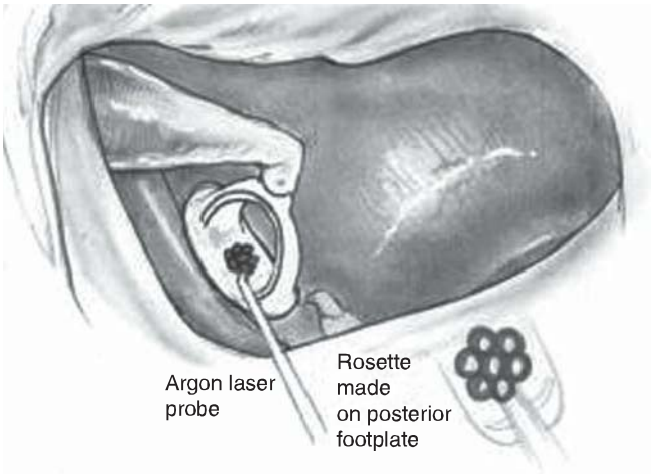

Figure 154.11 A rosette pattern is created with a laser in the midportion of the footplate. This step can be completed prior to down fracturing the stapes or after this step.

Figure 154.12 A Skeeter drill is used to complete the stapedotomy.

After completion of the desired procedure, the TM flap is returned to its normal anatomic position. The EAC may be dressed in a variety of ways (e.g., packed with gelatin sponge, antibiotic ointment), depending on the surgeon's preference. The use of perioperative antibiotics is common, despite the lack of statistical evidence of their benefits. Perioperative steroids may be used to reduce the incidence of anesthesia-induced nausea, and vomiting. In the immediate postoperative period, the patient is asked to avoid lifting and straining for about 1 month. Nose blowing should be discouraged. The patient should also cough or sneeze with the mouth open, to reduce the risk of increased middle ear pressure and displacement of the TM. The patient is kept on dry ear precautions until the TM has completely healed.

Immediate hearing improvement is noted in some patients intraoperatively when the procedure is done

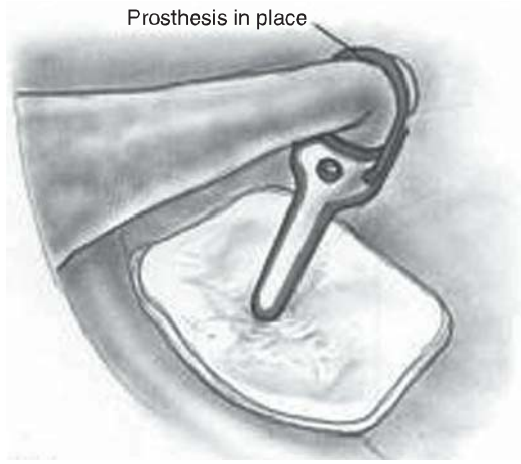

Figure 154.13 A tissue graft can be used to cover the stapedotomy prior to placement of the prosthesis to decrease the risk of a postoperative perilymph fistula. The prosthesis is then engaged between the incus lenticular process and the stapedotomy.

under local anesthesia or in the post anesthesia care unit in those undergoing a general anesthesia. Other patients report a more gradual hearing improvement with occasional associated vestibular symptoms, probably due to serous labyrinthitis. Balance disturbances usually resolve within 1 to 2 days but occasionally linger for a few weeks. A postoperative audiogram is obtained 2 to 3 months after surgery, allowing enough time for middle ear fluid and blood to resorb. Postoperative hearing results reveal closure of the air–bone gap to within 10 dB of the preoperative bone-conduction level in 90% of patients (46). About 10% of patients experience either worsening hearing or no improvement. About 2% of patients suffer persistent and profound SNHL. Recent evidence has suggested a progressive high-frequency SNHL in some poststapedectomy patients. It is unclear whether this is due to cochlear OS or long-term postsurgical effects (47).

The otolaryngologist should be aware of certain complicating factors associated with stapes surgery. Anatomic variations of the middle ear sometimes alter the surgical procedure. Occasionally, a high or dehiscent jugular bulb is encountered. If it is injured, the middle ear must be packed to tamponade the bleeding before continuing with surgery. Continued or persistent bleeding may require termination of the procedure. One must be sure that the bleeding is due to a jugular bulb and not an aberrant internal carotid artery. A persistent stapedial artery that courses in the obturator foramen of the stapes can be a complicating factor due to its bleeding potential. This artery is the embryologic remnant of the second branchial arch. To gain access to the footplate, the vessel must be divided or displaced or the procedure will need to be aborted. Blood that enters the vestibule increases the risk of postoperative SNHL (48).

Careful and complete inspection of the middle ear should be performed at each exploratory tympanotomy. Other causes of CHL, such as malleus head fixation, can be associated with OS. Malleus head fixation can be congenital or caused by immobility of the ossicular chain, allowing for ankylosis to the attic wall. Mobilization of the malleus can sometimes be accomplished through a limited atticotomy if the fixation point is at the head. Calcification of the anterior or posterior malleolar ligaments can readily be removed and is facilitated with the laser. Addressing lateral chain fixation should only proceed after the IS joint has been divided. Unfortunately, mobilization is often followed by refixation (49).

A dehiscent or inferiorly displaced fallopian canal with or without a prolapsed facial nerve can at times obscure the OW. If footplate removal and prosthesis placement can be achieved safely, surgery should continue. If the surgeon believes the nerve is in jeopardy, the procedure should be aborted.

A profuse perilymph gusher (i.e., CSF leak) is rarely encountered. A perilymph gusher is believed to be due to a patent cochlear aqueduct or more commonly a modiolar defect with communication to the fundus of the internal auditory canal. This finding is more frequently identified in patients with congenital footplate fixation. Complete stapes footplate removal in the presence of a gusher increases the risk of postoperative cochlear deafness. The fenestration (control hole) placed before footplate removal should allow for early identification of this problem. Measures to control a perilymph gusher include elevation of the head of bed, small fenestra stapedotomy, and placement of a tissue seal over the footplate defect. Wiet (10) recommended placing a prosthesis in order to hold the tissue seal in place. At times, a lumbar drain may be needed to decompress the subarachnoid space to allow for adherence of the graft to the defect in the footplate (10).

Fracture of the incus long process can occur during stapedectomy. It may follow separation of the IS joint, placement of the prosthesis, or curettage of the scutum. Usually, the prosthesis can be placed on the remaining incus, but a malleus to OW prosthesis may be needed. A notched bucket-handle prosthesis is ideally suited for short to medium incus long process defects and frequently produces excellent hearing results (50). Staging the procedure and coming back at a later time may allow the incus to heal and be utilized in the future, because a malleus to OW prosthesis is more difficult to place and typically has poorer postoperative hearing results (51).

It is difficult to remove a nonfixed (floating) stapedial footplate after the crural arches have been fractured. Attempts to manipulate the footplate may push it medially into the vestibule. This is a case in which the laser may be used to atraumatically remove or ablate the footplate. In addition, one of the purposes of the control hole made before fracturing the crura is to provide access to the footplate, if it inadvertently becomes mobilized. Small right angle hooks or needles can be placed through the hole to lift the footplate out of the vestibule. An alternative strategy for managing a floating footplate is to drill a shallow groove in the inferior part of the OW niche. A small hook can then be passed beside the footplate to remove it. If all or part of the footplate is significantly depressed into the vestibule, it is best left there. Attempts to remove it can result in significant SNHL. A connective tissue graft and prosthesis can be placed lateral to the depressed footplate. In this setting, postoperative disequilibrium can be expected but is usually self-limited (52).

The use of a local anesthetic such as lidocaine can cause intraoperative or postoperative vertigo. Lateral canal stimulation from irrigation fluids can cause vertigo, as can chemical irritation of the labyrinth from the local anesthetic. Palpation of the footplate or a long prosthesis can cause vertigo from direct mechanical stimulation of the underlying otolith organs (saccule, utricle) (53).

TM tears should be avoided. If a small tear occurs, it can be repaired with a leftover piece of the OW grafting material. Persistent postoperative perforations should be repaired within 4 to 6 weeks after surgery to prevent any

TABLE 154.3 CLINICAL INDICATORS FOR STAPEDECTOMY

Strategy
Indicators (one of the following)
CHL without other source of conductive abnormality (e.g., perforated TM, serous otitis media)

Health of TM

The American Academy of Otolaryngology-Head and Neck Surgery and the American Society for Head and Neck Surgery have published clinical indicators for surgical procedures. These clinical indicators are educational statements that have been drafted to assist surgeons in their practice and to promote discussion. These indicators are not practice guidelines nor do they represent standards of practice with which individuals must conform.
TM, tympanic membrane.

problems with transcanal contamination of the middle ear and a subsequent otitis media and SNHL (54).

The most common cause for failure of stapedectomy has been prosthesis displacement, with or without incus erosion. Other causes of failure are footplate refixation, perilymph fistula, otosclerotic regrowth, and lateralization of the OW membrane. Patients need to be informed that revision surgery is usually not as successful as primary surgery. The possibility of postoperative cochlear deafness is also more common with revision surgery. Patients who seem to achieve better results in revision procedures are those who experienced an initial improvement in hearing followed by a gradual increase of the air–bone gap over a period of months or years (Table 154.3) (55).

COMPLICATIONS/PITFALLS

Complications after stapes surgery can occur immediately or in a delayed fashion. Vertigo or disequilibrium immediately after surgery is usually due to loss of perilymph, surgical trauma, or serous labyrinthitis. This symptom generally subsides within a few days. If dizziness does not improve within the first postoperative week, the use of corticosteroids may be of some benefit. Persistent vertigo may be due to a depressed footplate fragment, long prosthesis, OW fistula, or a reparative granuloma. Benign paroxysmal positional vertigo can also be seen during the postoperative course due to surgical injury to the utricle. This is usually self-limiting and resolves within several months (56).

Acute otitis media is a rare postoperative complication; if it does occur, it poses a serious threat to hearing in the operated ear. The newly created OW partition allows a middle ear infection to quickly involve the labyrinth (suppurative labyrinthitis) and potentially meningitis. Historically, a beveled prosthesis on a gelatin sponge appeared to increase the risk of suppurative labyrinthitis. Intensive systemic antibiotic therapy for otitis media is begun immediately; if diagnosed early, the condition may improve without significant sequelae (57).

The incidence of poststapedectomy granulation (i.e., reparative granuloma) is approximately 0.1% and usually becomes manifest within 7 to 15 days after surgery, but it can occur as late as 6 weeks postoperatively. The hallmark of poststapedectomy granulation is progressive SNHL after earlier postoperative hearing improvement. The granuloma can also be associated with vertigo, aural fullness, or tinnitus. The TM appears thickened and the posterior superior aspect is erythematous. The audiogram typically reveals an MHL or SNHL that often is most severe in the high frequencies. The discrimination score is usually significantly lower than expected from the degree of hearing loss. If this complication is suspected, early surgical intervention is warranted. A CT scan can be helpful in the diagnosis of this process and to assess the status of the prosthesis/vestibule. Findings at surgery include a significant amount of granulation tissue around the OW and possible filling the middle ear. Acute and chronic inflammation with capillaries, foreign body giant cells, chronic inflammatory cells, and fibroblastic proliferation is seen on histologic examination of the resected granuloma. Treatment involves removal of the OW seal and prosthesis with replacement using a different material. Risk factors for reparative granuloma include total stapedectomy, the use of gelatin sponge as the OW sealant, or the presence of powder on operating gloves. The overall outcome of this potentially devastating process is related to early diagnosis and treatment (58).

Perilymph fistulae may occur in the early postoperative period or may be seen many years later. The initial complaints usually include fluctuating or progressive hearing loss associated with tinnitus or vertigo. A history of sudden barometric pressure change or trauma may also be reported but is not necessarily diagnostic. Fistula testing by pneumatic otoscopy may be helpful. Audiometric testing usually reveals the expected SNHL, although fistulae rarely occur without hearing loss. The most important factor in diagnosis is a high clinical index of suspicion. If a fistula is thought to be present, conservative measures may be appropriate particularly

in the immediate postoperative period, because surgical exploration is difficult. These conservative measures can include the use of acetazolamide and bed rest for 5 days. If symptoms continue, exploratory surgery with grafting of the OW is indicated. Findings at surgery may include a displaced prosthesis with or without an obvious fistula. Postoperative expectations include stabilization of the SNHL and resolution of the dizziness (55).

Persistent or progressive CHL can follow stapedectomy. Loosening or displacement of the prosthesis, resorption of the incus long process, adhesions around the prosthesis, and further OS lesions can produce postoperative CHL. Significant hearing loss may warrant surgical exploration. It must be remembered that removal of the prosthesis is associated with a higher incidence of SNHL and a reduced closure of the air–bone gap (55).

HIGHLIGHTS

- OS is a primary disease of the otic capsule that causes progressive CHL, SNHL, or MHL.
- The disease is present histologically in 8% to 10% of the Caucasian population, but only 12% of patients with histologic changes actually present with clinical symptoms.
- Histologically, the disease begins by bone resorption around vascular channels and later matures as dense, sclerotic bone.
- Patients suffering from OS typically present with a slowly progressive hearing loss over a period of years.
- The physical appearance of the TM is typically normal.
- The audiogram with acoustic immittance testing remains the key to diagnosis, revealing a CHL or MHL in most cases.
- Patients presenting with a conductive or mixed hearing loss and intact acoustic reflexes should not undergo stapes surgery as this typically represents an inner ear third window (i.e., semicircular canal dehiscence, enlarged vestibular aqueduct).
- Surgical therapy remains the mainstay of treatment for CHL from OS; however, this is an elective procedure. Patients must be given the alternative of amplification. Medical treatment can be given to all patients.
- Postoperative hearing results reveal closure of the air–bone group to within 10 dB of the preoperative bone-conduction level in 90% of patients.
- The possibility of postoperative cochlear deafness is higher with revision surgery when compared with primary stapedectomy.

Acute Paralysis of the Facial Nerve

155

Jeffrey T. Vrabec *Jerry W. Lin*

Acute facial palsy is a common diagnostic problem encountered by the otolaryngologist, but its presentation often provokes consternation on the physician's part. This reaction stems from our limited knowledge of facial nerve pathology, from the shortcomings of currently popular electrophysiologic tests in defining nerve injury, and from the controversy surrounding the management of facial palsy. This chapter presents contemporary opinions on management of acute facial palsy.

ANATOMY AND PHYSIOLOGY OF THE FACIAL NERVE

The cranial nerve VII is a complex motor/sensory nerve consisting of special visceral afferent, general visceral efferent, and special visceral efferent fibers (Fig. 155.1) (1). The special visceral afferent fibers convey the sense of taste from the sensory receptors on the anterior two-thirds of the tongue and project via the lingual and chorda tympani nerves to the geniculate ganglion and, hence, via the nervus intermedius to the tractus solitarius.

The general visceral efferent fibers constitute a parasympathetic system with three subsets of postsynaptic fibers. The preganglionic fibers arise in the superior salivatory nucleus. One subset of fibers exits the facial hiatus within the greater superficial petrosal nerve, joins the deep petrosal nerve in the vidian canal, and synapses at the sphenopalatine ganglion. Postsynaptic fibers then innervate the lacrimal and palatine glands. Another subset of preganglionic fibers within the lesser petrosal nerve synapses at the otic ganglion; the postsynaptic fibers provide secretory supply, in part, to the parotid gland. The third subset of this parasympathetic system exits the temporal bone along the chorda tympani nerve and passes along the lingual nerve to synapse at the submandibular ganglion. The postsynaptic fibers then provide the secretory supply to the submandibular and sublingual glands.

The special visceral efferent fibers arise within the facial motor nucleus and pass through the temporal bone, except for the fibers to the stapedius muscle, to exit the stylomastoid foramen and innervate the auricular, posterior belly of the digastric, stylohyoid, and platysma muscles and the superficial facial musculature.

Evidence that the sensory afferent fibers provide sensation from the external auditory canal and proprioception from the face is contradictory. These fibers are thought to account for the otalgia experienced in Bell palsy and the vesicular eruption in herpes zoster infection.

The intracranial segment of the facial nerve and the nervus intermedius exit the brainstem in a recess adjacent to the pons, cross the cerebellopontine angle ventral to the vestibuloacoustic nerve, and enter the internal auditory canal. The meatal segment of the facial nerve and the intermedius nerve occupy the anterior–superior quadrant within the canal and enter the fallopian canal at the meatal foramen superior to the crista transversa and anterior to the crista verticalis (Bill's bar). The labyrinthine segment of the nerve courses 2 to 4 mm within the narrowest part of the fallopian canal to the geniculate ganglion, where the nerve makes an acute turn of 40 to 80 degrees (external or first genu) to enter the middle ear. Coursing posteriorly and slightly inferiorly above the cochleariform process and the oval window, the tympanic segment (11 mm) curves into the second (pyramidal) turn inferior to the horizontal semicircular canal. This turn has a more obtuse angle of 110 to 120 degrees. The mastoid segment then descends 13 mm vertically to the stylomastoid foramen. There are several branches of the nerve in its intratemporal course. At the geniculate ganglion, the greater superficial petrosal nerve courses anterior and medially. The branch to the stapedius muscle arises from the proximal mastoid segment while the chorda tympani exits the distal mastoid segment. The nerve to the posterior belly of the digastric is the first branch distal to the stylomastoid foramen. The

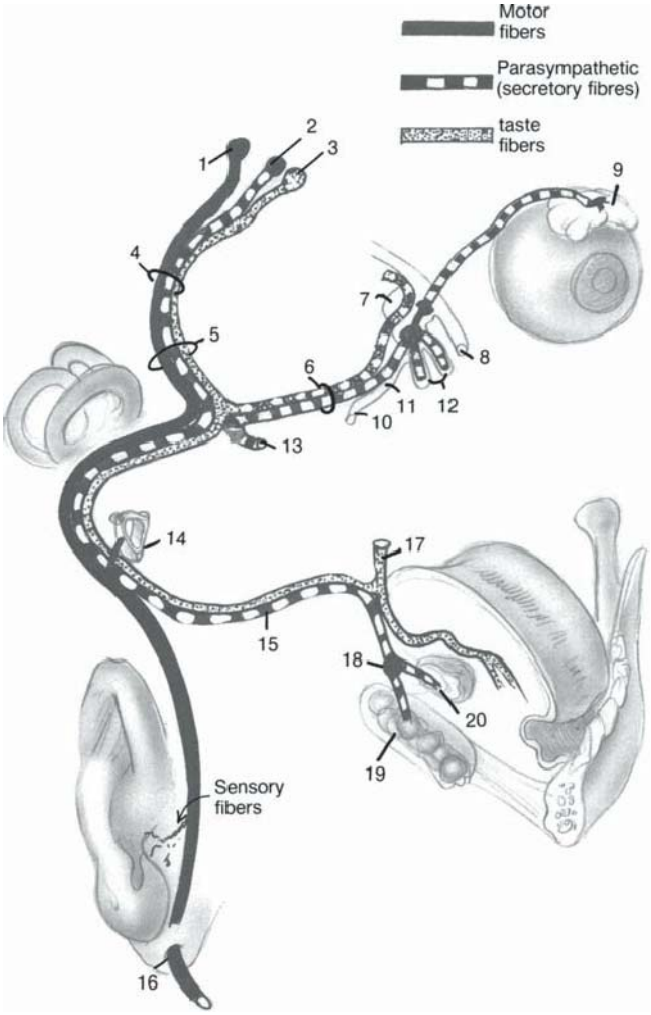

Figure 155.1 Efferent and afferent tracts of cranial nerve VII. The projection of the sensory fibers from the external auditory canal is undetermined. *1*, Nucleus of facial nerve; *2*, superior salivary nucleus; *3*, solitary tract; *4*, porus acusticus internus; *5*, meatal foramen; *6*, greater petrosal nerve; *7*, sphenopalatine ganglion; *8*, maxillary nerve; *9*, lacrimal gland; *10*, deep petrosal nerve; *11*, vidian nerve; *12*, innervation of glands of nose and palate; *13*, anastomosis with minor petrosal nerve; *14*, stapedial nerve; *15*, chorda tympani; *16*, stylomastoid foramen; *17*, lingual nerve; *18*, submandibular ganglion; *19*, submandibular gland; *20*, sublingual gland. (Modified from Miehlke A. *Surgery of the facial nerve*, 2nd ed. Baltimore, MD: Urban & Schwarzenberg, 1973:19, with permission.)

special visceral efferent fibers constituting the extracranial segment enter the posterior parotid gland and undergo secondary and tertiary branching. These fibers ultimately innervate the five regions of mimetic musculature: temporal, zygomatic, buccal, mandibular, and cervical. The peripheral branches of the nerve are the most variable in location.

Crossing nerve fibers at the level of the motor nucleus of the facial nerve in the brainstem leads to bihemispheric control of function in the upper half of the face and contralateral hemispheric control of function in the lower half of the face. Thus, forehead sparing can suggest a central versus a peripheral lesion of the facial motor pathway.

SURGICAL ANATOMY

Knowledge of the intratemporal anatomy of the facial nerve and the associated landmarks is critical to safe otologic surgery. The surgical approach to different segments of the nerve varies if middle and inner ear structures are to be preserved. When hearing is good, the meatal and labyrinthine segments of the nerve are approached via the middle cranial fossa (Fig. 155.2). This allows access to the internal auditory canal and/or geniculate ganglion. Important landmarks include the arcuate eminence, meatal plane, facial hiatus, and greater superficial petrosal nerve. The location of the internal auditory canal and meatal segment is approximated by bisection of the angle formed between the plane of the superior semicircular canal (arcuate eminence) and the greater superficial petrosal nerve. The nerve occupies the anterior quadrant of the internal auditory canal.

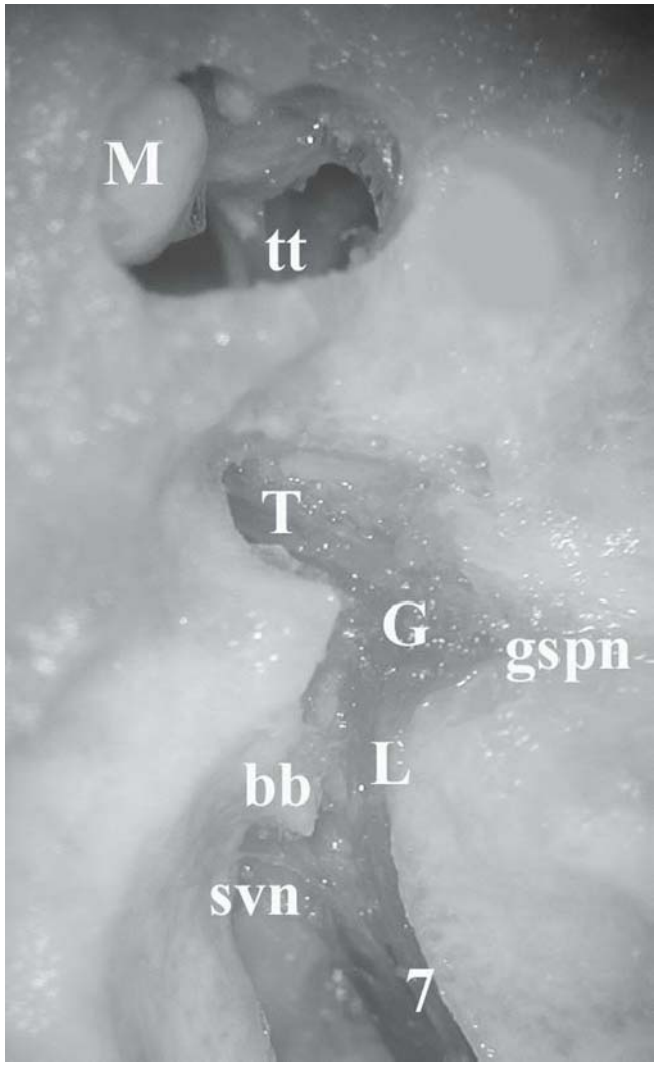

Figure 155.2 Surgical anatomy of the facial nerve in the middle cranial fossa. *7*, facial nerve in the internal auditory canal; *L*, labyrinthine segment; *G*, geniculate ganglion; *T*, tympanic segment; *M*, malleus; *tt*, tensor tympani; *bb*, Bill's bar; *svn*, superior vestibular nerve.

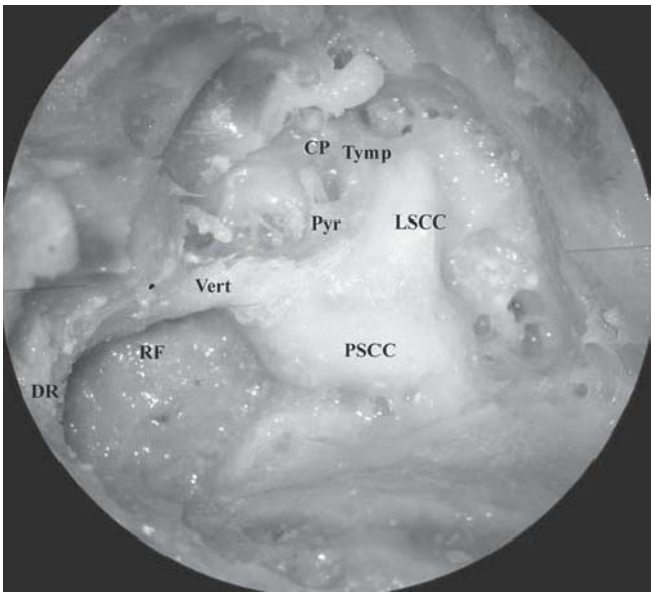

Figure 155.3 Surgical landmarks to the facial nerve in the middle ear and mastoid. *LSCC*, lateral semicircular canal; *PSCC*, posterior semicircular canal; *DR*, digastric ridge; *RF*, retrofacial air cells; *Vert*, vertical segment proximal to stylomastoid foramen; *Tymp*, tympanic segment; *CP*, cochleariform process; *Pyr*, pyramidal eminence.

Important landmarks for identification of the tympanic segment in the middle ear are the cochleariform process and the oval window. The nerve is located superior to these structures and inferior to the horizontal semicircular canal. The upper mastoid segment lies posterior and medial to the chorda tympani and medial to the facial recess air cell tract. The stapedius muscle and posterior semicirular canal are medial to the facial nerve. The lower mastoid segment is at the same level as the digastric ridge (Fig. 155.3), lateral to the retrofacial air cell tract. The mastoid segment of the nerve can be identified by removing the bone from the posterior aspect of the external auditory canal, thereby exposing the nerve on its lateral aspect. The surgeon should expect the nerve along a line drawn between the horizontal semicircular canal and digastric ridge.

When hearing preservation is not an issue, the entire intratemporal course of the nerve can be exposed via the translabyrinthine approach. The mastoid segment is defined as above. Removal of the labyrinth allows skeletonization of the tympanic segment along its superior aspect. The labyrinthine segment is located just anterior and superior to the ampulla of the superior canal. The internal auditory canal is identified medial to the vestibule. In the lateral end of the canal, the facial nerve is separated from the superior vestibular nerve by the vertical crest (Bill's bar).

Anomalies of the Facial Nerve

Anomalies of the facial nerve are rare, but their existence makes even the most experienced otologic surgeon wary. The most common "anomaly" is a dehiscence in the facial canal, which exposes the nerve to injury during temporal bone surgery. The most common location is the tympanic segment over the oval window, followed by the geniculate ganglion and the mastoid segment adjacent to the retrofacial air cells (2). The intratemporal course of the nerve is usually constant, but variations do occur. Deviations in the labyrinthine segment are exceedingly uncommon; usually the finding in this area is a difference in the angulation of the nerve between the meatal foramen and the geniculate ganglion, which relates to the depth of the internal auditory canal below the floor of the middle fossa. In the tympanic segment, the nerve may prolapse against the arch of the stapes, bifurcate around the stapes, or course below the oval window. Below the horizontal semicircular canal, the nerve may curve more acutely, making the prominent turn more susceptible to injury during an antrotomy. In the mastoid segment, bifurcations and trifurcations are exceedingly rare, but when duplication exists, the nerves occupy separate bony canals and exit individual foramina. Anomalies of the fallopian canal are suspect in congenital atresia of the middle ear and anomalies of the otic capsule (3). Thin-section high-resolution computed tomography (CT) of the facial canal is recommended to provide as much preoperative information as possible about the course of the facial nerve.

Topographic Organization of the Facial Nerve

Topographic organization of the intracranial or intratemporal efferent and afferent fibers is not likely based on animal studies (4,5). Thus, suggestions that the site of lesion within the temporal bone can be determined according to the degree of muscle weakness in different regions of the face are inaccurate. This lack of intratemporal organization makes interfascicular repair of the nerve proximal to the stylomastoid foramen impractical and unnecessary. Synkinesis is inevitable with any reanastomosis or nerve grafting procedure.

Arterial Supply to the Facial Nerve

Both the carotid and vertebrobasilar arterial systems vascularize the intratemporal facial nerve. The labyrinthine artery, a branch of the anterior inferior cerebellar artery, provides the blood supply to the nerve within the internal auditory canal. The petrosal artery, a branch of the middle meningeal, supplies the nerve in the perigeniculate region and anastomoses with the stylomastoid artery, which feeds the mastoid and tympanic segments. The intratemporal facial nerve has a rich extrinsic anastomotic network to prevent ischemia, except in the labyrinthine segment at the junction between the carotid and vertebrobasilar systems.

EVALUATION

History

A careful history narrows the scope of the differential diagnosis and reduces the number of laboratory studies necessary to establish the cause. First, the onset of the paralysis

is defined as sudden, delayed, or gradual. Sudden refers to acute deterioration of facial function over a few days, either with or without an antecedent event. Delayed refers to acute deterioration in close temporal relationship with an antecedent event, though facial function is normal immediately following the event. Gradual refers to progressive loss over a period of weeks or longer. These definitions assume normal function prior to onset. When rapid deterioration occurs in a nerve exhibiting abnormal function, the onset is considered gradual or progressive unless there has been a lengthy period of stable facial function. Recurrent refers to facial palsy that occurs after a long period of stable recovery from a previous facial palsy.

Next, the degree of paralysis is designated as complete or incomplete. This is often of great prognostic importance. Incomplete paralysis or paresis is usually associated with good prognosis for recovery, unless a neoplasm is diagnosed. Complete paralysis typically carries a guarded prognosis for return of normal facial movement, especially when accompanied by electrical evidence of complete degeneration.

Associated symptoms provide additional diagnostic clues. Numbness in the middle and lower face, otalgia, hyperacusis, diminished tearing, and an alteration in taste are common in Bell palsy and Ramsay Hunt syndrome. Intense ear pain and a vesicular eruption are the hallmarks of herpes zoster oticus. Sensorineural hearing loss and vertigo are symptoms of advanced disease involving the labyrinth, the internal auditory canal, or brainstem.

Recurrent facial palsy also may indicate a tumor, although some persistent dysfunction is likely in between episodes of worsening function. More common causes of recurrent palsy include Bell palsy and Melkersson-Rosenthal syndrome. About 7% of patients with Bell palsy develop recurrent palsy, with half of the recurrences on the ipsilateral side (6). Melkersson-Rosenthal syndrome is often familial, and the first episode of facial palsy usually occurs before 20 years (7). Associated findings include facial edema, particularly of the upper lip; fissured tongue; and migraine headaches.

Any thorough history encompasses other medical conditions that may be incriminated in the differential diagnosis of the palsy: cancer, sarcoidosis, autoimmune disorders, and previous surgeries in the posterior fossa, temporal bone, or parotid.

Physical Examination

The physical examination includes a complete head and neck evaluation with microscopic examination of the ear, a thorough assessment of the upper aerodigestive tract, and a cranial nerve assessment (III to XII) (Table 155.1). Obvious physical findings confirm many infectious, neoplastic, and traumatic diagnoses. Otorrhea, purulent middle-ear effusion, or obvious cholesteatoma indicate an infectious etiology. Slowly progressive weakness, temporal bone or parotid mass lesion, or segmental weakness (some branches paralyzed while others are spared) suggest a neoplasm.

TABLE 155.1 ASSESSMENT OF FACIAL PALSY

History
Onset
Duration
Rate of progression
Recurrent or familial
Associated symptoms
Major medical illness or previous surgery
Physical examination
Complete head and neck evaluation
Microscopic otoscopy
Upper aerodigestive tract examination
Cranial nerve assessment (III–XII)
Palpation of parotid gland and neck
Neurologic evaluation
Cerebellar signs
Motor
Facial palsy
Complete vs. incomplete (paresis)
Segmental vs. uniform involvement
Unilateral vs. bilateral
Schirmer test
Laboratory studies

Electrophysiologic tests
Nerve excitability test (NET)
Maximal stimulation test (MST)
Electroneurography (ENoG)
Electromyography (EMG)
Radiographic studies
Computed tomography
Magnetic resonance imaging
Other considerations
Complete blood cell count and differential with sedimentation rate
Serum antibody tests (Lyme titers)
Chest x-ray radiograph
Lumbar puncture with cerebrospinal fluid assay

Forehead sparing suggests a central motor pathway lesion. Contusion or laceration over the distribution of the extracranial nerve, Battle sign (mastoid ecchymosis), or hemotympanum are evidence of trauma. Multiple cranial nerve deficits typically indicate an advanced intracranial or skull base infection, extensive neoplasm involving the temporal bone, or a neurologic disorder, such as Guillain-Barré syndrome.

The examination focuses on the motor function of the facial nerve. Compare the range of facial movement between the affected and unaffected sides. The subject should attempt a broad range of facial expressions while the examiner watches for movement in each of the major branches of the nerve. The subject is asked to raise the eyebrows, close the eyes as tightly as possible, wrinkle the nose, smile broadly, pucker, or grimace. A common error is to attribute the movement in the upper eyelid due to the levator palpebrae superioris muscle (cranial nerve III) to

TABLE 155.2 FACIAL NERVE GRADING SCALE 2.0

facial nerve function and to misrepresent the finding as a facial paresis. Grading of the injury follows the outline in Table 155.2 (8).

The more common causes of acute facial paralysis are outlined in Table 155.3. Over half of the presentations are due to Bell palsy. Trauma is the second most common etiology, producing about 20% of cases. The palsy is not Bell's in the presence of any of the following: signs of tumor, vesicles, multiple cranial nerve involvement, temporal bone infection, trauma, palsy at birth, signs of a central nervous system lesion, and acute infectious mononucleosis. Bilateral facial nerve involvement occurs in fewer than 1% of patients who have facial palsy. Common etiologies include brainstem tumors, intracranial infection or malignancy, extensive skull base fractures, Guillain-Barré syndrome, or Lyme disease (9).

Laboratory Studies

Several studies may be indicated in the evaluation of acute facial paralysis (Table 155.1), depending on the findings in the history and physical examination. Because of numerous problems arising within the temporal bone and the proximity of the cranial nerves VII and VIII in the posterior fossa, pure tone and speech audiometry is recommended.

The once-popular topognostic testing (Schirmer test, stapedial reflex assessment, electrogustometry, and salivary flow) for determining the site of the lesion and for prognostication is obsolete. Imaging is more efficient for diagnosis and is essential in any case when the etiology is uncertain or the paralysis is recurrent or atypical. High-resolution CT of the temporal bone is the study of choice for assessment of the fallopian canal. Any potential cause of facial paralysis associated with bone destruction (mastoiditis, cholesteatoma, tumors, temporal bone trauma) is seen best on CT. MRI is most useful when infectious or neoplastic involvement of the nerve (idiopathic facial palsy, herpes zoster oticus, facial schwannoma) is suspected.

When paralysis is complete, electrophysiologic studies are done to establish the degree of degeneration and prognosis for recovery. The Schirmer test remains useful to quantitate the amount of tearing in the involved eye. Reduced tear secretion suggests the need for aggressive treatment to protect the cornea. When the diagnosis is uncertain, other laboratory studies can be considered to

TABLE 155.3 DIFFERENTIAL DIAGNOSIS FACIAL PALSIES

Infection
- Bell palsy (herpes simplex mononeuritis)
- Herpes zoster oticus (Ramsay Hunt syndrome)
- Otitis media with effusion
- Acute suppurative otitis media
- Coalescent mastoiditis
- Chronic otitis media
- Malignant otitis externa (skull base osteomyelitis)
- Tuberculosis
- Lyme disease[a]
- Acquired immunodeficiency syndrome
- Infectious mononucleosis

Trauma
- Temporal bone fractures[a]
- Birth trauma
- Facial contusions/lacerations
- Penetrating wounds, face and temporal bone
- Iatrogenic injury
- Radiation injury

Neoplasia
- Cholesteatoma
- Glomus jugulare or tympanicum
- Carcinoma (primary or metastatic)
- Facial neuroma
- Schwannoma of lower cranial nerves
- Meningioma
- Leukemia
- Histiocytosis
- Rhabdomyosarcoma

Congenital
- Compression injury
- Möbius syndrome
- Lower lip paralysis

Idiopathic

Metabolic and systemic
- Sarcoidosis[a]
- Guillain-Barré syndrome[a]
- Autoimmune disorders

[a]May present with bilateral palsy.

exclude blood dyscrasias, autoimmune disorders, Lyme disease, sarcoidosis, and central nervous system diseases.

PATHOPHYSIOLOGY OF NERVE INJURY

One of the greatest shortcomings in our understanding of neural degeneration and regeneration is the lack of knowledge of events occurring at the molecular level after insult. Current electrophysiologic tests cannot differentiate levels of injury; hence, prognostication is limited, which explains why a "completely degenerated" nerve can have either total recovery or none at all.

Classically, nerve injury is described in terms of neurapraxia, axonotmesis, or neurotmesis. Neurapraxia results when a lesion compresses the flow of axoplasm from the nerve cell body to the distal axons. The nerve is viable and recovers normal function when the blockade is removed. A neurapraxic nerve will demonstrate normal findings on the nerve excitability test (NET), the maximal stimulation test (MST), and electroneurography or evoked electromyography (ENoG). Electromyography (EMG), however, fails to show voluntary motor action potentials, as these cannot be conducted across the blockade.

Axonotmesis describes a state of Wallerian degeneration distal to the lesion characterized by the preservation of endoneural sheaths of the motor axons. Electrically, if the axonotmesis is complete and pure, the NET, MST, and ENoG will indicate rapid and complete degeneration. The EMG will not demonstrate voluntary motor units, and after 10 to 14 days, myogenic fibrillation potentials become evident. As long as the endoneural tubules are preserved, regeneration to the original motor end plates will proceed until recovery is total.

In neurotmesis, the lesion leads to Wallerian degeneration and the loss of endoneural tubules. Consequently, the electrophysiologic tests yield results similar to those found in axonotmesis; however, the outcome is less predictable. The regeneration process depends on the completeness of injury to all connective tissue components of the nerve, including the endoneurium, the perineurium binding the axons into fascicles, and the epineurium enclosing the fascicles into a common nerve. Endoneurium compromise disrupts axonal organization and ensures a synkinetic result if regeneration occurs. Furthermore, the growth of neurofilaments is governed by conditions at the injury site and can be hindered by ischemia and scar.

Electrophysiologic Tests

The currently popular tests used to establish prognosis for return of function are the NET, the MST, ENoG, and EMG. Serial testing can establish the end point of degeneration, but any one test given at one point in time during the paralysis provides only limited information. The tests are complementary and when used appropriately can describe the completeness of degeneration relatively accurately. The indications, interpretations, and limitations of these tests are outlined in Table 155.4.

General rules apply to the use of these tests. The NET, MST, and ENoG are most applicable in the evaluation of acute paralysis (i.e., while the nerve is in the degenerative phase). During degeneration, the NET will demonstrate increasing side-to-side threshold differences, the MST greater degrees of facial weakness, and the ENoG lower percentages of intact motor axons. The results will reach a nadir, and the nerve will enter the recovery phase. This may be evident immediately on clinical examination or may be delayed, depending on the cause and extent of nerve injury. The tests are not indicated in patients with paresis, as facial movement on examination indicates that

TABLE 155.4 ELECTROPHYSIOLOGIC TESTS

Test	Indication	Interpretation	Limitation
Nerve excitability test	Complete paralysis <2 wk duration	≤3.5 mA threshold difference: prognosis good	Not useful in first 3 d after onset or during recovery
Maximal stimulation test	Same as NET	Marked weakness or no muscle contraction: advanced degeneration with guarded prognosis	Subjective
Electroneurography	Same as NET and MST	<90% degeneration: good prognosis >90%: prognosis in question	False-positive results in deblocking phase
Electromyography	Acute paralysis <1 wk duration	Active mu: intact motor axons	Cannot assess degree of degeneration of prognosis for recovery
	Chronic paralysis >3 wk duration	mu + fibrillation potentials: partial degeneration Polyphasic mu: regenerating nerve	

NET, nerve excitability test; MST, maximal stimulation test; mu, motor units.

the nerve is intact, primarily neurapraxic, and the prognosis for recovery is good. The most common causes of acute facial paralysis (Bell palsy, trauma, herpes zoster oticus) produce nerve degeneration within the first 3 weeks after onset of palsy, and the NET, MST, and ENoG provide the most accurate information within this time frame. Nevertheless, when the neurapraxic axons begin recovery, asynchronous depolarization, differing conduction velocities in the motor axons, poor summation of the myogenic action potentials, and poor muscular contraction can give a false-positive report of nerve status and may even suggest that the nerve has completely degenerated.

EMG in combination with NET, MST, and ENoG greatly aids in eliminating these false-positive results, as the demonstration of voluntary active motor units confirms the integrity of intact axons in the recovery phase. This test is useful in the earliest phase of degeneration, as the presence of motor units indicates an intact nerve with incomplete injury. Within the first 3 days after onset of complete paralysis, the results of NET, MST, and ENoG yield little useful information, as Wallerian degeneration distal to the stimulation areas has not occurred; the results always indicate incomplete degeneration and good prognosis (10). Because of this limitation, the prognosis is best established by using NET, MST, or ENoG around the sixth or seventh day after onset of paralysis. The primary limitation of EMG is the inability to differentiate a totally neurapraxic nerve from a completely degenerated one in the acute phase of degeneration. Nevertheless, the EMG is complementary in the evaluation of acute paralysis and essential in the evaluation of long-standing paralysis. The presence of myogenic fibrillation potentials and the absence of voluntary motor units denote complete nerve degeneration, the coexistence of both fibrillation potentials and motor units indicates an incomplete lesion, and the appearance of polyphasic motor units signifies a regenerating nerve. The polyphasic action potentials may not be present until several weeks after the onset of paralysis.

In the NET, the current thresholds required to elicit just-visible muscle contraction on the normal side of the face are compared with those values required over corresponding sites on the side of the paralysis. The current, measured in milliamperes, is delivered percutaneously in a square-wave pulse of 0.3-ms duration at a rate of one per second over the main trunk and branches of the facial nerve. A side-to-side threshold difference is calculated for the respective sites of stimulation. A side-to-side difference of 3.0 to 3.5 mA is compatible with advanced degeneration, with an unfavorable prognosis for differences exceeding 3.5 mA (10).

The MST is a modification of the NET that uses a level of current sufficient to depolarize all motor axons underlying the stimulating probe (11). The facial muscular responses are graded subjectively according to the degree of contraction (equal, slightly decreased, markedly decreased, or absent compared with the uninvolved side). Markedly decreased or absent facial movement signifies advanced degeneration. When the response to MST remains normal for 10 days, approximately 90% of patients have complete return of facial function. If the response is decreased, most have incomplete return of function. If the response is lost, return does not begin until the fourth month (11).

Introduced by Esslen and popularized by Fisch (12), ENoG allows quantitative analysis of nerve degeneration. A supramaximal level of current applied with bipolar electrodes percutaneously over the main trunk of the facial nerve creates synchronous depolarization of the motor axons, thereby evoking a compound myogenic action potential in the facial musculature that is recorded with bipolar surface electrodes (Fig. 155.4). The peak-to-peak amplitude of this potential is directly proportional to the number of intact motor axons. Compared with the amplitude of potential evoked on the normal side, it can be used to calculate the percentage of intact axons. Greater than 90% degeneration indicates a poor prognosis for immediate or complete restoration of facial function. Traumatic injuries undergoing

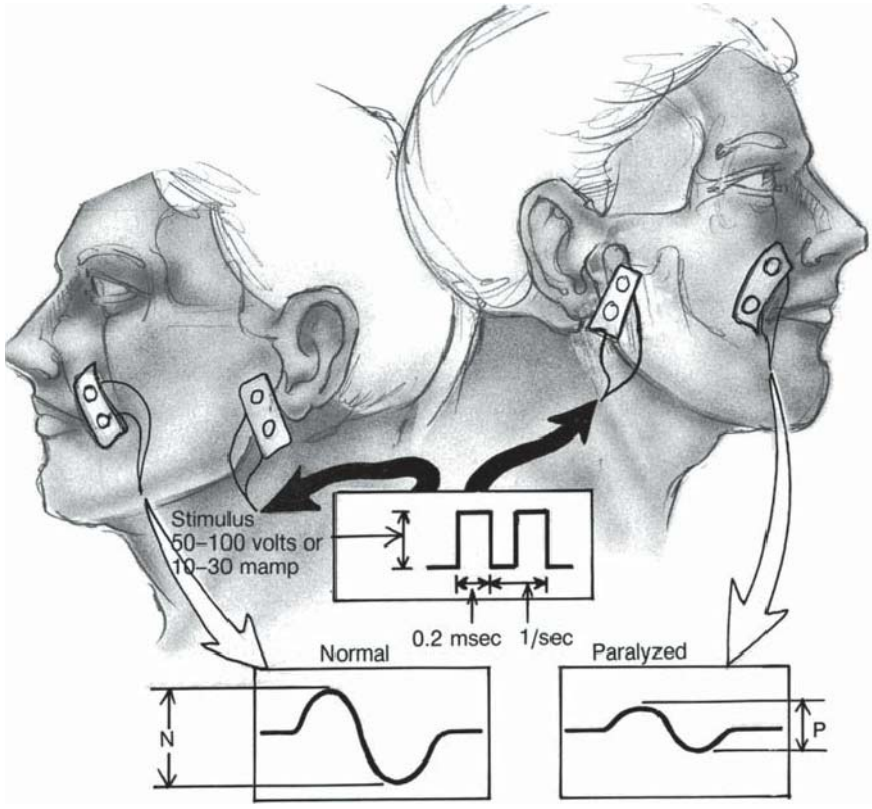

Figure 155.4 Clinical electroneurography in the assessment of acute facial paralysis. Percentage of viable motoneurons = P/N × 100. (Modified from Coker NJ, Fordice JO, Moore S. Correlation of the nerve excitability test and electroneurography in acute facial paralysis. *Am J Otol* 1992;13:127–133, with permission.)

more than 90% degeneration within 6 days of the injury represent complete lesions. In Bell palsy, patients exceeding 95% degeneration within the first 2 weeks of onset fall into the guarded prognostic category (13).

It is important for the clinician to understand potential sources of testing error. Naturally, the level of experience of the physician or technician performing the test is a significant variable. Placement of the recording electrodes can impact the test accuracy. Testing paradigms used for ENoG include standard lead placement, optimal lead placement (OLP), and the recently introduced midline electrode placement (14). The former test places recording electrodes at the same anatomic location on both sides of the face, usually at the lateral edge of the nasolabial crease and lateral and inferior to the oral commissure. The OLP technique uses repeated repositioning of recording electrodes until the maximal response is detected. A midline technique may allow recording of larger amplitude action potentials and is unlikely to be affected by masseter stimulation. The use of electrode paste and the amount of pressure applied to the stimulating and recording electrodes can influence results of any method of electrical testing. Patient factors such as age, obesity, and facial edema also influence test results.

Coker et al. (15) assessed correlation of the results of NET and ENoG testing in patients with acute facial paralysis. They found that the tests display an exponential relationship, not a linear one. The highest levels of correlation were seen when OLP technique was used in ENoG testing. The lack of exact correlation between the two tests illustrates the inability to achieve consistent synchronous depolarization of viable axons, which the authors suggest may be explained by a deblocking phenomenon or partial demyelination. The authors concluded that the two tests are complementary in assessment of acute facial paralysis.

BELL PALSY

The term Bell palsy has been used to describe a facial paralysis of acute onset and limited duration, the etiology of which was deemed idiopathic. Contemporary studies provide convincing evidence that the herpes simplex virus (HSV) is the infecting agent in Bell palsy. The development of polymerase chain reaction techniques has allowed identification of HSV in the geniculate ganglion. Murakami et al. (16) sampled endoneurial fluid and muscle from patients undergoing decompression surgery for Bell palsy and Ramsay Hunt syndrome. Control specimens were obtained during repair of the facial nerve after trauma, excision of parotid malignancies, and facial neuromas. Samples from 10 of 13 patients who had Bell palsy were positive for HSV, whereas none of the controls showed evidence of the virus. Eight of nine patients with Ramsay Hunt syndrome had evidence of varicella zoster virus, but none had HSV.

Additional support is given by replication of the clinical syndrome in an animal model. Sugita et al. (17) produced

transient facial palsy in an animal model by inoculation with HSV. In this experiment, HSV was inoculated into the auricle or lateral tongue. Paralysis developed in 56% of animals inoculated in the auricle and 20% inoculated in the tongue. The paralysis developed 6 to 9 days later and persisted for 3 to 7 days. Spontaneous resolution occurred in all cases. Histopathology revealed significant edema and inflammation about the geniculate ganglion. HSV antigens could be isolated from the nerve, geniculate ganglion, and facial motor nucleus in some of the animals that developed paralysis. Antigen could not be detected on the contralateral side in any animal.

Bell palsy is the most common diagnosis given to patients with acute facial paralysis. The incidence is between 30 and 45 cases per 1,00,000 per year (18,19). The incidence varies with age, being rare in children and increasing through the sixth decade. Women may have a slightly increased risk and incidence appears greater in arid climates and during winter months. Differences in incidence by ethnicity likely reflect differing prevalence of HSV infection within the respective populations (20).

The clinical picture is defined by rapid onset of the facial palsy, minimal associated symptoms, and spontaneous recovery. Facial nerve dysfunction developing over several weeks or months is not Bell palsy. Peitersen (19) characterized the natural history of untreated Bell palsy. Thirty percent of patients develop only a paresis, and 94% of these patients recover without sequelae. The other 70% developed a complete paralysis, with only 61% of this group achieving full recovery. Time to return of movement is associated with ultimate recovery. Some return of facial tone or movement is seen in 85% of all patients within 3 weeks. Full recovery is typically achieved by 2 months. Patients who develop complete paralysis may not have return of function for 3 to 5 months. The longer the delay until some recovery is evident, the greater the likelihood of adverse sequelae, including synkinesis, residual weakness, and muscle spasms. Other factors that are associated with poor recovery include advanced age and pain at presentation. Peitersen (19) expressed final outcome using a modification of the Jongkees grading system. Extrapolation of his findings to the more familiar (in the United States) House-Brackmann scale reveals an estimated 71% of all patients achieving grade I and 12% grade II outcome.

Histopathologic studies of patients with Bell palsy were reviewed by Liston and Kleid (21). The reported findings are not uniform, reflecting the different periods from onset of paralysis to nerve examination, methods of preparation, portion of the nerve studied, and possibly etiology of the facial paralysis. Most recent reports, however, demonstrate inflammatory infiltrates throughout the course of the facial nerve. Vascular thrombosis is generally not observed, although intraneural hemorrhage is seen occasionally.

The high rate of spontaneous recovery has made it difficult to prove efficacy of any medical or surgical intervention in patients with Bell palsy. Two recent, large, randomized trials have established the utility of oral steroids in promoting recovery (22,23). Both trials prospectively randomized patients presenting within 72 hours of onset of the facial palsy to receive oral steroids or placebo combined with antivirals or placebo. In each trial, patients receiving steroids had a significantly greater probability of full recovery. Sullivan et al. (22) studied 551 patients in Scotland. In this study, only three examiners rated all the patients using a series of four photographs for evaluation according to the House-Brackmann scale. The steroid treatment was prednisolone 500 mg (50 mg/day ×10) and the antiviral was acyclovir 2,000 mg/day for 10 days. In this study, 83% of patients displayed grade I function at 3 months when treated with prednisone versus 64% in those not receiving prednisone ($P < 0.001$). At the last assessment at 9 months, 94% of patients receiving prednisone were judged to be grade I versus 82% of those not receiving steroids.

Engström et al. (23) analyzed a group of 839 patients in Sweden and Finland. The study used both the House-Brackmann scale and the Sunnybrook scale as rating instruments. The steroid treatment was prednisolone 450 mg (60 mg/day ×5, then taper by 10 mg/day) and the antiviral was valacyclovir 3,000 mg/day for 7 days. A large number of examiners (greater than 49) were used to record the data in this study. The study found 62% of patients receiving prednisone displayed normal function (Sunnybrook score of 100) at 3 months versus 51% in the patients not receiving prednisone ($P = 0.0007$). At 12 months, the comparable figures are 72% normal in prednisone-treated patients versus 57% in those without.

The addition of antiviral medications may provide additional benefit, though conclusive evidence is lacking. It is clear that antivirals alone are not better than placebo. However, the addition of antivirals to steroid treatment may enhance recovery. Adour et al. (24) were the first to report the benefit of antivirals combined with steroid treatment in a double-blind study. Patients were randomized to receive either acyclovir 2,000 mg/day in five doses and prednisone or placebo and prednisone. All patients enrolled in this trial were within 3 days of onset of the paralysis. Only 20% of patients progressed to complete paralysis (House-Brackmann grade VI) within 2 weeks of onset, and these were evenly distributed between the two treatment groups. Acyclovir-treated patients demonstrated less evidence of degeneration as measured by MST and a lower incidence of unsatisfactory recovery (House-Brackmann grades III and IV). A meta-analysis of trials investigating efficacy of antiviral agents in Bell palsy (BP) was performed by de Almeida et al. (25). The absence of benefit of antivirals alone compared to placebo was confimed. However, individuals who received antivirals combined with steroids had a relative risk of incomplete recovery of 0.75 ($P = 0.05$). Secondary analysis did not find a significant difference in outcomes according to antiviral dosage.

Selection of a medical regimen for any patient with Bell palsy must consider potential side effects of medications, concurrent illness, and the patient's wishes. Treatment must be initiated promptly for maximal efficacy. The treatment effect is greatest for those patients with complete paralysis, but waiting for a mild weakness to progress undermines the efficacy of the treatment regimen. Prednisone dosage in adults should be 450 to 500 mg administered in divided doses over 7 to 10 days. A gradual taper is optional. Antivirals can be added if treatment is initiated within the first 72 hours; beyond this time, additional efficacy is less likely. Valacyclovir is given at a dose of 1,000 mg three times daily for 7 days or famciclovir may be given at 1,500 mg daily for 7 days. Dosage adjustment in pediatric patients is indicated.

Debate continues as to how to manage best those patients who progress to severe electrical degeneration despite medical intervention. Those patients who display greater than 90% degeneration on ENoG in the first 2 weeks of the paralysis recover to House-Brackmann grade I or II function only 50% of the time (26). Although histopathologic studies demonstrate inflammatory involvement of the entire nerve, it is postulated the maximal nerve injury occurs at the meatal foramen. In this location, the nerve occupies a greater proportion of the lumen of the fallopian canal than elsewhere. Further support for this theory was given by Fisch and Esslen (12), who confirmed the presence of a conduction block proximal to the meatal foramen in 11 of 12 patients undergoing total facial nerve decompression. Surgical intervention thus is directed at unroofing the labyrinthine segment of the nerve via a middle fossa approach. Incision of the epineurium is advocated by some for additional neural decompression. Decompression of the mastoid and tympanic segments of the nerve has no effect on recovery of facial function.

Gantz et al. (26) presented the results of a prospective multi-institutional trial of middle fossa decompression. Criteria for entry into the study were development of more than 90% degeneration on ENoG (OLP technique) within 14 days of onset of the paralysis and no voluntary motor unit potentials on EMG. Patients meeting these criteria were offered middle fossa decompression. Patients self-selected treatment, choosing either surgical decompression or continued medical treatment. Good outcome (House-Brackmann grade I or II) was achieved in 91% of the surgical patients (N = 34) versus only 42% in the medical treatment–only group (N = 36). Patients who progressed to a complete paralysis but did not develop more than 90% degeneration achieved a final House-Brackmann grade I in 89% of cases. They concluded that the 90% degeneration threshold on ENoG accurately separates patients into a good or poor prognostic category. In addition, middle fossa decompression of the labyrinthine segment (including the geniculate ganglion and internal auditory canal) performed within 14 days of onset of paralysis significantly improves outcome in those patients with a poor prognosis. Decompression performed after 14 days provides no additional benefit. None of the patients in the medical treatment group received antiviral therapy; however, the potential benefit of antivirals is in preventing progression to severe degeneration. Antivirals are not expected to provide additional benefit once severe degeneration has occurred.

HERPES ZOSTER OTICUS

Varicella zoster virus establishes a latent infection in many cranial nerve ganglia at the time of the initial infection. The latent virus can be reactivated years later by an unknown mechanism. Reactivation of latent virus within the geniculate ganglion produces herpes zoster oticus or Ramsay Hunt syndrome. The patient presents with acute facial paralysis, severe ear pain, and a vesicular eruption of the external auditory canal and concha. The pain often precedes the facial paralysis by a few days. Associated symptoms of sensorineural hearing loss and vestibular dysfunction are present in more than 30% of patients.

Ramsay Hunt syndrome has an annual incidence about one-tenth that of Bell palsy. The incidence increases with age, consistent with zoster at other sites. The prognosis for spontaneous recovery of normal facial function is poorer than in Bell palsy (27). Satisfactory return of facial movement occurs in about 50% of patients; others will suffer varying grades of weakness, synkinesis, contractures, and spasm. Unlike Bell palsy, in which degeneration proceeds rapidly within the first 2 weeks after onset, degeneration of the facial nerve in herpes zoster oticus may evolve more slowly over the course of 3 weeks. When the degeneration is total, regeneration requires 3 to 6 months before facial movement becomes evident on clinical examination.

Jackson et al. (28) reported intraoperative findings in a patient with Ramsay Hunt syndrome demonstrating no return of function after 1 year. An excisional biopsy demonstrated a sharp demarcation between normal and devitalized nerve in the labyrinthine segment. Proximal and distal portions of the nerve appeared grossly normal. This observation suggests an increased susceptibility of the labyrinthine segment to inflammation-induced degeneration.

Management of herpes zoster oticus includes intervention directed at the underlying viral infection and associated complications. As stated earlier, antiviral therapy must be initiated promptly for maximal effectiveness. Antiviral medications are beneficial in treatment of herpes zoster infections, reducing pain and shortening time to resolution of skin lesions. Specific medications and dosages are the same as outlined earlier (Valacyclovir 1,000 mg tid for 7 days, or Famciclovir 500 mg tid for 7 days). Steroids are also given at the same doses as in Bell palsy. Few studies have examined the benefits of both steroids and antiviral therapy in herpes zoster oticus, but preliminary reports

are encouraging (29). The role of surgical decompression remains investigational. It is difficult to identify those with a poor prognosis because electrical test data are less well established than in Bell palsy.

OTITIS MEDIA AND FACIAL PALSY

Facial palsy can present as a complication of acute suppurative otitis media, otitis media with effusion, chronic otitis media, and mastoiditis. Infection involving the fallopian canal leads to inflammation and neural edema. Immediate treatment should be directed toward eradicating the infection. When a middle-ear effusion is present, myringotomy is performed promptly to drain the middle-ear space. Cultures of the middle-ear aspirate direct antibiotic therapy against the offending organism.

The incidence of facial palsy in acute otitis media is approximately 1:20,000 cases (30). Most cases are seen in children due to the greater incidence of otitis media in the pediatric population. The prognosis of facial palsy in acute otitis media is excellent (31,32). Recovery of facial function begins rapidly in conjunction with resolution of infection. Operative management is usually limited to myringotomy and tube.

Facial paralysis in association with chronic otitis media, cholesteatoma, or skull base osteomyelitis carries a more ominous prognosis (33,34). The development of the paralysis is often more insidious, suggesting possible ischemic nerve injury. Aural toilet and antibiotics are intiated promptly. If the tympanic membrane is intact, myringotomy is performed. CT is recommended to evaluate the fallopian canal before surgery. Suspicion of intracranial complications is appropriate in this setting. Tympanomastoid surgery is usually necessary to remove infected tissue from the middle ear and mastoid. The facial nerve is inspected carefully. Granulation tissue, cholesteatoma matrix, and infected bone are removed if easily separated; however, great care is advised to avoid iatrogenic injury. Incision of the epineurium is not advised. Facial nerve function is most likely to improve in those cases where onset of paralysis is acute and treatment is prompt. Facial paralysis that has been present for several weeks or more rarely improves despite aggressive management.

TRAUMA

Facial nerve injuries occur in a variety of ways, including blunt or penetrating trauma and iatrogenic harm. Management differs according to extent of injury, though the severity of the injury is not always easy to establish. History, physical exam, imaging, and electrophysiologic testing are all important in determining the probability of spontaneous recovery.

Immediate evaluation of the motor function of the facial nerve after trauma to the head and neck provides key information. All facial nerve branches should be inspected carefully to document movement. If a paresis is present, spontaneous return of satisfactory facial function will occur without intervention. Soft tissue swelling and ecchymosis impair the assessment of facial movement; thus, repeated examinations are necessary. Immediate complete paralysis indicates a severe nerve injury and warrants surgical exploration in cases of penetrating trauma.

Electrophysiologic testing is employed when the severity of injury is uncertain. The presence of voluntary motor units on EMG establishes continuity of the nerve, and this test may be performed at any time. Evoked EMG or ENoG testing is usually deferred for several days after the injury to avoid a false positive evoked response. Severe nerve injuries lead to rapid and complete degeneration, characterized by the absence of both voluntary and evoked responses. Predicting spontaneous recovery in traumatic lesions remains imprecise; additional data correlating the rate of neural degeneration on ENoG to degree of spontaneous recovery are needed.

Pure-tone and speech audiometry is necessary for intratemporal lesions to document the type and degree of hearing loss. Imaging is usually limited to high-resolution CT scan, with the intent of defining any fractures traversing the fallopian canal. MRI or angiography is indicated if a major vascular injury is suspected, as with penetrating injuries at the skull base. Cervical spine films are requested if neck injury is suspected.

The recommended management of injuries with complete facial paralysis is outlined in Table 155.5 (35). For extracranial lacerations, the transected trunk or major branches should be repaired as soon as practical. This usually requires either direct end-to-end anastomosis or interpositional grafting, preferably at the time of soft tissue closure. Branches medial to the lateral canthus of the eye rarely need repair because of the rich cross-anastomotic connections of the nerve in the midface. Observe patients who have closed soft tissue injuries for resolution of the paralysis.

Temporal bone fractures are the most common cause of traumatic injury to the facial nerve. The fractures are categorized according to involvement of the otic capsule (36). Fewer than 5% of all temporal bone fractures involve the otic capsule. However, facial nerve injury occurs in half of all otic capsule fractures. Otic capsule sparing fractures are associated with facial paralysis in less than 10% of cases. Most injuries occur in the perigeniculate region. Less commonly, the nerve is injured in the upper mastoid segment by the fracture in the posterior osseous external auditory canal.

Once the injured segment of the nerve is identified, an operative approach is selected according to residual hearing. The middle fossa approach provides complete access to the perigeniculate region in those patients with good hearing. A transmastoid approach with a posterior tympanotomy allows examination of the tympanic and mastoid

TABLE 155.5 MANAGEMENT OF TRAUMATIC INJURIES WITH COMPLETE FACIAL NERVE PARALYSIS

Mechanism of Injury	Tests	Critical Result	Management
Intratemporal Injury			
Blunt trauma (temporal bone fracture)	CT	Fracture involving fallopian canal	
	NET	>3.5 mA difference	
	ENoG	>90% degeneration	
	EMG	Absent volitional activity	Surgical exploration if all of above present
	Audiometry	Conductive loss	Transmastoid–middle fossa approach
		Sensorineural loss—severe	Translabyrinthine approach
	History	Delayed onset	Observation
Penetrating trauma	Follow algorithm above, add: Angiography	Suspicion of major vascular injury	Endovascular or open repair
Iatrogenic	History	Immediate onset	Surgical exploration
		Delayed onset (>3 d)	Observation
Extratemporal Injury			
Penetrating trauma	Physical exam		Exploration and repair
Blunt trauma	Physical exam		Observation
Iatrogenic	History	Suspected transection by report	Exploration and repair
		Nerve intact	Observation

NET, nerve excitability test; ENoG, electroneurography; EMG, electromyography.

segments of the nerve. If profound sensorineural hearing loss is present, a translabyrinthine approach allows access to all segments of the nerve.

Blunt injuries rarely result in nerve transection. The most common findings are edema and contusion (intraneural hemorrhage) (Fig. 155.5) (35). The injured segment is inspected and any bone impaling or compressing the nerve is removed. Additional decompression of the fallopian canal may be performed proximal and distal to the injury. Intraneural hematomas are evacuated after incision of the epineural sheath. Complete transection of the nerve requires rerouting of the nerve with direct end-to-end anastomosis or an interpositional graft if direct anastomosis is not feasible.

Gunshot injuries of the temporal bone produce facial nerve paralysis in more than half of all cases (37). This unique form of penetrating injury often produces severe neural damage. The nerve can be directly involved (i.e., transected) or secondarily injured by the kinetic energy imparted by the projectile or by the bony fragmentation of the temporal bone. The most common sites of injury are the mastoid and tympanic segments of the nerve. When the nerve is transected, interpositional grafting is advised. Determining extent of injury may be difficult, as the damage is often more extensive along the proximal and distal segments than anticipated. As a result, outcome of facial function is poorer than in blunt temporal bone fractures.

The incidence of facial nerve injury during middle-ear and mastoid surgery is much less than 1%. Delayed onset paresis (more than 3 days postsurgery) is more common but usually due to viral reactivation (38). The most common site of iatrogenic injury is the tympanic segment adjacent to the oval window (39). The nerve is more susceptible in this region because it is the most common site of fallopian canal dehiscence. The next most common site of injury is the mastoid segment. At times, cholesteatoma and granulation tissue obscure landmarks, increasing the risk of nerve injury. When in doubt, remove diseased tissue to confirm the location of the horizontal semicircular canal, digastric ridge, and incus to aid facial nerve dissection. Iatrogenic injury frequently results in complete transection of the nerve. Once again, end-to-end anastomosis or interpositional graft is required to restore continuity. Partial injuries, involving 50% of the diameter of the nerve or less, are best treated by decompression proximal and distal to the injury.

Nerve anastomosis is accomplished using interrupted epineural sutures of a 9-0 monofilament, such as nylon. General principles of neurorrhaphy attempt to maximize the number of regenerating axons sprouting across the anastomotic site. All neural tissue is handled atraumatically by using microinstruments designed for neural repair. Approximation of nerve endings is done best under the illumination and magnification of the operating microscope. Exact end-to-end approximation is performed without tension on the anastomosis.

Interpositional grafts are used when a direct end-to-end anastomosis creates tension or when segments of the nerve

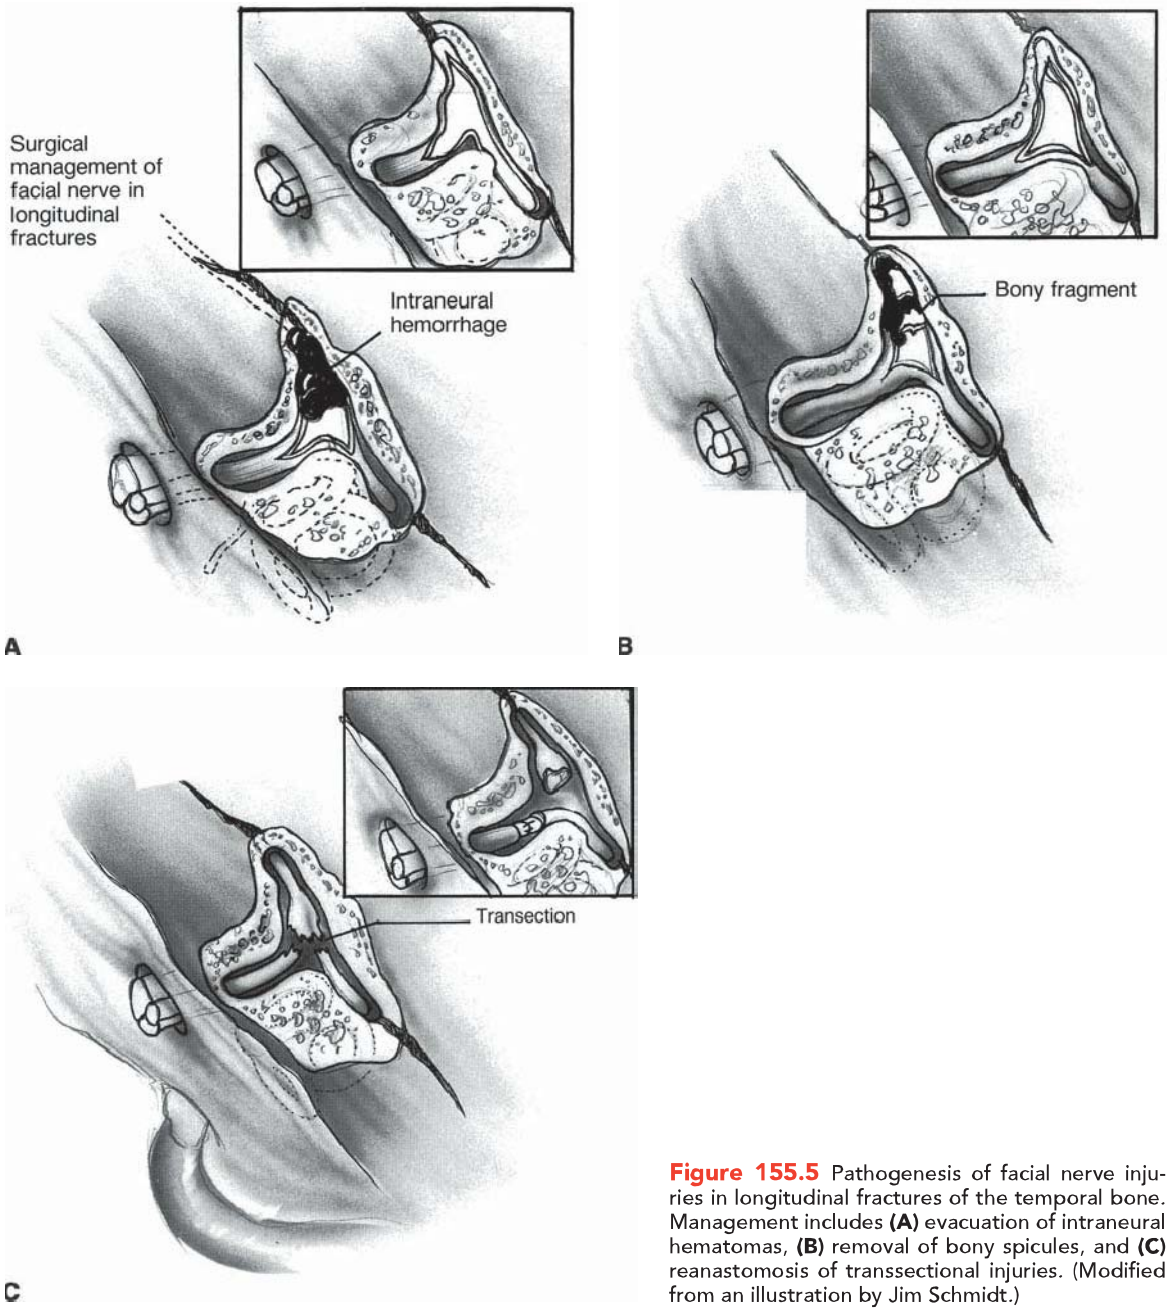

Figure 155.5 Pathogenesis of facial nerve injuries in longitudinal fractures of the temporal bone. Management includes **(A)** evacuation of intraneural hematomas, **(B)** removal of bony spicules, and **(C)** reanastomosis of transsectional injuries. are missing or severely damaged. Donor nerves for use in grafting include the greater auricular, median antebrachial cutaneous, and sural nerves (Fig. 155.6). Resulting sensory deficits are modest and show some improvement with time.

TUMORS OF THE SKULL BASE AND FACIAL NERVE

Tumors rarely present with acute facial paralysis. It is estimated that only 5% of tumors involving the facial nerve present in this manner. Opinions differ on the guidelines for obtaining radiographic evaluation in patients with acute facial paralysis, but certain circumstances do increase the probability of neoplastic discovery, including the following:

- A paresis evolving slowly over a period exceeding 3 weeks
- No return of facial function when the process has had an opportunity for regeneration
- Recurrent palsy on the same side
- Coexistence of facial twitching with an evolving paresis
- Development of chronic, unilateral eustachian tube dysfunction in a patient with no prior history of chronic middle-ear disease
- Presence of multiple cranial nerve deficits
- Presence of a neck or parotid mass
- History of cutaneous malignancy

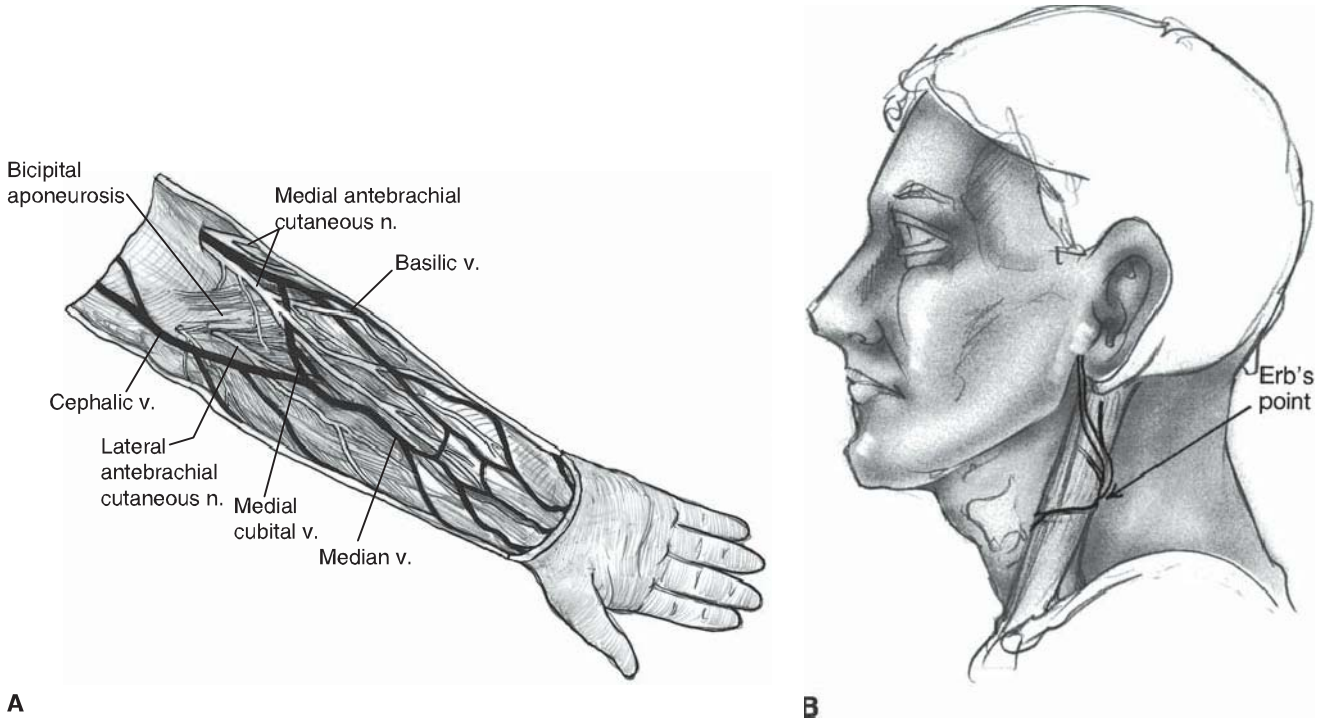

Figure 155.6 Popular interpositional grafts for repair of the facial nerve include the medial antebrachial cutaneous (**A**) and greater auricular (**B**) nerves.

Several benign and malignant tumors can involve the facial nerve along its intracranial, intratemporal, or extracranial course. The most common tumor of the nerve is the facial schwannoma. Initial symptoms vary, depending on the involved segment of the nerve. Tumors involving only the cerebellopontine angle or internal auditory canal portions of the nerve will present with hearing loss or tinnitus. Intratemporal tumors often present with a slowly evolving facial paralysis, middle-ear mass, or conductive hearing loss. Extratemporal tumors present as a parotid mass and rarely exhibit any facial nerve dysfunction. All segments of the nerve may be involved, although the geniculate and labyrinthine segments are most common (40). Excision usually requires the use of interpositional grafting for restoration of continuity (41). One of the most difficult decisions on discovery of the tumor is the timing of management. In the geriatric population, a small tumor with minimal facial or middle-ear involvement is best observed. In the young patient, the tumor is best resected and the nerve grafted. If the tumor is allowed to grow, more motor axons will undergo degeneration with irreversible changes in both the axons and muscle endplates, such that any neural reinnervation technique will be compromised. A grade III return of facial function is the best result anticipated from grafting, so the patient needs preparation for a less than perfect outcome.

Skull base tumors present an array of management problems regarding the facial nerve, and the otologic surgeon must be capable of any number of procedures to preserve the integrity of the nerve: transposition, rerouting, division and reanastomosis, interpositional grafting, and cranial nerve crossover. Anterior transposition of the facial nerve spares the greater superficial petrosal nerve and preserves normal tearing and is preferred for benign tumors of the infralabyrinthine compartment. Posterior transposition provides access to the petrous apex. Division and reanastomosis may aid exposure to the parapharyngeal space, but it should be avoided, as any transection of the nerve followed by neural anastomosis will result in synkinesis or mass movement. When the tumor is benign, the continuity of the nerve should be preserved by mobilization techniques. Exceptions to this rule include facial nerve schwannomas, which usually require resection of nerve with interpositional grafting; benign tumors invading the nerve (e.g., cranial nerve schwannomas, paragangliomas, cholesteatoma); and recurrent tumors adherent to the nerve, which necessitate excision of the nerve to ensure complete tumor removal.
